Document Purpose

The *Software Architecture Design* document purpose is to describe the implications of each software requirement specification on all the affected software modules for the *Synopse mORMot Framework* project.

The current revision of this document is 1.18.

1. Synopse mORMot Overview

1.1. Client-Server ORM/SOA framework	74
1.2. Highlights	75
1.3. Benefits	76
1.4. Legacy code and existing projects	77
1.5. FAQ	78

2. Architecture principles

2.1. General design	82
2.2. Architecture Design Process	84
2.3. Model-View-Controller	86
2.4. Multi-tier architecture	88
2.5. Service-Oriented Architecture (SOA)	90
2.6. Object-Relational Mapping (ORM)	92
2.7. NoSQL and Object-Document Mapping (ODM)	96
2.8. Domain-Driven Design	99
2.8.1. Definition	99
2.8.2. Patterns	99

2.8.3. Is DDD good for you?	100
2.8.4. Introducing DDD	100
3. Enter new territory	
<hr/>	
3.1. Meet the mORMot	101
3.2. Main units	103
4. SynCommons unit	
<hr/>	
4.1. Unicode and UTF-8	105
4.2. Currency handling	106
4.3. TDynArray dynamic array wrapper	107
4.3.1. TList-like properties	107
4.3.2. Enhanced features	108
4.3.3. Capacity handling via an external Count	109
4.3.4. JSON serialization	109
4.3.5. Daily use	109
4.3.6. TDynArrayHashed	111
4.3.7. TSynDictionary	111
4.4. TDocVariant custom variant type	112
4.4.1. TDocVariant documents	112
4.4.1.1. Variant object documents	113
4.4.1.2. FPC restrictions	115
4.4.1.3. Variant array documents	116
4.4.1.4. Create variant object or array documents from JSON	117
4.4.1.5. Per-value or per-reference	117
4.4.2. Advanced TDocVariant process	118
4.4.2.1. Number values options	119
4.4.2.2. Object or array document creation options	119
4.4.2.3. Integration with other mORMot units	120
4.5. Cross-cutting functions	120
4.5.1. Iso8601 time and date	120
4.5.1.1. TDateTime and TDateTimeMS	120

4.5.1.2. TTimeLog and TTimeLogBits	121
4.5.1.3. TUnixTime and TUnixMSTime	122
4.5.2. Time Zones	122
4.5.3. Safe locks for multi-thread applications	123
4.5.3.1. Protect your resources	123
4.5.3.2. Fixing TRTLCriticalSection	124
4.5.3.3. Introducing TSynLocker	124
4.5.3.4. Inheriting from T*Locked	126
4.5.3.5. Injecting TAutoLocker instances	127
4.5.3.6. Injecting IAutoLocker instances	127
4.5.3.7. Safe locked storage in TSynLocker	128
4.5.3.8. Thread-safe TSynDictionary	129
5. Object-Relational Mapping	
5.1. TSQLRecord fields definition	131
5.1.1. Property Attributes	135
5.1.2. Text fields	135
5.1.3. Date and time fields	136
5.1.4. TSessionUserID field	136
5.1.5. Enumeration fields	137
5.1.6. Floating point and Currency fields	137
5.1.7. TSQLRecord fields	138
5.1.8. TID fields	138
5.1.9. TRecordReference and TRecordReferenceToBeDeleted	139
5.1.10. TSQLRecord, TID, TRecordReference deletion tracking	140
5.1.11. Variant fields	140
5.1.12. Record fields	140
5.1.13. BLOB fields	141
5.1.14. TNullable* fields for NULL storage	142
5.2. Working with Objects	144
5.3. Queries	144
5.3.1. Return a list of objects	144

5.3.2. Query parameters	145
5.3.3. Introducing TSQLTableJSON	146
5.3.4. Note about query parameters	148
5.4. Automatic TSQLRecord memory handling	149
5.5. Objects relationship: cardinality	151
5.5.1. "One to one" or "One to many"	151
5.5.1.1. TSQLRecord published properties are IDs, not instance	151
5.5.1.2. Transtyping IDs	152
5.5.1.3. Automatic instantiation and JOINed query	153
5.5.2. "Has many" and "has many through"	154
5.5.2.1. Shared nothing architecture (or sharding)	155
5.5.2.1.1. Embedding all needed data within the record	155
5.5.2.1.2. Nesting objects and arrays	156
5.5.2.1.2.1. TDocVariant and variant fields	156
5.5.2.1.2.1.1. Schemaless storage via a variant	157
5.5.2.1.2.1.2. JSON operations from SQL code	158
5.5.2.1.2.2. Dynamic arrays fields	159
5.5.2.1.2.2.1. Dynamic arrays from Delphi Code	159
5.5.2.1.2.2.2. Dynamic arrays from SQL code	161
5.5.2.1.2.3. TPersistent/TCollection fields	162
5.5.2.1.2.4. Any TObject, including TObjectList	164
5.5.2.1.2.5. Sharding on NoSQL engines	165
5.5.2.2. ORM implementation via pivot table	165
5.5.2.2.1. Introducing TSQLRecordMany	165
5.5.2.2.2. Automatic JOIN query	169
5.6. ORM Data Model	171
5.6.1. Creating an ORM Model	171
5.6.2. Several Models	171
5.6.3. Filtering and Validating	172
5.7. ORM Cache	174

5.8. Calculated fields	176
5.8.1. Setter for TSQLRecord	176
5.8.2. TSQLRecord.ComputeFieldsBeforeWrite	177
5.9. Audit Trail for change tracking	178
5.9.1. Enabling audit-trail	178
5.9.2. A true Time Machine for your objects	178
5.9.3. Automatic history packing	179
5.10. Master/slave replication	180
5.10.1. Enable synchronization	180
5.10.2. From master to slave	181
5.10.3. Real-time synchronization	183
5.10.4. Replication use cases	185
6. Daily ORM	
<hr/>	
6.1. ORM is not Database	189
6.1.1. Objects, not tables	189
6.1.2. Methods, not SQL	190
6.1.3. Think multi-tier	192
6.2. One ORM to rule them all	192
6.2.1. Rude class definition	192
6.2.2. Persist TSQLRecord, not any class	193
6.2.3. Several ORMs at once	194
6.2.4. The best ORM is the one you need	195
7. Database layer	
<hr/>	
7.1. SQLite3-powered, not SQLite3-limited	196
7.1.1. SQLite3 as core	197
7.1.2. Extended by SQLite3 virtual tables	198
7.1.3. Data access benchmark	199
7.1.3.1. Software and hardware configuration	199
7.1.3.2. Insertion speed	201
7.1.3.3. Reading speed	203

7.1.3.4. Analysis and use case proposal	206
7.2. SQLite3 implementation	209
7.2.1. Statically linked or using external dll	209
7.2.1.1. Static bcc-compiled .obj	210
7.2.1.2. Official MinGW-compiled sqlite3.dll	211
7.2.1.3. Visual C++ compiled sqlite3.dll	212
7.2.2. Prepared statement	213
7.2.3. R-Tree inclusion	214
7.2.4. FTS3/FTS4/FTS5	215
7.2.4.1. Dedicated FTS3/FTS4/FTS5 record type	215
7.2.4.2. Stemming	216
7.2.4.3. FTS searches	217
7.2.4.4. FTS4 index tables without content	218
7.2.5. Column collations	219
7.2.6. REGEXP operator	221
7.2.6.1. Default REGEXP Engine	221
7.2.6.2. PCRE REGEXP Engine	222
7.2.7. ACID and speed	222
7.2.7.1. Synchronous writing	223
7.2.7.2. File locking	223
7.2.7.3. Performance tuning	224
7.2.8. Database backup	224
7.3. Virtual Tables magic	226
7.3.1. Virtual Table module classes	226
7.3.2. Defining a Virtual Table module	227
7.3.3. Using a Virtual Table module	230
7.3.4. Virtual Table, ORM and TSQLRecord	230
7.3.5. In-Memory "static" process	231
7.3.5.1. In-Memory tables	232
7.3.5.2. In-Memory virtual tables	232
7.3.5.3. In-Memory and ACID	234

7.3.6. Redirect to an external TSQLRest	234
7.3.7. Virtual Tables to access external databases	237
7.3.8. Virtual tables from the client side	237
8. External SQL database access	
8.1. SynDB direct RDBMS access	242
8.1.1. Direct access to any RDBMS engine	243
8.1.2. Data types	244
8.1.3. Database types	245
8.1.4. SynDB Units	246
8.1.5. SynDB Classes	246
8.1.6. ISQLDBRows interface	248
8.1.7. Using properly the ISQLDBRows interface	249
8.1.8. Late-binding	250
8.1.9. TDataset and SynDB	251
8.1.10. TQuery emulation class	251
8.1.11. Storing connection properties as JSON	252
8.2. SynDB clients	254
8.2.1. OleDB or ODBC to rule them all	254
8.2.2. ZEOS via direct ZDBC	255
8.2.2.1. The mORMot's best friend	255
8.2.2.2. Recommended version	256
8.2.2.3. Connection samples	256
8.2.3. Oracle via OCI	257
8.2.3.1. Optimized client library	257
8.2.3.2. Direct connection without Client installation	258
8.2.3.3. Oracle Wallet support	259
8.2.4. SQLite3	260
8.2.5. DB.pas libraries	260
8.2.5.1. NexusDB access	261
8.2.5.2. FireDAC / AnyDAC library	261
8.2.5.3. UniDAC library	262

8.2.5.4. BDE engine	262
8.2.6. Remote access via HTTP	264
8.2.6.1. Server and Client classes	264
8.2.6.2. Publish a SynDB connection over HTTP	265
8.2.6.3. SynDB client access via HTTP	266
8.2.6.4. Advanced use cases	267
8.2.6.5. Integration with SynDBExplorer	267
8.2.6.6. Do not forget the mORMot!	267
8.3. SynDB ORM Integration	269
8.3.1. Code-first or database-first	269
8.3.2. Code-first ORM	269
8.3.3. Database-first ORM	271
8.3.4. Sharing the database with legacy code	272
8.3.5. Auto-mapping of SQL conflictual field names	273
8.3.6. External database ORM internals	274
8.3.7. Tuning the process	278
9. External NoSQL database access	
<hr/>	
9.1. SynMongoDB client	280
9.1.1. Connecting to a server	281
9.1.2. Adding some documents to the collection	281
9.1.3. Retrieving the documents	283
9.1.3.1. Updating or deleting documents	285
9.1.4. Write Concern and Performance	286
9.2. MongoDB + ORM = ODM	288
9.2.1. Define the TSQLRecord class	288
9.2.2. Register the TSQLRecord class	291
9.2.3. ORM/ODM CRUD methods	291
9.2.4. ODM complex queries	292
9.2.5. BATCH mode	294
9.2.6. ORM/ODM performance	294

10. JSON RESTful Client-Server

10.1. JSON	296
10.1.1. Why use JSON?	296
10.1.2. Values serialization	298
10.1.3. Record serialization	298
10.1.3.1. Automatic serialization via Enhanced RTTI	298
10.1.3.2. Serialization for older Delphi versions	299
10.1.3.2.1. Default Binary/Base64 serialization	299
10.1.3.2.2. Custom serialization	299
10.1.3.2.3. Defining callbacks	300
10.1.3.2.4. Text-based definition	301
10.1.4. Dynamic array serialization	304
10.1.4.1. Standard JSON arrays	304
10.1.4.2. Customized serialization	305
10.1.5. TSQLRecord TPersistent TStringList TRawUTF8List	307
10.1.6. TObject serialization	307
10.1.6.1. Custom class serialization	308
10.1.6.2. Custom field names serialization	309
10.1.6.3. TObjectList serialization	310
10.2. REST	312
10.2.1. What is REST?	312
10.2.1.1. Resource-based	312
10.2.1.2. Unique Identifier	312
10.2.1.3. Interfaces	313
10.2.1.4. By Representation	313
10.2.1.5. Stateless	313
10.2.2. RESTful mORMot	314
10.2.2.1. BLOB fields	314
10.2.2.2. JSON representation	315
10.2.2.3. Stateless ORM	315
10.3. REST and JSON	317

10.3.1. JSON format density	317
10.3.2. JSON (not) expanded layouts	317
10.3.3. JSON global cache	318
11. Client-Server process	
<hr/>	
11.1. Client-Server cheat sheet	319
11.2. Protocols	320
11.3. TSQLRest classes	322
11.3.1. Server classes	322
11.3.2. Storage classes	323
11.3.3. Client classes	323
11.4. In-process/stand-alone application	325
11.5. Local access via named pipes or Windows messages	325
11.6. Network and Internet access via HTTP	326
11.6.1. HTTP server(s)	326
11.6.2. High-performance http.sys server	327
11.6.2.1. Use the http.sys server	327
11.6.2.2. URI authorization as Administrator	328
11.6.2.2.1. Secure specific authorization	328
11.6.2.2.2. Automatic authorization	329
11.6.2.2.3. Manual URI authorization	329
11.6.2.3. HTTP API 2.0 Features	330
11.6.3. HTTP client(s)	330
11.6.4. HTTPS server	332
11.6.4.1. Certificates	332
11.6.4.2. Configure a Port with an SSL certificate	333
11.6.5. Custom Encodings	334
11.6.5.1. SynLZ/deflate compression	334
11.6.5.2. AES encryption over HTTP	334
11.6.5.3. Prefer WebSockets between mORMot nodes	335
11.7. Thread-safety	336

11.7.1. Thread safe design	336
11.7.2. Advanced threading settings	337
11.7.3. Proven behavior	338
11.7.4. Highly concurrent clients performance	339
12. Client-Server ORM	
<hr/>	
12.1. ORM as local or remote	342
12.2. Stateless design	348
12.2.1. Server side synchronization	348
12.2.2. Client side synchronization	348
12.2.3. Let applications be responsive	349
12.3. BATCH sequences for adding/updating/deleting records	351
12.3.1. BATCH process	351
12.3.2. Transmitted JSON	353
12.3.3. Unit Of Work pattern	354
12.3.3.1. Several Batches	354
12.3.3.2. Updating only the mapped fields	354
12.3.4. Local network as bottleneck	356
12.3.4.1. Array binding	357
12.3.4.1.1. For faster BATCH mode	357
12.3.4.1.2. For faster IN clause	358
12.3.4.2. Optimized SQL for bulk insert	358
12.4. CRUD level cache	360
12.4.1. Where to cache	360
12.4.2. When to cache	361
12.4.3. What to cache	361
12.4.4. How to cache	362
12.4.5. Business logic and API cache	363
13. Server side SQL/ORM process	
<hr/>	
13.1. Optimize for performance	365

13.1.1. Profiling your application	365
13.1.2. Client-side caching	365
13.1.3. Write business logic as Services	366
13.1.4. Using ORM full power	366
13.2. Stored procedures	367
13.2.1. Why to avoid stored procedures	367
13.2.2. Stored procedures, anyway	367
13.2.2.1. Custom SQL functions	368
13.2.2.1.1. Implementing a function	368
13.2.2.1.2. Registering a function	369
13.2.2.1.2.1. Direct low-level SQLite3 registration	369
13.2.2.1.2.2. Class-driven registration	369
13.2.2.1.2.3. Custom class definition	370
13.2.2.2. Low-level SQLite3 stored procedure in Delphi	372
13.2.2.3. External stored procedure	372
13.3. Server side Services	373
14. Client-Server services via methods	
<hr/>	
14.1. Publishing a service on the server	374
14.2. Defining the client	376
14.3. Direct parameter marshalling on server side	377
14.4. Returns non-JSON content	378
14.5. Advanced process on server side	379
14.6. Browser speed-up for unmodified requests	380
14.7. Returning file content	380
14.8. JSON Web Tokens (JWT)	380
14.9. Handling errors	384
14.10. Benefits and limitations of this implementation	385
15. Interfaces	
<hr/>	
15.1. Delphi and interfaces	386

15.1.1. Declaring an interface	386
15.1.2. Implementing an interface with a class	387
15.1.3. Using an interface	387
15.1.4. There is more than one way to do it	388
15.1.5. Here comes the magic	389
15.2. SOLID design principles	390
15.2.1. Single Responsibility Principle	390
15.2.1.1. Splitting classes	390
15.2.1.2. Do not mix UI and logic	392
15.2.2. Open/Closed Principle	394
15.2.2.1. Applied to our framework units	394
15.2.2.2. Open/Closed in practice	395
15.2.2.3. No Singleton nor global variables	395
15.2.3. Liskov Substitution Principle	396
15.2.3.1. Use parent classes	397
15.2.3.2. I'm your father, Luke	398
15.2.3.3. Don't check the type at runtime	398
15.2.3.4. Partially abstract classes	399
15.2.3.5. Messing units dependencies	399
15.2.3.6. Practical advantages	400
15.2.4. Interface Segregation Principle	401
15.2.4.1. Consequence of the other principles	401
15.2.4.2. Using interfaces	401
15.2.5. Dependency Inversion Principle	401
15.2.5.1. Upside Down Development	402
15.2.5.2. Injection patterns	402
15.3. Circular reference and (zeroing) weak pointers	403
15.3.1. Weak pointers	403
15.3.2. Handling weak pointers	404
15.3.3. Zeroing weak pointers	404
15.3.4. Weak pointers functions implementation details	405

15.4. Interfaces in practice: dependency injection, stubs and mocks	407
15.4.1. Dependency Injection at constructors	407
15.4.2. Why use fake / emulated interfaces?	408
15.4.2.1. Stubs and mocks	408
15.4.2.2. Defining stubs	409
15.4.2.3. Defining a mock	409
15.4.2.4. Running the test	410
15.5. Stubs and Mocks in mORMot	411
15.5.1. Direct use of interface types without TypeInfo()	411
15.5.2. Manual dependency injection	411
15.5.3. Stubbing complex return values	413
15.5.4. Stubbing via a custom delegate or callback	413
15.5.4.1. Delegate with named variant parameters	414
15.5.4.2. Delegate with indexed variant parameters	414
15.5.4.3. Delegate with JSON parameters	415
15.5.4.4. Accessing the test case when mocking	415
15.5.5. Calls tracing	416
15.6. Dependency Injection and Interface Resolution	418
16. Client-Server services via interfaces	
<hr/>	
16.1. Implemented features	421
16.2. How to make services	422
16.3. Defining a service contract	423
16.3.1. Define an interface	423
16.3.2. Service Methods Parameters	424
16.3.3. TPersistent / TSQLRecord parameters	425
16.3.4. Record parameters	427
16.3.5. TCollection parameters	427
16.3.5.1. Use of TCollection	427
16.3.5.2. Inherit from TInterfacedCollection	428
16.3.5.3. Register a TCollection type	428

16.4. Server side	430
16.4.1. Implementing the service contract	430
16.4.2. Set up the Server factory	430
16.4.3. Instances life time implementation	430
16.4.4. Accessing low-level execution context	433
16.4.4.1. Retrieve information from the global ServiceContext	433
16.4.4.2. Implement your service from TInjectableObjectRest	434
16.4.5. Using services on the Server side	434
16.5. Client side	436
16.5.1. Set up the Client factory	436
16.5.2. Using services on the Client side	436
16.6. Sample code	438
16.6.1. The shared contract	438
16.6.2. The server sample application	438
16.6.3. The client sample application	439
16.6.4. Enhanced sample: remote SQL access	440
16.7. Asynchronous callbacks	445
16.7.1. WebSockets support	445
16.7.1.1. Using a "Saga" callback to notify long term end-of-process	447
16.7.1.2. Client service consumption	447
16.7.1.3. Server side implementation	448
16.7.2. Publish-subscribe for events	449
16.7.2.1. Defining the interfaces	450
16.7.2.2. Writing the Publisher	451
16.7.2.3. Consuming the service from the Subscriber side	452
16.7.2.4. Subscriber multiple redirection	453
16.7.2.5. Proper threaded implementation	454
16.7.2.6. Interacting with UI/VCL	454
16.7.3. Interface callbacks instead of class messages	455

16.7.3.1. Using service and callback interfaces	455
16.7.3.2. Classical message(s) event	456
16.7.3.3. Workflow adaptation	457
16.7.3.4. From interfaces comes abstraction and ease	458
16.8. Implementation details	459
16.8.1. Error handling	459
16.8.2. Security	460
16.8.3. Implementation class types	462
16.8.4. Server-side execution options (threading)	462
16.8.5. Audit Trail for Services	464
16.8.5.1. When logging is not enough	464
16.8.5.2. Tracing Service Methods	464
16.8.5.3. Tracing Asynchronous External Calls	466
16.8.6. Transmission content	467
16.8.6.1. Request format	467
16.8.6.1.1. REST mode	468
16.8.6.1.1.1. Parameters transmitted as JSON array	468
16.8.6.1.1.2. Parameters transmitted as JSON object	468
16.8.6.1.1.3. Parameters encoded at URI level	469
16.8.6.1.1.4. Sending a JSON object	470
16.8.6.1.1.5. Sending raw binary	470
16.8.6.1.2. JSON-RPC	470
16.8.6.1.2.1. Parameters transmitted as JSON array	470
16.8.6.1.2.2. Parameters transmitted as JSON object	471
16.8.6.1.3. REST mode or JSON-RPC mode?	471
16.8.6.2. Response format	471
16.8.6.2.1. Standard answer as JSON object	471
16.8.6.2.1.1. JSON answers	471
16.8.6.2.1.1.1. Returning as JSON array	471
16.8.6.2.1.1.2. Returning a JSON object	473
16.8.6.2.1.2. Returning raw JSON content	474

16.8.6.2.1.3. Returning errors	474
16.8.6.2.2. Returning content as XML	475
16.8.6.2.2.1. Always return XML content	475
16.8.6.2.2.2. Return XML content on demand	476
16.8.6.2.3. Custom returned content	477
16.9. Comparison with WCF	479
17. Cross-Platform clients	
<hr/>	
17.1. Available client platforms	484
17.1.1. Delphi FMX / FreePascal FCL cross-platform support	484
17.1.1.1. Cross-platform JSON	484
17.1.1.2. Delphi OSX and NextGen	486
17.1.1.3. FreePascal clients	486
17.1.1.4. Local or remote logging	487
17.1.2. Smart Mobile Studio support	487
17.1.2.1. Beyond JavaScript	488
17.1.2.2. Using Smart Mobile Studio with mORMot	488
17.1.3. Remote logging	489
17.2. Generating client wrappers	490
17.2.1. Publishing the code generator	490
17.2.2. Delphi / FreePascal client samples	492
17.2.2.1. Connection to the server	493
17.2.2.2. CRUD/ORM remote access	493
17.2.2.3. Service consumption	495
17.2.3. Smart Mobile Studio client samples	497
17.2.3.1. Adding two numbers in AJAX	497
17.2.3.2. CRUD/ORM remote access	500
18. MVC pattern	
<hr/>	
18.1. Model	503
18.2. Views	503
18.2.1. Desktop clients	504

18.2.1.1. RTTI	504
18.2.1.2. User Interface	505
18.2.2. Web clients	506
18.2.2.1. Mustache template engine	506
18.2.2.2. Mustache principles	506
18.2.2.3. Mustache templates	507
18.2.2.3.1. Variables	509
18.2.2.3.2. Sections	509
18.2.2.3.3. Inverted Sections	511
18.2.2.3.4. Partials	511
18.2.2.4. SynMustache unit	512
18.2.2.4.1. Variables	513
18.2.2.4.2. Sections	514
18.2.2.4.3. Partials	514
18.2.2.4.4. Expression Helpers	515
18.2.2.4.5. Internationalization	516
18.2.2.5. Low-level integration with method-based services	517
18.2.2.6. MVC/MVVM Design	517
19. MVC/MVVM Web applications	
<hr/>	
19.1. MVCModel	520
19.1.1. Data Model	520
19.1.2. Hosted in a REST server over HTTP	522
19.2. MVCViewModel	523
19.2.1. Defining the commands	523
19.2.2. Implementing the Controller	527
19.2.3. Variable input parameters	529
19.2.4. Using Services in the Controller	530
19.2.5. Controller Thread Safety	530
19.2.6. Web Sessions	531
19.3. Writing the Views	534

20. Hosting

20.1. Windows and Linux hosted	538
20.2. Deployment Architecture	538
20.2.1. Shared server	539
20.2.2. Two servers	541
20.2.3. Two instances on the same server	542
20.2.4. Scaling via CDN	543

21. Security

21.1. Authentication	547
21.1.1. Principles	547
21.1.1.1. HTTP basic auth over HTTPS	547
21.1.1.2. Session via Cookies	548
21.1.1.3. Query Authentication	548
21.1.2. Framework authentication	548
21.1.2.1. Per-User authentication	549
21.1.2.2. Session handling	551
21.1.3. Authentication schemes	552
21.1.3.1. Class-driven authentication	552
21.1.3.2. mORMot secure RESTful authentication	553
21.1.3.3. Authentication using Windows credentials	554
21.1.3.3.1. Windows Authentication	554
21.1.3.3.2. Using NTLM or Kerberos	555
21.1.3.4. Weak authentication	556
21.1.3.5. HTTP Basic authentication	557
21.1.4. Clients authentication	557
21.1.4.1. Client interactivity	557
21.1.4.2. Authentication using AJAX	557
21.1.5. JWT Authentication	558
21.2. Authorization	559
21.2.1. Per-table access rights	559

21.2.2. Additional safety	560
21.2.2.1. SQL remote execution	560
21.2.2.2. Service execution	561
22. Scripting Engine	
<hr/>	
22.1. Scripting abilities	562
22.2. SpiderMonkey integration	563
22.2.1. A powerful JavaScript engine	563
22.2.2. Direct access to the SpiderMonkey API	564
22.2.3. Execution scheme	564
22.2.4. Creating your execution context	565
22.2.5. Blocking threading model	566
22.3. Interaction with existing code	567
22.3.1. Proper engine initialization	567
22.3.2. Calling Delphi code from JavaScript	568
22.3.3. TSMVariant custom type	570
22.3.4. Calling JavaScript code from Delphi	570
23. Asymmetric Encryption	
<hr/>	
23.1. Public-key Cryptography	573
23.1.1. Keys Generation and Distribution	573
23.1.2. Message Authentication	574
23.1.3. Certificates and Public Key Infrastructure	574
23.1.4. Message encryption	575
23.2. Elliptic Curve Cryptography	577
23.2.1. Introducing SynEcc	577
23.2.2. ECC command line tool	578
23.2.3. Keys and Certificates Generation	579
23.2.4. TECCCertificate and TECCCertificateSecret	583
23.2.5. File Signature	584
23.2.6. Signing in Code	585
23.2.7. File Encryption	586

23.2.8. Private Keys Passwords Cheat Mode	588
23.2.9. Encryption in Code	591
23.3. Application Locking	591
23.3.1. From the User perspective	592
23.3.2. From the Support Team perspective	593
23.3.3. Benefits of Asymmetric Encryption for License management	594
24. Domain-Driven-Design	
<hr/>	
24.1. Domain	596
24.2. Modeling	597
24.2.1. Several Models to rule them all	597
24.2.2. The state of the model	597
24.2.3. Composition	598
24.3. DDD model	599
24.3.1. Ubiquitous Language	599
24.3.2. Value Objects and Entities	599
24.3.3. Aggregates	600
24.3.4. Factory and Repository patterns	600
24.3.5. DTO and Events to avoid domain leaking	601
24.3.6. Services	602
24.3.7. Clean Uncoupled Architecture	603
24.4. mORMot's DDD	606
24.4.1. Designer's commitments	606
24.4.2. Defining objects in Delphi	606
24.4.3. Defining DDD objects in mORMot	607
24.4.3.1. Use framework types for DDD objects	607
24.4.3.2. Define uncoupled DDD objects	608
24.4.3.3. Specialize your simple types	608
24.4.3.4. Define your PODO classes	609
24.4.3.5. Store your Entities in CQRS Repositories	611
24.4.3.5.1. CQRS Interfaces	611

24.4.3.5.2. Queries Interface	612
24.4.3.5.3. Commands Interface	614
24.4.3.5.4. Automated Repository using the ORM	615
24.4.3.5.4.1. DDD / ORM mapping	615
24.4.3.5.4.2. Define the Factory	617
24.4.3.5.4.3. Implement the CQRS methods	619
24.4.3.6. Isolate your Domain using DTOs	621
24.4.4. Defining services	621
24.4.5. Event-Driven Design	622
24.4.5.1. Events as Callbacks	622
24.4.5.2. Event Sourcing via Event Oriented Databases	623
24.4.6. Building a Clean architecture	624
25. Testing and logging	
<hr/>	
25.1. Automated testing	628
25.1.1. Involved classes in Unitary testing	628
25.1.2. First steps in testing	629
25.1.3. Framework test coverage	630
25.2. Enhanced logging	632
25.2.1. Setup logging	632
25.2.2. Call trace	634
25.2.3. Including symbol definitions	634
25.2.4. Exception handling	634
25.2.5. Serialization	636
25.2.6. Multi-threaded applications	636
25.2.7. Log to the console	637
25.2.8. Remote logging	637
25.2.9. Log to third-party libraries	638
25.2.10. Automated log archival	638
25.2.11. Log files rotation	639
25.2.12. Integration within tests	640
25.2.13. Log Viewer	640

25.2.13.1. Open log files	640
25.2.13.2. Log browser	641
25.2.13.3. Customer-side profiler	641
25.2.13.4. Per-thread inspection	642
25.2.13.5. Server for remote logging	642
25.2.14. Framework log integration	642
26. Source code	
<hr/>	
26.1. License	644
26.1.1. Three Licenses Model	644
26.1.2. Publish modifications and credit for the library	645
26.1.3. Derivate Open Source works	645
26.1.4. Commercial licenses	646
26.2. Availability	647
26.2.1. Obtaining the Source Code	647
26.2.2. Expected compilation platform	647
26.2.3. SQLite3 static linking for Delphi and FPC	648
26.2.4. SpiderMonkey library	649
26.2.5. Folder layout	649
26.2.5.1. Root folder	650
26.2.5.2. SynDBDataset folder	652
26.2.5.3. SQLite3 folder	652
26.2.5.4. CrossPlatform folder	653
26.3. Delphi Installation	654
26.3.1. Manual download	654
26.3.2. Get from GitHub	654
26.3.3. Setup the Delphi IDE	654
26.4. FreePascal / Lazarus Installation	656
26.4.1. Possible targets	656
26.4.2. Setup your dedicated FPC / Lazarus environment with fpcupdeluxe	656
26.4.3. Missing RTTI for interfaces in old FPC 2.6	657

26.4.4. Writing your project for FPC	658
26.4.5. Linux VM installation tips	659
26.5. CrossKylix support	660
26.5.1. What is Cross-Kylix?	660
26.5.2. Running Kylix 32-bit executables on 64-bit Linux	662
26.6. Upgrading from a 1.17 revision	663

Foreword

The whole Software documentation process follows the typical steps of this diagram:

Design Inputs, FMEA and Risk Specifications

Purpose

This *Software Architecture Design (SAD)* document applies to the 1.18 release of the *Synopse mORMot Framework* library.

After a deep presentation of the framework architecture and main features, each source code unit is detailed, with clear diagrams and tables showing the dependencies between the units, and the class hierarchy of the objects implemented within.

The *SynFile* main demo is presented on its own, and can be used as a general *User Guide* of its basic ORM features and User Interface generation - see below (page 2515).

At the end of this document, *Software Requirements Specifications* (SWRS) document items are linked directly to the class or function involved with the *Software Design Document* (SDD) document, from the source code.

Responsibilities

- Support is available in the project forum - <https://synopse.info/forum..> - from the *mORMot* Open Source community;
- Tickets can be created in a public Tracker web site located at <https://synopse.info/fossil..>, which publishes also the latest version of the project source code;
- Synopse can provide additional support, expertise or enhancements, on request;
- Synopse work on the framework is distributed without any warranty, according to the chosen license terms - see below (page 644);
- This documentation is released under the GPL (*GNU General Public License*) terms, without any warranty of any kind.

GNU General Public License

GNU GENERAL PUBLIC LICENSE
Version 3, 29 June 2007

Copyright (C) 2007 Free Software Foundation, Inc. <<http://fsf.org/>>
Everyone is permitted to copy and distribute verbatim copies
of this license document, but changing it is not allowed.

Preamble

The GNU General Public License is a free, copyleft license for
software and other kinds of works.

The licenses for most software and other practical works are designed
to take away your freedom to share and change the works. By contrast,
the GNU General Public License is intended to guarantee your freedom to
share and change all versions of a program--to make sure it remains free
software for all its users. We, the Free Software Foundation, use the
GNU General Public License for most of our software; it applies also to
any other work released this way by its authors. You can apply it to
your programs, too.

When we speak of free software, we are referring to freedom, not
price. Our General Public Licenses are designed to make sure that you
have the freedom to distribute copies of free software (and charge for
them if you wish), that you receive source code or can get it if you
want it, that you can change the software or use pieces of it in new
free programs, and that you know you can do these things.

To protect your rights, we need to prevent others from denying you
these rights or asking you to surrender the rights. Therefore, you have
certain responsibilities if you distribute copies of the software, or if
you modify it: responsibilities to respect the freedom of others.

For example, if you distribute copies of such a program, whether
gratis or for a fee, you must pass on to the recipients the same
freedoms that you received. You must make sure that they, too, receive
or can get the source code. And you must show them these terms so they
know their rights.

Developers that use the GNU GPL protect your rights with two steps:
(1) assert copyright on the software, and (2) offer you this License

giving you legal permission to copy, distribute and/or modify it.

For the developers' and authors' protection, the GPL clearly explains that there is no warranty for this free software. For both users' and authors' sake, the GPL requires that modified versions be marked as changed, so that their problems will not be attributed erroneously to authors of previous versions.

Some devices are designed to deny users access to install or run modified versions of the software inside them, although the manufacturer can do so. This is fundamentally incompatible with the aim of protecting users' freedom to change the software. The systematic pattern of such abuse occurs in the area of products for individuals to use, which is precisely where it is most unacceptable. Therefore, we have designed this version of the GPL to prohibit the practice for those products. If such problems arise substantially in other domains, we stand ready to extend this provision to those domains in future versions of the GPL, as needed to protect the freedom of users.

Finally, every program is threatened constantly by software patents. States should not allow patents to restrict development and use of software on general-purpose computers, but in those that do, we wish to avoid the special danger that patents applied to a free program could make it effectively proprietary. To prevent this, the GPL assures that patents cannot be used to render the program non-free.

The precise terms and conditions for copying, distribution and modification follow.

TERMS AND CONDITIONS

0. Definitions.

"This License" refers to version 3 of the GNU General Public License.

"Copyright" also means copyright-like laws that apply to other kinds of works, such as semiconductor masks.

"The Program" refers to any copyrightable work licensed under this License. Each licensee is addressed as "you". "Licensees" and "recipients" may be individuals or organizations.

To "modify" a work means to copy from or adapt all or part of the work in a fashion requiring copyright permission, other than the making of an exact copy. The resulting work is called a "modified version" of the earlier work or a work "based on" the earlier work.

A "covered work" means either the unmodified Program or a work based on the Program.

To "propagate" a work means to do anything with it that, without permission, would make you directly or secondarily liable for infringement under applicable copyright law, except executing it on a computer or modifying a private copy. Propagation includes copying, distribution (with or without modification), making available to the public, and in some countries other activities as well.

To "convey" a work means any kind of propagation that enables other parties to make or receive copies. Mere interaction with a user through a computer network, with no transfer of a copy, is not conveying.

An interactive user interface displays "Appropriate Legal Notices" to the extent that it includes a convenient and prominently visible

feature that (1) displays an appropriate copyright notice, and (2) tells the user that there is no warranty for the work (except to the extent that warranties are provided), that licensees may convey the work under this License, and how to view a copy of this License. If the interface presents a list of user commands or options, such as a menu, a prominent item in the list meets this criterion.

1. Source Code.

The "source code" for a work means the preferred form of the work for making modifications to it. "Object code" means any non-source form of a work.

A "Standard Interface" means an interface that either is an official standard defined by a recognized standards body, or, in the case of interfaces specified for a particular programming language, one that is widely used among developers working in that language.

The "System Libraries" of an executable work include anything, other than the work as a whole, that (a) is included in the normal form of packaging a Major Component, but which is not part of that Major Component, and (b) serves only to enable use of the work with that Major Component, or to implement a Standard Interface for which an implementation is available to the public in source code form. A "Major Component", in this context, means a major essential component (kernel, window system, and so on) of the specific operating system (if any) on which the executable work runs, or a compiler used to produce the work, or an object code interpreter used to run it.

The "Corresponding Source" for a work in object code form means all the source code needed to generate, install, and (for an executable work) run the object code and to modify the work, including scripts to control those activities. However, it does not include the work's System Libraries, or general-purpose tools or generally available free programs which are used unmodified in performing those activities but which are not part of the work. For example, Corresponding Source includes interface definition files associated with source files for the work, and the source code for shared libraries and dynamically linked subprograms that the work is specifically designed to require, such as by intimate data communication or control flow between those subprograms and other parts of the work.

The Corresponding Source need not include anything that users can regenerate automatically from other parts of the Corresponding Source.

The Corresponding Source for a work in source code form is that same work.

2. Basic Permissions.

All rights granted under this License are granted for the term of copyright on the Program, and are irrevocable provided the stated conditions are met. This License explicitly affirms your unlimited permission to run the unmodified Program. The output from running a covered work is covered by this License only if the output, given its content, constitutes a covered work. This License acknowledges your rights of fair use or other equivalent, as provided by copyright law.

You may make, run and propagate covered works that you do not convey, without conditions so long as your license otherwise remains in force. You may convey covered works to others for the sole purpose of having them make modifications exclusively for you, or provide you with facilities for running those works, provided that you comply with

the terms of this License in conveying all material for which you do not control copyright. Those thus making or running the covered works for you must do so exclusively on your behalf, under your direction and control, on terms that prohibit them from making any copies of your copyrighted material outside their relationship with you.

Conveying under any other circumstances is permitted solely under the conditions stated below. Sublicensing is not allowed; section 10 makes it unnecessary.

3. Protecting Users' Legal Rights From Anti-Circumvention Law.

No covered work shall be deemed part of an effective technological measure under any applicable law fulfilling obligations under article 11 of the WIPO copyright treaty adopted on 20 December 1996, or similar laws prohibiting or restricting circumvention of such measures.

When you convey a covered work, you waive any legal power to forbid circumvention of technological measures to the extent such circumvention is effected by exercising rights under this License with respect to the covered work, and you disclaim any intention to limit operation or modification of the work as a means of enforcing, against the work's users, your or third parties' legal rights to forbid circumvention of technological measures.

4. Conveying Verbatim Copies.

You may convey verbatim copies of the Program's source code as you receive it, in any medium, provided that you conspicuously and appropriately publish on each copy an appropriate copyright notice; keep intact all notices stating that this License and any non-permissive terms added in accord with section 7 apply to the code; keep intact all notices of the absence of any warranty; and give all recipients a copy of this License along with the Program.

You may charge any price or no price for each copy that you convey, and you may offer support or warranty protection for a fee.

5. Conveying Modified Source Versions.

You may convey a work based on the Program, or the modifications to produce it from the Program, in the form of source code under the terms of section 4, provided that you also meet all of these conditions:

a) The work must carry prominent notices stating that you modified it, and giving a relevant date.

b) The work must carry prominent notices stating that it is released under this License and any conditions added under section 7. This requirement modifies the requirement in section 4 to "keep intact all notices".

c) You must license the entire work, as a whole, under this License to anyone who comes into possession of a copy. This License will therefore apply, along with any applicable section 7 additional terms, to the whole of the work, and all its parts, regardless of how they are packaged. This License gives no permission to license the work in any other way, but it does not invalidate such permission if you have separately received it.

d) If the work has interactive user interfaces, each must display Appropriate Legal Notices; however, if the Program has interactive

interfaces that do not display Appropriate Legal Notices, your work need not make them do so.

A compilation of a covered work with other separate and independent works, which are not by their nature extensions of the covered work, and which are not combined with it such as to form a larger program, in or on a volume of a storage or distribution medium, is called an "aggregate" if the compilation and its resulting copyright are not used to limit the access or legal rights of the compilation's users beyond what the individual works permit. Inclusion of a covered work in an aggregate does not cause this License to apply to the other parts of the aggregate.

6. Conveying Non-Source Forms.

You may convey a covered work in object code form under the terms of sections 4 and 5, provided that you also convey the machine-readable Corresponding Source under the terms of this License, in one of these ways:

- a) Convey the object code in, or embodied in, a physical product (including a physical distribution medium), accompanied by the Corresponding Source fixed on a durable physical medium customarily used for software interchange.
- b) Convey the object code in, or embodied in, a physical product (including a physical distribution medium), accompanied by a written offer, valid for at least three years and valid for as long as you offer spare parts or customer support for that product model, to give anyone who possesses the object code either (1) a copy of the Corresponding Source for all the software in the product that is covered by this License, on a durable physical medium customarily used for software interchange, for a price no more than your reasonable cost of physically performing this conveying of source, or (2) access to copy the Corresponding Source from a network server at no charge.
- c) Convey individual copies of the object code with a copy of the written offer to provide the Corresponding Source. This alternative is allowed only occasionally and noncommercially, and only if you received the object code with such an offer, in accord with subsection 6b.
- d) Convey the object code by offering access from a designated place (gratis or for a charge), and offer equivalent access to the Corresponding Source in the same way through the same place at no further charge. You need not require recipients to copy the Corresponding Source along with the object code. If the place to copy the object code is a network server, the Corresponding Source may be on a different server (operated by you or a third party) that supports equivalent copying facilities, provided you maintain clear directions next to the object code saying where to find the Corresponding Source. Regardless of what server hosts the Corresponding Source, you remain obligated to ensure that it is available for as long as needed to satisfy these requirements.
- e) Convey the object code using peer-to-peer transmission, provided you inform other peers where the object code and Corresponding Source of the work are being offered to the general public at no charge under subsection 6d.

A separable portion of the object code, whose source code is excluded from the Corresponding Source as a System Library, need not be included in conveying the object code work.

A "User Product" is either (1) a "consumer product", which means any tangible personal property which is normally used for personal, family, or household purposes, or (2) anything designed or sold for incorporation into a dwelling. In determining whether a product is a consumer product, doubtful cases shall be resolved in favor of coverage. For a particular product received by a particular user, "normally used" refers to a typical or common use of that class of product, regardless of the status of the particular user or of the way in which the particular user actually uses, or expects or is expected to use, the product. A product is a consumer product regardless of whether the product has substantial commercial, industrial or non-consumer uses, unless such uses represent the only significant mode of use of the product.

"Installation Information" for a User Product means any methods, procedures, authorization keys, or other information required to install and execute modified versions of a covered work in that User Product from a modified version of its Corresponding Source. The information must suffice to ensure that the continued functioning of the modified object code is in no case prevented or interfered with solely because modification has been made.

If you convey an object code work under this section in, or with, or specifically for use in, a User Product, and the conveying occurs as part of a transaction in which the right of possession and use of the User Product is transferred to the recipient in perpetuity or for a fixed term (regardless of how the transaction is characterized), the Corresponding Source conveyed under this section must be accompanied by the Installation Information. But this requirement does not apply if neither you nor any third party retains the ability to install modified object code on the User Product (for example, the work has been installed in ROM).

The requirement to provide Installation Information does not include a requirement to continue to provide support service, warranty, or updates for a work that has been modified or installed by the recipient, or for the User Product in which it has been modified or installed. Access to a network may be denied when the modification itself materially and adversely affects the operation of the network or violates the rules and protocols for communication across the network.

Corresponding Source conveyed, and Installation Information provided, in accord with this section must be in a format that is publicly documented (and with an implementation available to the public in source code form), and must require no special password or key for unpacking, reading or copying.

7. Additional Terms.

"Additional permissions" are terms that supplement the terms of this License by making exceptions from one or more of its conditions. Additional permissions that are applicable to the entire Program shall be treated as though they were included in this License, to the extent that they are valid under applicable law. If additional permissions apply only to part of the Program, that part may be used separately under those permissions, but the entire Program remains governed by this License without regard to the additional permissions.

When you convey a copy of a covered work, you may at your option remove any additional permissions from that copy, or from any part of it. (Additional permissions may be written to require their own removal in certain cases when you modify the work.) You may place additional permissions on material, added by you to a covered work, for which you have or can give appropriate copyright permission.

Notwithstanding any other provision of this License, for material you add to a covered work, you may (if authorized by the copyright holders of that material) supplement the terms of this License with terms:

- a) Disclaiming warranty or limiting liability differently from the terms of sections 15 and 16 of this license; or
- b) Requiring preservation of specified reasonable legal notices or author attributions in that material or in the Appropriate Legal Notices displayed by works containing it; or
- c) Prohibiting misrepresentation of the origin of that material, or requiring that modified versions of such material be marked in reasonable ways as different from the original version; or
- d) Limiting the use for publicity purposes of names of licensors or authors of the material; or
- e) Declining to grant rights under trademark law for use of some trade names, trademarks, or service marks; or
- f) Requiring indemnification of licensors and authors of that material by anyone who conveys the material (or modified versions of it) with contractual assumptions of liability to the recipient, for any liability that these contractual assumptions directly impose on those licensors and authors.

All other non-permissive additional terms are considered "further restrictions" within the meaning of section 10. If the Program as you received it, or any part of it, contains a notice stating that it is governed by this License along with a term that is a further restriction, you may remove that term. If a license document contains a further restriction but permits relicensing or conveying under this License, you may add to a covered work material governed by the terms of that license document, provided that the further restriction does not survive such relicensing or conveying.

If you add terms to a covered work in accord with this section, you must place, in the relevant source files, a statement of the additional terms that apply to those files, or a notice indicating where to find the applicable terms.

Additional terms, permissive or non-permissive, may be stated in the form of a separately written license, or stated as exceptions; the above requirements apply either way.

8. Termination.

You may not propagate or modify a covered work except as expressly provided under this License. Any attempt otherwise to propagate or modify it is void, and will automatically terminate your rights under this License (including any patent licenses granted under the third paragraph of section 11).

However, if you cease all violation of this License, then your license from a particular copyright holder is reinstated (a) provisionally, unless and until the copyright holder explicitly and finally terminates your license, and (b) permanently, if the copyright holder fails to notify you of the violation by some reasonable means prior to 60 days after the cessation.

Moreover, your license from a particular copyright holder is

reinstated permanently if the copyright holder notifies you of the violation by some reasonable means, this is the first time you have received notice of violation of this License (for any work) from that copyright holder, and you cure the violation prior to 30 days after your receipt of the notice.

Termination of your rights under this section does not terminate the licenses of parties who have received copies or rights from you under this License. If your rights have been terminated and not permanently reinstated, you do not qualify to receive new licenses for the same material under section 10.

9. Acceptance Not Required for Having Copies.

You are not required to accept this License in order to receive or run a copy of the Program. Ancillary propagation of a covered work occurring solely as a consequence of using peer-to-peer transmission to receive a copy likewise does not require acceptance. However, nothing other than this License grants you permission to propagate or modify any covered work. These actions infringe copyright if you do not accept this License. Therefore, by modifying or propagating a covered work, you indicate your acceptance of this License to do so.

10. Automatic Licensing of Downstream Recipients.

Each time you convey a covered work, the recipient automatically receives a license from the original licensors, to run, modify and propagate that work, subject to this License. You are not responsible for enforcing compliance by third parties with this License.

An "entity transaction" is a transaction transferring control of an organization, or substantially all assets of one, or subdividing an organization, or merging organizations. If propagation of a covered work results from an entity transaction, each party to that transaction who receives a copy of the work also receives whatever licenses to the work the party's predecessor in interest had or could give under the previous paragraph, plus a right to possession of the Corresponding Source of the work from the predecessor in interest, if the predecessor has it or can get it with reasonable efforts.

You may not impose any further restrictions on the exercise of the rights granted or affirmed under this License. For example, you may not impose a license fee, royalty, or other charge for exercise of rights granted under this License, and you may not initiate litigation (including a cross-claim or counterclaim in a lawsuit) alleging that any patent claim is infringed by making, using, selling, offering for sale, or importing the Program or any portion of it.

11. Patents.

A "contributor" is a copyright holder who authorizes use under this License of the Program or a work on which the Program is based. The work thus licensed is called the contributor's "contributor version".

A contributor's "essential patent claims" are all patent claims owned or controlled by the contributor, whether already acquired or hereafter acquired, that would be infringed by some manner, permitted by this License, of making, using, or selling its contributor version, but do not include claims that would be infringed only as a consequence of further modification of the contributor version. For purposes of this definition, "control" includes the right to grant patent sublicenses in a manner consistent with the requirements of this License.

Each contributor grants you a non-exclusive, worldwide, royalty-free patent license under the contributor's essential patent claims, to make, use, sell, offer for sale, import and otherwise run, modify and propagate the contents of its contributor version.

In the following three paragraphs, a "patent license" is any express agreement or commitment, however denominated, not to enforce a patent (such as an express permission to practice a patent or covenant not to sue for patent infringement). To "grant" such a patent license to a party means to make such an agreement or commitment not to enforce a patent against the party.

If you convey a covered work, knowingly relying on a patent license, and the Corresponding Source of the work is not available for anyone to copy, free of charge and under the terms of this License, through a publicly available network server or other readily accessible means, then you must either (1) cause the Corresponding Source to be so available, or (2) arrange to deprive yourself of the benefit of the patent license for this particular work, or (3) arrange, in a manner consistent with the requirements of this License, to extend the patent license to downstream recipients. "Knowingly relying" means you have actual knowledge that, but for the patent license, your conveying the covered work in a country, or your recipient's use of the covered work in a country, would infringe one or more identifiable patents in that country that you have reason to believe are valid.

If, pursuant to or in connection with a single transaction or arrangement, you convey, or propagate by procuring conveyance of, a covered work, and grant a patent license to some of the parties receiving the covered work authorizing them to use, propagate, modify or convey a specific copy of the covered work, then the patent license you grant is automatically extended to all recipients of the covered work and works based on it.

A patent license is "discriminatory" if it does not include within the scope of its coverage, prohibits the exercise of, or is conditioned on the non-exercise of one or more of the rights that are specifically granted under this License. You may not convey a covered work if you are a party to an arrangement with a third party that is in the business of distributing software, under which you make payment to the third party based on the extent of your activity of conveying the work, and under which the third party grants, to any of the parties who would receive the covered work from you, a discriminatory patent license (a) in connection with copies of the covered work conveyed by you (or copies made from those copies), or (b) primarily for and in connection with specific products or compilations that contain the covered work, unless you entered into that arrangement, or that patent license was granted, prior to 28 March 2007.

Nothing in this License shall be construed as excluding or limiting any implied license or other defenses to infringement that may otherwise be available to you under applicable patent law.

12. No Surrender of Others' Freedom.

If conditions are imposed on you (whether by court order, agreement or otherwise) that contradict the conditions of this License, they do not excuse you from the conditions of this License. If you cannot convey a covered work so as to satisfy simultaneously your obligations under this License and any other pertinent obligations, then as a consequence you may not convey it at all. For example, if you agree to terms that obligate you to collect a royalty for further conveying from those to whom you convey the Program, the only way you could satisfy both those terms and this License would be to refrain entirely from conveying the Program.

13. Use with the GNU Affero General Public License.

Notwithstanding any other provision of this License, you have permission to link or combine any covered work with a work licensed under version 3 of the GNU Affero General Public License into a single combined work, and to convey the resulting work. The terms of this License will continue to apply to the part which is the covered work, but the special requirements of the GNU Affero General Public License, section 13, concerning interaction through a network will apply to the combination as such.

14. Revised Versions of this License.

The Free Software Foundation may publish revised and/or new versions of the GNU General Public License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns.

Each version is given a distinguishing version number. If the Program specifies that a certain numbered version of the GNU General Public License "or any later version" applies to it, you have the option of following the terms and conditions either of that numbered version or of any later version published by the Free Software Foundation. If the Program does not specify a version number of the GNU General Public License, you may choose any version ever published by the Free Software Foundation.

If the Program specifies that a proxy can decide which future versions of the GNU General Public License can be used, that proxy's public statement of acceptance of a version permanently authorizes you to choose that version for the Program.

Later license versions may give you additional or different permissions. However, no additional obligations are imposed on any author or copyright holder as a result of your choosing to follow a later version.

15. Disclaimer of Warranty.

THERE IS NO WARRANTY FOR THE PROGRAM, TO THE EXTENT PERMITTED BY APPLICABLE LAW. EXCEPT WHEN OTHERWISE STATED IN WRITING THE COPYRIGHT HOLDERS AND/OR OTHER PARTIES PROVIDE THE PROGRAM "AS IS" WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESSED OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. THE ENTIRE RISK AS TO THE QUALITY AND PERFORMANCE OF THE PROGRAM IS WITH YOU. SHOULD THE PROGRAM PROVE DEFECTIVE, YOU ASSUME THE COST OF ALL NECESSARY SERVICING, REPAIR OR CORRECTION.

16. Limitation of Liability.

IN NO EVENT UNLESS REQUIRED BY APPLICABLE LAW OR AGREED TO IN WRITING WILL ANY COPYRIGHT HOLDER, OR ANY OTHER PARTY WHO MODIFIES AND/OR CONVEYS THE PROGRAM AS PERMITTED ABOVE, BE LIABLE TO YOU FOR DAMAGES, INCLUDING ANY GENERAL, SPECIAL, INCIDENTAL OR CONSEQUENTIAL DAMAGES ARISING OUT OF THE USE OR INABILITY TO USE THE PROGRAM (INCLUDING BUT NOT LIMITED TO LOSS OF DATA OR DATA BEING RENDERED INACCURATE OR LOSSES SUSTAINED BY YOU OR THIRD PARTIES OR A FAILURE OF THE PROGRAM TO OPERATE WITH ANY OTHER PROGRAMS), EVEN IF SUCH HOLDER OR OTHER PARTY HAS BEEN ADVISED OF THE POSSIBILITY OF SUCH DAMAGES.

17. Interpretation of Sections 15 and 16.

If the disclaimer of warranty and limitation of liability provided

above cannot be given local legal effect according to their terms, reviewing courts shall apply local law that most closely approximates an absolute waiver of all civil liability in connection with the Program, unless a warranty or assumption of liability accompanies a copy of the Program in return for a fee.

END OF TERMS AND CONDITIONS

How to Apply These Terms to Your New Programs

If you develop a new program, and you want it to be of the greatest possible use to the public, the best way to achieve this is to make it free software which everyone can redistribute and change under these terms.

To do so, attach the following notices to the program. It is safest to attach them to the start of each source file to most effectively state the exclusion of warranty; and each file should have at least the "copyright" line and a pointer to where the full notice is found.

```
<one line to give the program's name and a brief idea of what it does.>
Copyright (C) <year> <name of author>
```

This program is free software: you can redistribute it and/or modify it under the terms of the GNU General Public License as published by the Free Software Foundation, either version 3 of the License, or (at your option) any later version.

This program is distributed in the hope that it will be useful, but WITHOUT ANY WARRANTY; without even the implied warranty of MERCHANTABILITY or FITNESS FOR A PARTICULAR PURPOSE. See the GNU General Public License for more details.

You should have received a copy of the GNU General Public License along with this program. If not, see <http://www.gnu.org/licenses/>.

Also add information on how to contact you by electronic and paper mail.

If the program does terminal interaction, make it output a short notice like this when it starts in an interactive mode:

```
<program> Copyright (C) <year> <name of author>
This program comes with ABSOLUTELY NO WARRANTY; for details type `show w'.
This is free software, and you are welcome to redistribute it
under certain conditions; type `show c' for details.
```

The hypothetical commands `show w' and `show c' should show the appropriate parts of the General Public License. Of course, your program's commands might be different; for a GUI interface, you would use an "about box".

You should also get your employer (if you work as a programmer) or school, if any, to sign a "copyright disclaimer" for the program, if necessary. For more information on this, and how to apply and follow the GNU GPL, see <http://www.gnu.org/licenses/>.

The GNU General Public License does not permit incorporating your program into proprietary programs. If your program is a subroutine library, you may consider it more useful to permit linking proprietary applications with the library. If this is what you want to do, use the GNU Lesser General Public License instead of this License. But first, please read <http://www.gnu.org/philosophy/why-not-lgpl.html>.

1. Synapse mORMot Overview

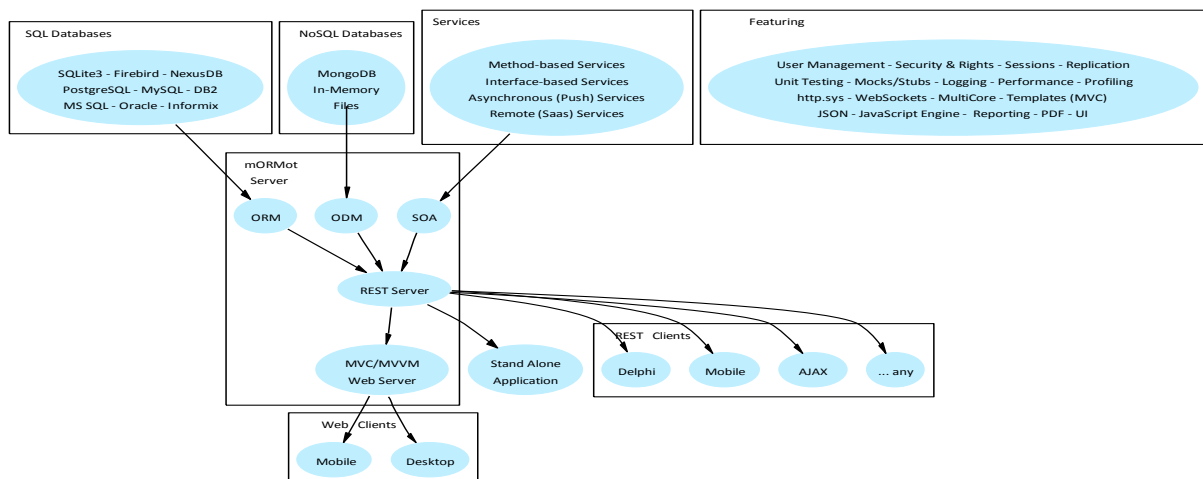

Meet the mORMot

Synapse mORMot is an Open Source Client-Server ORM SOA MVC framework for *Delphi* 6 up to the latest available *Delphi* version and FPC 3.2, targeting *Win/Linux* for the server, and any platform for clients (including mobile or AJAX).

The main features of *mORMot* are therefore:

- *ORM/ODM*: objects persistence on almost any database (SQL or NoSQL);
- *SOA*: organize your business logic into REST services;
- *Clients*: consume your data or services from any platform, via ORM classes or SOA interfaces;
- *Web MVC*: publish your ORM/SOA process as responsive Web Applications.

With local or remote access, via an auto-configuring Client-Server REST design.

General mORMot architecture

mORMot offers all features needed for building any kind of modern software project, with state-of-the-art integrated software components, designed for both completeness and complementarity, offering *convention over configuration* solutions, and implemented for speed and efficiency.

For *storing some data*, you define a `class`, and the framework will take care of everything: routing, JSON marshalling, table creation, SQL generation, validation.

For *creating a service*, you define an interface and a `class`, and you are done. Of course, the same ORM/ODM or SOA methods will run on both server and client sides: code once, use everywhere!

For *building a MVC web site*, write a Controller class in Delphi, then some HTML Views using *Mustache* templates, leveraging the same ORM/ODM or SOA methods as Model.

If you need a HTTP server, a proxy redirection, master/slave replication, publish-subscribe, a test, a mock, add security, define users or manage rights, a script engine, a report, User Interface, switch to XML format or publish HTML dynamic pages - just pick up the right `class` or method. If you need a tool or feature, it is probably already there, waiting for you to use it.

The table content of this document makes it clear: this is no ordinary piece of software.

The *mORMot* framework provides an Open Source *self-sufficient set of units* (even *Delphi* starter edition is enough) for creating any *Multi-tier* application, up to the most complex *Domain-Driven* design - see below (page 99):

- *Presentation layer* featuring MVC UI generation with i18n and reporting for rich *Delphi* clients, *Mustache*-based templates for web views - see below (page 520) - or rich AJAX clients;
- *Application layer* implementing Service Oriented Architecture via interface-based services (like WCF) and Client-Server ORM - following a RESTful model using JSON over several communication protocols (e.g. HTTP/1.1 and HTTPS);
- *Domain Model layer* handling all the needed business logic in plain *Delphi* objects, including high-level managed types like dynamic arrays or records for *Value Objects*, dedicated classes for *Entities* or *Aggregates*, and variant storage with late-binding for dynamic documents - your business logic may also be completed in *JavaScript* on the server side as stated below (page 562);
- *Data persistence infrastructure layer* with ORM persistence on direct Oracle, MS SQL, OleDb, ODBC, Zeos connection or any DB.pas provider (e.g. NexusDB, DBExpress, FireDAC, AnyDAC, UniDAC...), with a powerful SQLite3 kernel, and direct SQL access if needed - including SQL auto-generation for *SQLite3*, *Oracle*, *Jet/MSAccess*, *MS SQL*, *Firebird*, *DB2*, *PostgreSQL*, *MySQL*, *Informix* and *NexusDB* - the ORM is also able to use NoSQL engines via a native *MongoDB* connection, for ODM persistence;
- *Cross-Cutting infrastructure layers* for handling data filtering and validation, security, session, cache, logging and testing (framework uses test-driven approach and features stubbing and mocking).

If you do not know some of those concepts, don't worry: this document will detail them - see below (page 81).

With *mORMot*, *ORM* is not used only for data persistence of objects in databases (like in other implementations), but as part of a global n-Tier, Service Oriented Architecture (SOA), ready to implement *Domain-Driven* solutions.

mORMot is not another ORM on which a transmission layer has been added, like almost everything existing in Delphi, C# or Java: this is a full Client-Server ORM/SOA from the ground up. This really makes the difference.

The business logic of your applications will be easily exposed as *Services*, and will be accessible from

light clients (written in *Delphi* or any other mean, including AJAX).

The framework Core is non-visual: it provides only a set of classes to be used from code. But you have also some UI units available (including screen auto-creation, reporting and ribbon GUI), and you can use it from any RAD, web, or AJAX clients.

No dependency is needed at the client side (no DB driver, or third-party runtime): it is able to connect via standard HTTP or HTTPS, even through a corporate proxy or a VPN. Rich *Delphi* clients can be deployed just by copying and running a stand-alone small executable, with no installation process. Client authentication is performed via several secure methods, and communication can be encrypted via HTTS or with a proprietary SHA/AES-256 algorithm. SOA endpoints are configured automatically for each published interface on both server and client sides, and creating a load-balancing proxy is a matter of one method call. Changing from one database engine to another is just a matter of one line of code; full audit-trail history is available, if needed, to track all changes of any class persisted by the ORM/ODM.

Cross-platform clients can be easily created, as *Win32* and *Win64* executables of course, but also for any platform supported by the *Delphi* compiler (including *Mac OSX*, *iPhone/iPad* and *Android*), or by *FreePascal* / *Lazarus*. AJAX applications can easily be created via *Smart Mobile Studio*, as will any mobile operating system be accessible as an HTML5 web rich client or stand-alone *PhoneGap* application, ready to be added to the *Windows*, *Apple* or *Google* store. See below (page 482) for how *mORMot* client code generation leverages all platforms.

Speed and scalability has been implemented from the ground up - see below (page 199): a genuine optimized multi-threaded core let a single server handle more than 50,000 concurrent clients, faster than *DataSnap*, WCF or *node.js*, and our rich SOA design is able to implement both vertical and horizontal scalable hosting, using recognized enterprise-level SQL or NoSQL databases for storage.

In short, with *mORMot*, your ROI is maximized.

1.1. Client-Server ORM/SOA framework

The *Synapse mORMot framework* implements a Client-Server RESTful architecture, trying to follow some MVC, N-Tier, ORM, SOA best-practice patterns - see below (page 81).

Several clients, can access to the same remote or local server, using diverse communication protocols:

General mORMot architecture - Client / Server

Or the application can be stand-alone:

General mORMot architecture - Stand-alone application

Switch from this embedded architecture to the Client-Server one is just a matter of how *mORMot* classes are initialized. For instance, the very same executable can even be running as a stand-alone application, a server, or a client, depending on some run-time parameters!

1.2. Highlights

At first, some points can be highlighted, which make this framework distinct to other available solutions:

- Client-Server orientation, with optimized request caching and intelligent update over a RESTful architecture - but can be used in stand-alone applications;
- No RAD components, but true ORM and SOA approach;
- Multi-Tier architecture, with integrated Business rules as fast ORM-based classes and *Domain-Driven* design;
- *Service-Oriented-Architecture* model, using custom RESTful JSON services - you can send as JSON any TStrings, TCollection, TPersistent or TObject (via registration of a custom serializer) instance, or even a *dynamic array*, or any record content, with integrated JSON serialization, via an interface-based contract shared on both client and server sides;
- Truly RESTful authentication with a dual security model (session + per-query);
- Very fast JSON producer and parser, with caching at SQL level;
- Fast a configuration-less HTTP / HTTPS server using *http.sys* kernel-mode server - but may communicate via named pipes, Windows Messages or in-process as lighter alternatives;
- Using *SQLite3* as its kernel, but able to connect to any other database (via OleDB / ODBC / Zeos or direct client library access e.g. for Oracle) - the SynDB.pas classes are self-sufficient, and do not depend on the *Delphi* DB.pas unit nor any third-party (so even the *Delphi* Starter edition is enough) - but the SynDBDataset unit is also available to access any DB.pas based solution (e.g. NexusDB, DBExpress, FireDAC, AnyDAC, UniDAC or even the BDE...);
- RESTful ORM access to a NoSQL database engine like *MongoDB* with the same code base;
- Ability to use SQL and RESTful requests over multiple databases at once (thanks to *SQLite3* unique Virtual Tables mechanism);
- Full Text Search engine included, with enhanced Google-like ranking algorithm;
- Server-side JavaScript engine, for defining your business intelligence;
- Direct User Interface generation: grids are created on the fly, together with a modern Ribbon ('Office 2007'-like) screen layout - the code just has to define actions, and assign them to the tables, in order to construct the whole interface from a few lines of code, without any IDE usage;
- Integrated Reporting system, which could serve complex PDF reports from your application;
- Designed to be as fast as possible (asm used when needed, buffered reading and writing avoid most memory consumption, multi-thread ready architecture...) so benchmarks sound impressive when compared to other solutions - see below (page 199);
- More than 1800 pages of documentation;
- *Delphi*, *FreePascal*, mobile and AJAX clients can share the same server, and ORM/SOA client access code can be generated on request for any kind of application - see below (page 482);
- Full source code provided - so you can enhance it to fulfill any need;
- Works from *Delphi* 6 up to the latest available *Delphi* version and FPC 3.2.x, truly Unicode (uses UTF-8 encoding in its kernel, just like JSON), with any version of *Delphi* (no need to upgrade your IDE).

1.3. Benefits

As you can see from the previous section, *mORMot* provides a comprehensive set of features that can help you to manage your crosscutting concerns through a reusable set of components and core functionality.

Meet the mORMot

Of course, like many developers, you may suffer from the well-known NIH ("Not Invented Here") syndrome. On the other side, it is a commonly accepted fact that the use of standard and proven code libraries and components can save development time, minimize costs, reduce the use of precious test resources, and decrease the overall maintenance effort.

Benefits of *mORMot* are therefore:

- *KISS convention over configuration* design: you have all needed features at hand, but with only one way of doing it - less configuration and less confusion for the developer and its customers;
- *Pascal oriented*: implementation is not following existing Java or C# patterns (with generics (ab)use, variable syntaxes and black-box approach), but try to unleash the object pascal genius;
- *Integrated*: all crosscutting scenarios are coupled, so you benefit of consisting APIs and documentation, a lot of code-reuse, JSON/RESTful orientation from the ground up;
- *Tested*: most of the framework is test-driven, and all regression tests are provided, including system-wide integration tests;
- *Do-not-reinvent-the-wheel*, since we did it for you: it is now time to focus on your business;
- *Open Source, documented and maintained*: project is developed since years, with some active members - *mORMot* won't leave you soon!

1.4. Legacy code and existing projects

Even if *mORMot* will be more easily used in a project designed from scratch, it fits very well the purpose of evolving any existing *Delphi* project, or creating the server side part of an AJAX application. One benefit of such a framework is to facilitate the transition from a traditional Client-Server architecture to a N-Tier layered pattern.

Due to its modular design, you can integrate some framework bricks to your existing application:

- You may add logging to your code - see below (page 632), to track unresolved issues, and add customer-side performance profiling;
- Use low-level classes like *record* or *dynamic array* wrappers - see below (page 107), or our dynamic document storage via *variant* - see below (page 112), including JSON or binary persistence;
- You can use the direct DB layers, including the TQuery emulation class - see below (page 251) - to replace some BDE queries, or introduce nice unique features like direct database access or *array binding* for very fast data insertion - see below (page 240), or switch to a NoSQL database - see below (page 279);
- Reports could benefit of the *mORMotReport.pas* code-based system, which is very easy to use even on the server side (serving PDF files), when your business logic heavily relies on objects, not direct DB - see below (page 2529);
- HTTP requests may be made available using Client-Server services via methods - see below (page 374), e.g. for rendering HTML pages generated on the fly with *Mustache* templates- see below (page 506), pictures or PDF reports;
- You can little by little move your logic out of the client side code into some server services defined via interfaces, without the overhead of SOAP or WCF - see below (page 420); migration to SOA is the main benefit of *mORMot* for existing projects;
- Make your application ready to offer a RESTful interface, e.g. for consuming JSON content via AJAX or mobile clients - see below (page 482);
- New tables may be defined via the ORM/ODM features of *mORMot*, still hosted in your external SQL server - see below (page 240), as any previous data; in particular, mixed pure-ORM and regular-SQL requests may coexist; or *mORMot*'s data modeling may balance your storage among several servers (and technologies, like NoSQL);
- Sharing the same tables between legacy code SQL and *mORMot* ORM is possible, but to avoid consistency problems, you should better follow some rules detailed below (page 272);
- You may benefit from our very fast in-memory engine, a dedicated *SQLite3*-based consolidation database or even the caching features - see below (page 174), shared on the server side, when performance is needed - it may help integrating some CQRS pattern (*Command Query Responsibility Segregation*) into your application via a RESTful interface, and delegate some queries from your main database;
- If you are still using an old version of *Delphi*, and can't easily move up due to some third party components or existing code base, *mORMot* will offer all the needed features to start ORM, N-Tier and SOA, starting with a *Delphi* 6 edition.

mORMot implements the needed techniques for introducing what Michael Feathers calls, in his book *Working Effectively With Legacy Code*, a seam. A seam is an area where you can start to cleave off some legacy code and begin to introduce changes. Even mocking abilities of *mORMot* - see below (page 407) - will help you in this delicate task - see <http://www.infoq.com/articles/Utilizing-Logging..>

Do not forget that *Synapse*, as a company, is able to offer dedicated audit and support for such a migration. The sooner, the better.

1.5. FAQ

Before you start going any further, we propose here below a simple FAQ containing the most frequent questions we received on our forums.

First of all, take a look at the *keyword index* available at the very beginning of this document. The underlined entries target the main article(s) about a given concept or technical term.

Feel free to give your feedback at <https://synopse.info/forum..> asking new questions or improving answers!

Should I use *mORMot 1* since *mORMot 2* is alive and appear to be more maintained?

You are right, *mORMot 2* is the way to go for any new project: *mORMot 1* is considered in a bug-fix-only state. For an existing *mORMot 1* project, we will continue to fix the identified bugs and supply the *SQLite3* static updates, but no new feature or enhancement will appear any more on this branch. Consider migrating your project to *mORMot 2* as soon as you have a little time. It is not a complex process, since most of the code is compatible, once you change to the new units for your whole project.

Your SAD doc is too long to read through in a short period.

Too much documentation can kill the documentation! But you do not need to read the whole document: most of it is a detailed description of every unit, object, or class. But the first part is worth reading, otherwise you are very likely to miss some main concepts or patterns. It just takes 15-30 minutes! Also read below (page 319) to find out in which direction you may need to go for writing your server code. Consider the slides available at <https://drive.google.com/folderview?id=0B0r8u-FwvxWdeVJVZnBhSEpKYkE..>

Where should I start?

Take a look at the *Architecture principles* below (page 81), then download and install the sources below (page 644), then compile and run the TestSQL3.dpr program. Check about ORM below (page 130), SOA below (page 420) and MVC below (page 520), then test the various samples (from the *SQLite3\Samples* folder), especially 01, 02, 04, 11, 12, 14, 17, 26, 28, 30 and the MainDemo.

So far, I can see your *mORMot* fits most of the requirement, but seems only for Database Client-Server apps.

First of all, the framework is a *set of bricks*, so you can use it e.g. to build interface based services, even with no database at all. We tried to make its main features modular and uncoupled.

I am not a great fan of ORM, sorry, I still like SQL and have some experience of that. Some times sophisticated SQL query is hard to change to ORM code.

ORM can make development much easier; but you can use e.g. interface-based services and "manual" SQL statements - in this case, you have at hand below (page 240) classes in *mORMot*, which allow very high performance and direct export to JSON.

I am tempted by using an ORM, but *mORMot* forces you to inherit from a root TSQLRecord type, whereas I'd like to use any kind of object.

We will discuss this in details below (page 192). Adding attributes to an existing class is tempting, but will pollute your code at the end, mixing persistence and business logic: see *Persistence Ignorance* and *Aggregates* below (page 600). The framework proposes a second level of *Object* mapping, allowing to persist any kind of *PODO* (*Plain Old Delphi Object*), by defining CQRS services - see below (page 611).

I would like to replace pieces of Delphi-code by using *mORMot* and the DDD-concept in a huge system, but its legacy database doesn't have integer primary keys, and *mORMot* ORM expects a

TID-like field.

By design, such legacy tables are not compatible with *SQLite3* virtual tables, or our ORM - unless you add an ID integer additional primary key, which may not be the best idea. Some hints: write a *persistence service* as interface/class (as required by DDD - see below (page 600)); uncouple persistence and SOA services (i.e. the SOA *TSQLRestServer* is a *TSQLRestServerFullMemory* and not a DB/ORM *TSQLRestServerDB*); reuse your existing SQL statements, with SynDB as access layer if possible (you will have better performance, and direct JSON support); use the ORM for MicroService local persistence (with *SQLite3*), and/or for new tables in your legacy DB (or another storage, e.g. MongoDB).

Why are you not using the latest features of the compiler, like generics or class attributes?

Our framework does not rely on *generics*, but on the power of the object pascal type system: specifying a class or interface type as parameter is safe and efficient - and generics tends to blow the executable size, lower down performance (the current RTL is not very optimized, and sometimes bugged), and hide implementation details. Some methods are available for newer version of the compiler, introducing access via generics; but it was not mandatory to depend on them. We also identified, as several Java or C# gurus, that *class attributes* may sound like a good idea, but tend to *pollute* the code, and introduce unexpected coupling. Last but not least, those features are incompatible with older version of Delphi we would like to support, and may reduce compatibility with FPC.

I also notice in your SAD doc, data types are different from Delphi. You have RawUTF8, etc, which make me puzzled, what are they?

You can for sure use standard *Delphi* string types, but some more optimized types were defined: since the whole framework is UTF-8 based, we defined a dedicated type, which works with all versions of *Delphi*, before and after *Delphi* 2009. By the way, just search for RawUTF8 in the *keyword index* of this document, or see below (page 105).

During my tests, my client receives non standard JSON with unquoted fields.

Internally, the framework uses JSON in *MongoDB* extended syntax, i.e. fields are not quoted - this gives better performance and reduces memory and bandwidth with a *mORMot* client. To receive "field":value instead of field:value, just add a proper User-Agent HTTP header to the client request (as any browser does), and the server will emit standard JSON.

I encounter strange issues about indexes or collations with external SQLite3 tools.

By default, our ORM uses its proprietary SYSTENOCASE collation, which is perfect for Win1252 accents, but unknown outside of *mORMot*. Use our SynDbExplorer tool instead. Or use a standard collation when defining a new ORM table as stated below (page 219).

When I work with floating points and JSON, sometimes numerical values with more than 4 decimals are converted into JSON strings.

By default, double values are disabled in the JSON serialization, to avoid any hidden precision lost during conversion: see below (page 119) how to enable it.

I got an access violation with SynDB ISQLDBRows.

You need to explicitly release the ISQLDBRows instance, by setting it to nil, *before* freeing the owner's connection - see below (page 249).

Deadlock occurs with interface callbacks.

When working with asynchronous notifications over *WebSockets*, you need to ensure you won't fire directly a callback from a main method execution - see below (page 454) for several solutions.

All the objects seem non-VCL components, meaning need code each property and remember them

all well.

This is indeed... a feature. The framework is not RAD, but fully object-oriented. Thanks to the *Delphi* IDE, you can access all properties description via auto-completion and/or code navigation. We tried to make the documentation exhaustive and accurate. Then you can still use RAD for UI design, but let business be abstracted in pure code. See e.g. the *mORMotVCL.pas* unit which can publish any ORM result as _ for your UI.

I know you have joined the *DataSnap* performance discussion and your performance won good reputation there. If I want to use your framework to replace my old project of *DataSnap*, how easy will it be?

If you used *DataSnap* to build method-based services, translation into *mORMot* will be just a matter of code refactoring. And you will benefit of new features like *Interface-based services* - see below (page 420) - which is much more advanced than the method-based pattern, and will avoid generating the client class via a wizard, and offers additional features - see below (page 460) or below (page 462).

What is the SMS? Do you know any advantage compared to JQuery or AngularJS?

Smart Mobile Studio is an IDE and some source runtime able to develop and compile an Object-Pascal project into a *HTML 5 / CSS 3 / JavaScript embedded* application, i.e. able to work stand alone with no remote server. When used with *mORMot* on the server side, you can use the very same object pascal language on both server and client sides, with strong typing and true OOP design. Then you feature secure authentication and JSON communication, with connected or off-line mode. Your *SmartPascal* client code can be generated by your *mORMot* server, as stated below (page 487). We currently focus on TMS Web Core integration, which seems a newer - and more supported - alternative.

I am trying to search a substitute solution to WebSnap. Do you have any sample or doc to describe how to build a robust web Server?

You can indeed easily create a modern MVC / MVVM scaling Web Application. Your *mORMot* server can easily publish its ORM / SOA business logic as *Model*, use *Mustache* logic-less templates rendering - see below (page 506) - for *Views*, and defining the *ViewModel / Controller* as regular Delphi methods. See below (page 520) for more details, and discovering a sample "blog" application.

Have you considered using a popular source coding host like Github or BitBucket?

We love to host our own source code repository, and find fossil a perfect match for our needs, with a friendly approach. But we created a parallel repository on *GitHub*, so that you may be able to monitor or fork our projects - see <https://github.com/synapse/mORMot..>

Note that you can get a daily snapshot of our official source code repository directly from <https://synapse.info/files/mORMotNightlyBuild.zip..>

Why is this framework named *mORMot*?

- Because its initial identifier was "*Synapse SQLite3 database framework*", which may induce a *SQLite3*-only library, whereas the framework is now able to connect to any database engine;
- Because we like mountains, and those large ground rodents;
- Because marmots do hibernate, just like our precious objects;
- Because marmots are highly social and use loud whistles to communicate with one another, just like our applications are designed not to be isolated;
- Because even if they eat greens, they use to fight at Spring for their realm;
- Because it may be an acronym for "Manage Object Relational Mapping Over Territory", or whatever you may think of...

2. Architecture principles

Adopt a mORMot

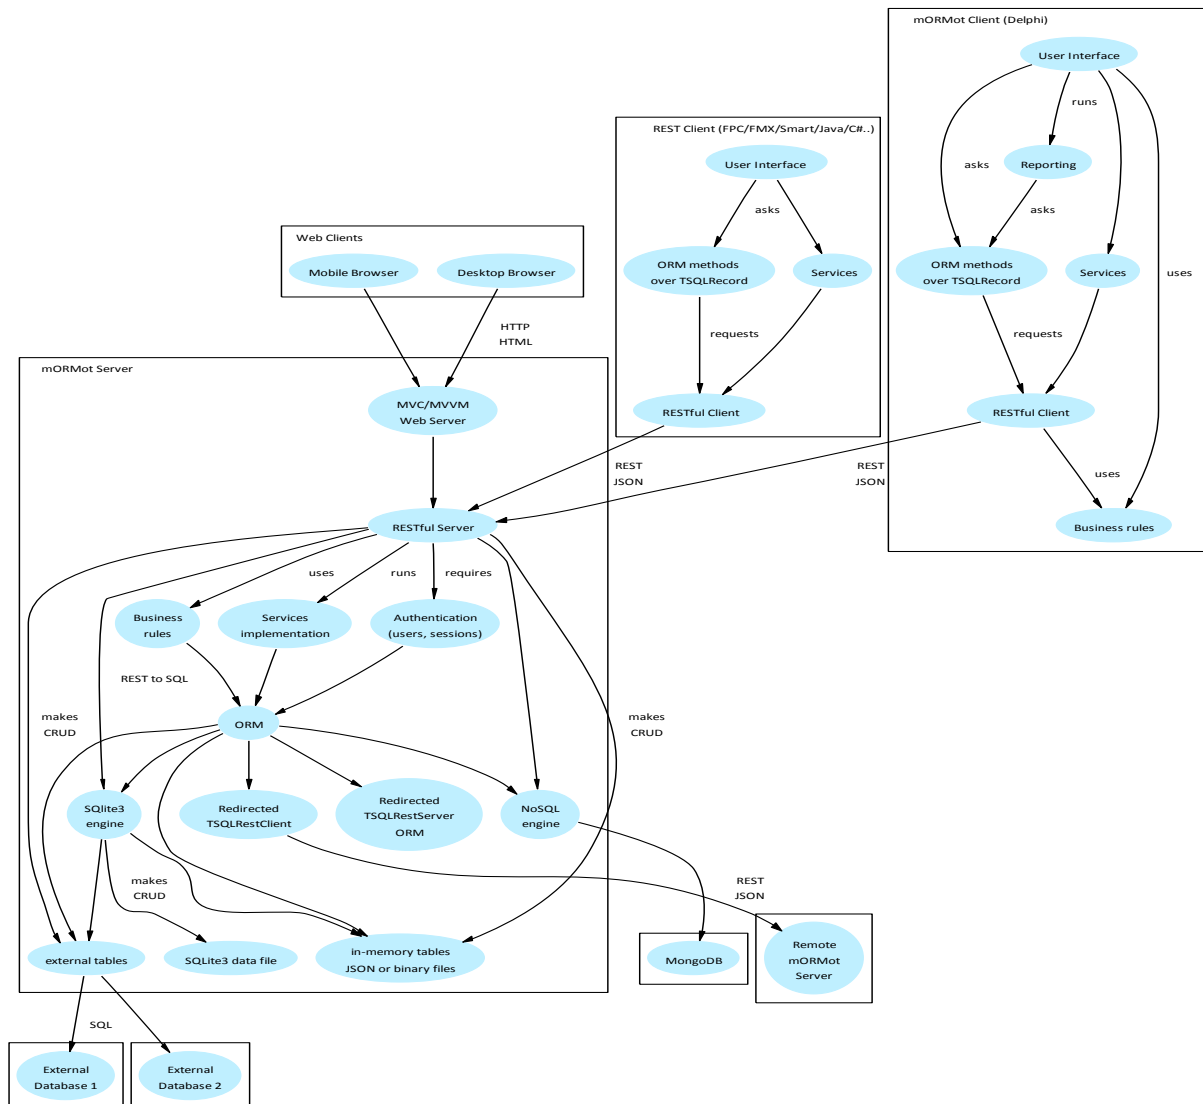

This framework tries to implement some "best-practice" patterns, among them:

- *Model-View Controller* - see below (page 86);
- *Multi-tier architecture* - see below (page 88);
- *Test-Driven Design* - see below (page 627);
- *Stateless CRUD/REST* - see below (page 312);
- *Object-Relational Mapping* - see below (page 92);
- *Object-Document Mapping* - see below (page 96);
- *Service-Oriented Architecture* - see below (page 90).

All those points render possible any project implementation, up to complex *Domain-Driven* design - see below (page 99).

2.1. General design

A general design of the *mORMot* architecture is shown in the following diagram:

General mORMot architecture - Client Server implementation

In addition, you may use the following transversal features:

General mORMot architecture - Cross-Cutting features

Don't be afraid. Such a drawing may sound huge and confusing, especially when you have a RAD background, and did not work much with modern design patterns.

Following pages will detail and explain how the framework implements this architecture, and sample code is available to help you discovering the amazing *mORMot* realm.

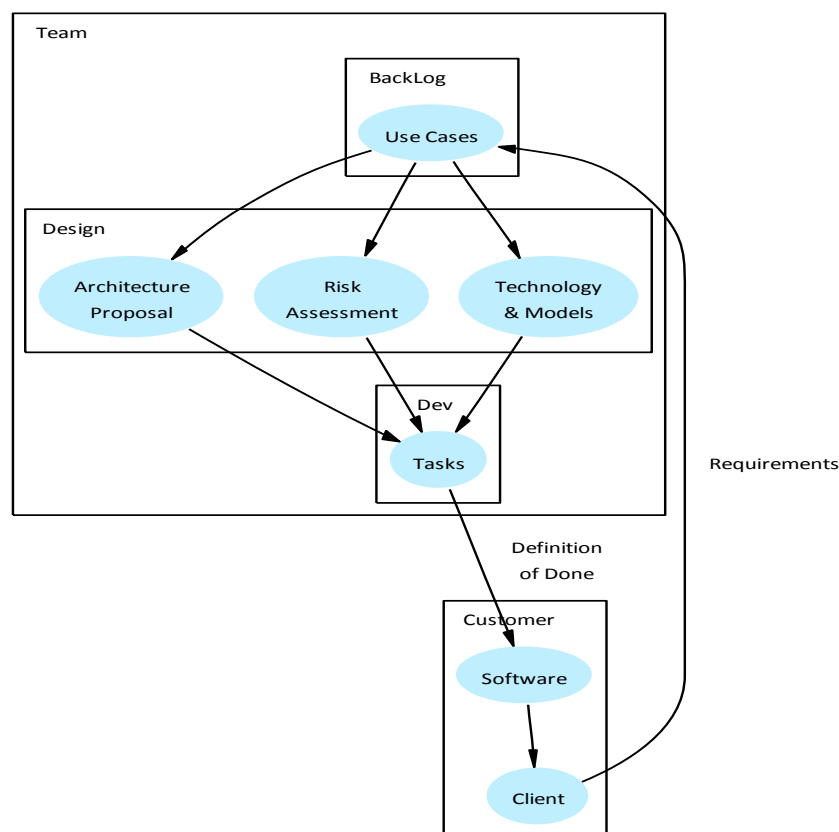

In the previous diagram, you can already identify some key concepts of *mORMot*:

- Cross-Platform, multi clients, and multi devices;
- Can integrate to an existing code base or architecture;
- Client-Server RESTful design;
- Layered (multi-tier) implementation;
- Process can be defined via a set of Services (SOA);
- Business rules and data model are shared by Clients and Server;
- Data is mapped by objects (ORM/ODM);
- Databases can be an embedded *SQLite3*, one or several standard RDBMS (with auto-generated SQL), a *MongoDB* NoSQL engine, fast in-memory objects lists, or another *mORMot* server;
- Security (authentication and authorization) is integrated to all layers;
- User interface and reporting classes are available;
- You can write a MVC/MVVM AJAX or Web Application from your ORM/SOA methods;
- Based on simple and proven patterns (REST, JSON, MVC, SOLID);
- A consistent testing and debugging API is integrated;
- Optimized for both scaling and stability.

2.2. Architecture Design Process

First point is to state that you can't talk about architecture in isolation. Architecture is always driven by the actual needs of the application, not by whatever the architect read about last night and is dying to see how it works in the real world. There is no such "one architecture fits all" nor "one framework fits all" solution. Architecture is just a thinking of *how* you are building your own software.

In fact, software architecture is not about theory and diagrams, nor just about best practice, but about a way of implementing a working solution for your customers.

Architecture Iterative Process (SCRUM)

This diagram presents how Architecture is part of a typical SCRUM iterative agile process. Even if some people of your company may be in charge of global software architecture, or even if your project managements follows a classic V-cycle and does not follow the agile manifesto, architecture should never be seen as a set of rules, to be applied by every and each developers. Architecture is part of the coding, but not all the coding.

Here are some ways of achieving weak design:

- Let each developer decides, from his/her own knowledge (and mood?), how to implement the use cases, with no review, implementation documentation, nor peer collaboration;
- Let each team decides, from its own knowledge (and untold internal leadership?), how to implement the use cases, with no system-wide collaboration;
- Let architecture be decided at so high level that it won't affect the actual coding style of the developers (just don't be caught);
- Let architecture be so much detailed that each code line has to follow a typical implementation

pattern, therefore producing over engineered code;

- Let architecture map the existing, with some middle-term objectives at best;
- Let technology, frameworks or just-blogged ideas be used with no discrimination (do not trust the sirens of dev marketing).

Therefore, some advices:

- Collaboration is a need - no one is alone, no team is better, no manager is always right;
- Sharing is a need - between individuals, as teams, with managers;
- Stay customer and content focused;
- Long term is prepared by today's implementation;
- Be lazy, i.e. try to make tomorrow's work easier for you and your team-workers;
- They did not know it was impossible, so they did it.

Purpose of frameworks like *mORMot* is to provide your teams with working and integrated set of classes, so that you can focus on your product, enjoying the collaboration with other Open Source users, in order to use evolving and pertinent software architecture.

2.3. Model-View-Controller

The *Model-View-Controller* (MVC) is a software architecture, currently considered an architectural pattern used in software engineering. The pattern isolates "domain logic" (the application logic for the user) from the user interface (input and presentation), permitting independent development, testing and maintenance of each (separation of concerns).

Model View Controller process

The **Model** manages the behavior and data of the application domain, responds to requests for information about its state (usually from the view), and responds to instructions to change state (usually from the controller). In Event-Driven systems, the model notifies observers (usually views) when the information changes so that they can react - but since our ORM is stateless, it does not need to handle those events - see below (page 315).

The **View** renders the model into a form suitable for interaction, typically a user interface element. Multiple views can exist for a single model for different purposes. A *viewport* typically has a one to one correspondence with a display surface and knows how to render to it.

The **Controller** receives user input and initiates a response by making calls on model objects. A controller accepts input from the user and instructs the model and viewport to perform actions based on that input.

Model View Controller concept

In the framework, the *model* is not necessarily merely a database; the *model* in MVC is both the data and the business/domain logic needed to manipulate the data in the application. In our ORM, a model is implemented via a `TSQLModel` class, which centralizes all `TSQLRecord` inherited classes used by an application, both database-related and business-logic related.

The *views* can be implemented using:

- For Desktop clients, a full set of User-Interface units of the framework, which is mostly auto-generated from code - they will consume the *model* as reference for rendering the data;

- For Web clients, an integrated high-speed *Mustache* rendering engine - see below (page 506) - is able to render HTML pages with logic-less templates, and *controller* methods written in Delphi - see below (page 520);
- For AJAX clients, the server side is easy to be reached from RESTful JSON services.

The *controller* is mainly already implemented in our framework, within the RESTful commands, and will interact with both the associated *view* (e.g. for refreshing the User Interface) and *model* (for data handling). Some custom actions, related to the business logic, can be implemented via some custom TSQLRecord classes or via custom RESTful Services - see below (page 373).

2.4. Multi-tier architecture

In software engineering, multi-tier architecture (often referred to as *n-tier* architecture) is a client-server architecture in which the presentation, the application processing, and the data management are logically separate processes. For example, an application that uses middle-ware to service data requests between a user and a database employs multi-tier architecture. The most widespread use of multi-tier architecture is the three-tier architecture.

In practice, a typical VCL/FMX RAD application written in Delphi has a two-tier architecture:

Two-Tier Architecture - Logical View

In this approach, the *Application Tier* mixes the UI and the logic in forms and modules.

Both ORM and SOA aspects of our RESTful framework make it easy to develop using a more versatile three-tier architecture.

Multi-Tier Architecture - Logical View

The *Synapse mORMot Framework* follows this development pattern:

- *Data Tier* is either *SQLite3* and/or an internal very fast in-memory database; most SQL queries are created on the fly, and database table layout are defined from *Delphi* classes; you can also use any external database, currently *SQLite3*, *Oracle*, *Jet/MSAccess*, *MS SQL*, *Firebird*, *DB2*, *PostgreSQL*, *MySQL*, *Informix* and *NexusDB* SQL dialects are handled, and even NoSQL engines like *MongoDB* can be directly used - see below (page 240);
- *Logic Tier* is performed by pure ORM aspect and SOA implementation: you write *Delphi* classes which are mapped by the *Data Tier* into the database, and you can write your business logic as Services called as *Delphi* interface, up to a *Domain-Driven* design - see below (page 99) - if your project reaches some level of complexity;
- *Presentation Tier* is either a *Delphi* Client, or an AJAX application, because the framework can communicate using RESTful JSON over HTTP/1.1 (the *Delphi* Client User Interface is generated from Code, by using RTTI and structures, not as a RAD - and the Ajax applications need to be written by using your own tools and JavaScript framework, there is no "official" Ajax framework included yet).

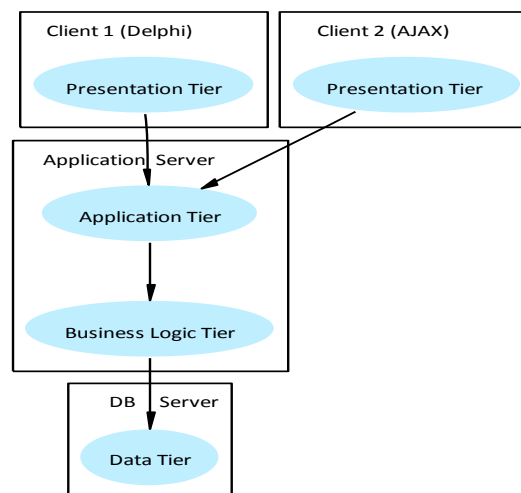

In fact, *mORMot* can scales up to a *Domain-Driven* Design four-tier architecture - see below (page 99) - as such:

- *Presentation Tier* which can be e.g. a *Delphi* or *AJAX* client;
- *Application Tier* which serves *JSON* content according to the client application;
- *Business Logic Tier* which centralizes all the *Domain* processing, shared among all applications;
- *Persistence/Data Tier* which can be either in-process (like *SQLite3* or in-memory) or external (e.g. *Oracle*, *MS SQL*, *DB2*, *PostgreSQL*, *MySQL*, *Informix*...).

Domain Driven Design n-Tier Architecture - Logical View

Note that you have to make a difference between *physical* and *logical* n-tier architecture. Most of the time, n-Tier is intended to be a *physical* (hardware) view, for instance a separation between the database server and the application server, placing the database on a separate machine to facilitate ease of maintenance. In *mORMot*, and more generally in *SOA* - see below (page 90), we deal with *logical* layout, with separation of layers through interfaces - see below (page 386) - and the underlying hardware implementation will usually not match the logical layout.

Domain Driven Design n-Tier Architecture - Physical View

In this document, we will focus on the logical way of thinking / coding, letting the physical deployment be made according to end-user expectations.

2.5. Service-Oriented Architecture (SOA)

Service-Oriented Architecture (SOA) is a flexible set of design principles used during the phases of systems development and integration in computing. A system based on a SOA will package functionality as a suite of inter-operable services that can be used within multiple, separate systems from several business domains.

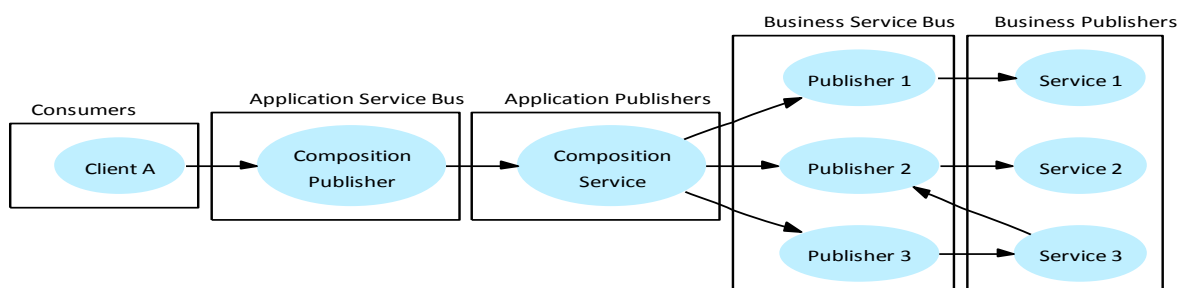

A software service is a logical representation of a repeatable activity that produce a precise result. In short, a *consumer* ask to a *producer* to act in order to produce a *result*. Most of the time, this invocation is free from any previous invocation (it is therefore called *stateless*).

The SOA implementations rely on a mesh of software services. Services comprise unassociated, *loosely coupled* units of functionality that have no calls to each other embedded in them. Each service implements *one action*, such as filling out an online application for an account, or viewing an online bank statement, or placing an online booking or airline ticket order. Rather than services embedding calls to each other in their source code, they use defined protocols that describe how services pass and parse messages using description meta-data.

Service Oriented Architecture - Logical View

Since most of those services are by definition stateless, some kind of *service composition* is commonly defined to provide some kind of logical multi-tier orchestration of services. A higher level service invokes several services to work as a self-contained, stateless service; as a result, lower-level services can still be stateless, but the consumer of the higher level service is able to safely process some kind of transactional process.

Service Oriented Architecture - Logical View of Composition

For more details about SOA, see http://en.wikipedia.org/wiki/Service-oriented_architecture..

SOA is mainly about *decoupling*.

That is, it enables implementation independence in a variety of ways, for instance:

Dependency	Desired decoupling	Decoupling technique
Platform	Hardware, Framework or Operating System should not constrain choices of the Services consumers	Standard protocols, mainly Web services (e.g. SOAP or RESTful/JSON)
Location	Consumers may not be impacted by service hosting changes	Routing and proxies will maintain Services access
Availability	Maintenance tasks shall be transparent	Remote access allows centralized support on Server side
Versions	New services shall be introduced without requiring upgrades of clients	Contract marshalling can be implemented on the Server side

SOA and ORM - see below (page 92) - do not exclude themselves. In fact, even if some software architects tend to use only one of the two features, both can coexist and furthermore complete each other, in any Client-Server application:

- ORM access could be used to access to the data with objects, that is with the native presentation of the Server or Client side (*Delphi, JavaScript...*) - so ORM can be used to provide efficient access to the data or the business logic - this is the idea of CQRS pattern;
- SOA will provide a more advanced way of handling the business logic: with custom parameters and data types, it is possible to provide some high-level Services to the clients, hiding most of the business logic, and reducing the needed bandwidth.

In particular, SOA will help leaving the business logic on the Server side, therefore will help increasing the *Multi-tier architecture* (page 88). By reducing the back-and-forth between the Client and the Server, it will also reduce the network bandwidth, and the Server resources (it will always cost less to run the service on the Server than run the service on the Client, adding all remote connection and serialization to the needed database access). Our interface-based SOA model allows the same code to run on both the client and the server side, with a much better performance on the server side, but a full interoperability of both sides.

2.6. Object-Relational Mapping (ORM)

In practice, ORM gives a set of methods to ease high-level objects persistence into a RDBMS.

Our *Delphi* `c`lass instances are not directly usable with a relational database, which is since decades the most convenient way of persisting data. So some kind of "glue" is needed to let class properties be saved into one or several tables. You can interact with the database using its native language, aka SQL. But SQL by itself is a full programming language, with diverse flavors depending on the exact backend engine (just think about how you define a column type able to store text). So writing and maintaining your SQL statements may become a time-consuming, difficult and error-prone task.

Sometimes, there will be nothing better than a tuned SQL statement, able to aggregate and join information from several tables. But most of the time, you will need just to perform some basic operations, known as CRUD (for *Create Retrieve Update Delete* actions) on well identified objects: this is where ORM may give you a huge hint, since it is able to generate the SQL statements for you.

The ORM works in fact as such:

ORM Process

The ORM core retrieve information to perform the mapping:

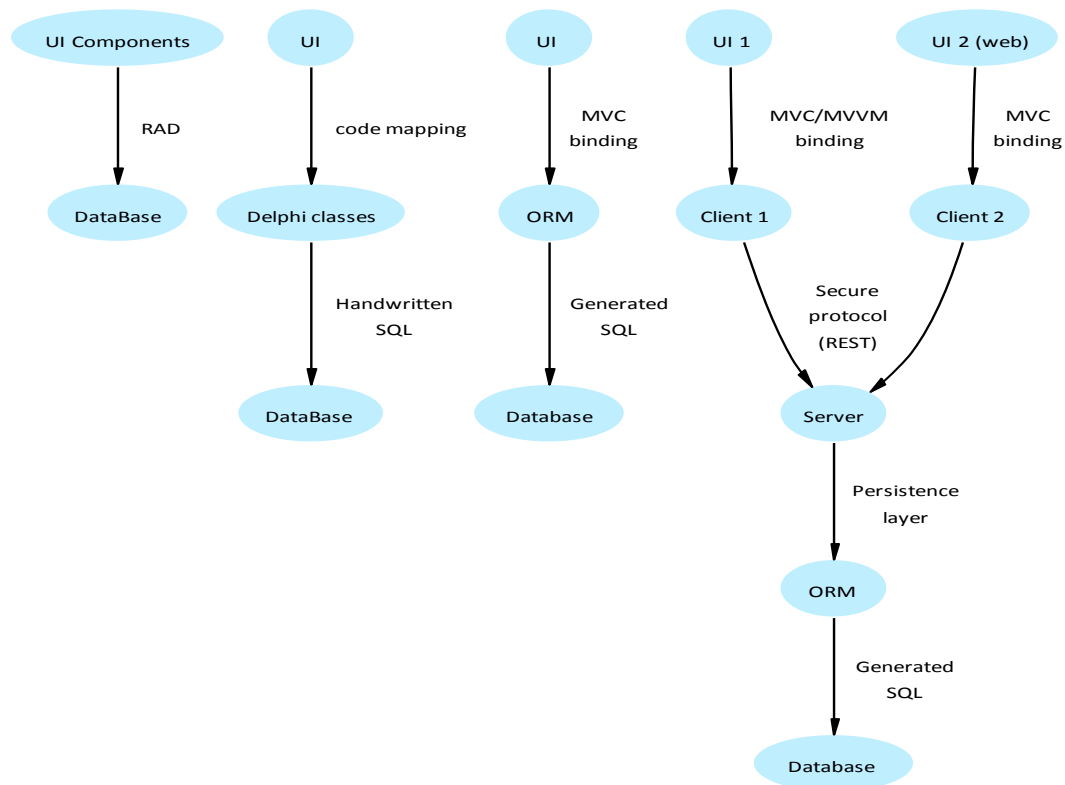

- Object definition via its `c`lass type (via RTTI);
- Database model as retrieved for each database engine.

ORM mapping

Since several implementation schemes are possible, we will first discuss the pros and the cons of each one.

First, here is a diagram presenting some common implementation schemes of database access with *Delphi* (which maps most other languages or frameworks, including C# or Java).

Why a Client-Server ORM

The table below is a very suggestive (but it doesn't mean wrong) *Resumé* of some common schemes, in the *Delphi* world. ORM is just one nice possibility among others.

Scheme	Pros	Cons
Use DB views and tables, with GUI components	<ul style="list-style-type: none"> - SQL is a powerful language - Can use high-level DB tools (UML) and RAD approach 	<ul style="list-style-type: none"> - Business logic can't be elaborated without stored procedures - SQL code and stored procedures will bind you to a DB engine - Poor Client interaction - Reporting must call the DB directly - No Multi-tier architecture
Map DB tables or views with <i>Delphi</i> classes	<ul style="list-style-type: none"> - Can use elaborated business logic, in <i>Delphi</i> - Separation from UI and data 	<ul style="list-style-type: none"> - SQL code must be coded by hand and synchronized with the classes - Code tends to be duplicated - SQL code could bind you to a DB engine - Reports can be made from code or via DB related tools - Difficult to implement true Multi-tier architecture
Use a Database ORM	<ul style="list-style-type: none"> - Can use very elaborated business logic, in <i>Delphi</i> - SQL code is generated (in most cases) by the ORM - ORM will adapt the generated SQL to the DB engine 	<ul style="list-style-type: none"> - More abstraction needed at design time (no RAD approach) - In some cases, could lead to retrieve more data from DB than needed - Not yet a true Multi-tier architecture, because ORM is for DB access only and business logic will need to create separated classes
Use a Client-Server ORM	<ul style="list-style-type: none"> - Can use very elaborated business logic, in <i>Delphi</i> - SQL code is generated (in most cases) by the ORM - ORM will adapt the generated SQL to the DB engine - Services will allow to retrieve or process only needed data - Server can create objects viewed by the Client as if they were DB objects, even if they are only available in memory or the result of some business logic defined in <i>Delphi</i> - Complete Multi-tier architecture 	<ul style="list-style-type: none"> - More abstraction needed at design time (no RAD approach)

Of course, you'll find out that our framework implements a Client-Server ORM, which can be down-sized to stand-alone mode if needed, but which is, thanks to its unique implementation, scalable to any complex Domain-Driven Design.

As far as we found out, looking at every language and technology around, almost no other ORM supports such a native Client-Server orientation. Usual practice is to use a *Service-Oriented*

Architecture (SOA) (page 90) for remote access to the ORM. Some projects allow remote access to an existing ORM, but they are separated projects. Our *mORMot* is pretty unique, in respect to its RESTful Client-Server orientation, from the ground up.

If you entered the *Delphi* world years ago, you may be pretty fluent with the RAD approach. But you probably also discovered how difficult it is to maintain an application which mixes UI components, business logic and database queries. Today's software users have some huge ergonomic expectations about software usability: some screens with grids and buttons, mapping the database, won't definitively be appealing. Using *mORMot*'s ORM /SOA approach will help you focus on your business and your clients expectations, letting the framework perform most of the plumbing for you.

2.7. NoSQL and Object-Document Mapping (ODM)

SQL is the De-Facto standard for data manipulation

- Schema-based;
- Relational-based;
- ACID by transactions;
- Time proven and efficient;
- "Almost" standard (each DB has its own column typing system).

NoSQL is a new paradigm, named as such in early 2009 (even if some database engines, like *Lotus Domino*, may fit the definition since decades):

- *NoSQL* stands for "Not Only SQL" - which is more positive than "no SQL";
- Designed to scale for the web and BigData (e.g. Amazon, Google, Facebook), e.g. via easy replication and simple API;
- Relying on no standard (for both data modeling and querying);
- A lot of diverse implementations, covering any data use - <http://nosql-database.org..> lists more than 150 engines.

We can identify two main families of NoSQL databases:

- *Graph-oriented* databases;
- *Aggregate-oriented* databases.

Graph-oriented databases store data by their relations / associations:

NoSQL Graph Database

Such kind of databases are very useful e.g. for developing any "social" software, which will value its data by the relations between every node. Such data model does not fit well with the relational model, whereas a *NoSQL* engine like *Neo4j* handles such kind of data natively. Note that by design, *Graph-oriented* databases are ACID.

But the main *NoSQL* database family is populated by the *Aggregate-oriented* databases. By *Aggregate*,

we mean the same definition as will be used below (page 99) for *Domain Driven Design*. It is a collection of data that we interact with as a unit, which forms the boundaries for ACID operations in a given model.

In fact, *Aggregate*-oriented databases can be specified as three main implementation/query patterns:

- Document-based (e.g. *MongoDB*, *CouchDB*, *RavenDB*);
- Key/Value (e.g. *Redis*, *Riak*, *Voldemort*);
- Column family (e.g. *Cassandra*, *HiBase*).

Some of them can be *schema-less* (meaning that the data layout is not fixed, and can evolve on the fly without re-indexing the whole database) - but column-driven bases do have a schema, or even storing plain BLOB of data (this is the purpose of Key/Value engines, which focus on storage speed and rely on the client side to process the data).

In short, RDBMS stores data per table, and need to JOIN the references to get the aggregated information:

SQL Aggregate via JOINed tables

Whereas *NoSQL* stores its aggregates as documents: the whole data is embedded in one.

NoSQL Aggregate as one document

Which may be represented as the following JSON - see below (page 296) - data:

```
{
  "ID": 1234,
  "UserName": "John Smith",
  "Contact": {
    "Phone": "123-456-789",
    "Email": "xyz@abc.com"
  },
  "Access": {
    "Level": 5,
    "Group": "dev"
  }
}
```

Such a document will fit directly with the object programming model, without the need of thinking about JOINed queries and database plumbing.

As a result, we can discuss the two data models:

- *Relational data Model* with highly-structured table organization, and rigidly-defined data formats and record structure;
- *Document data Model* as a collection of complex documents with arbitrary, nested data formats and varying "record" format.

The *Relational* model features *normalization* of data, i.e. organize the fields and tables of a relational database to minimize redundancy.

On the other hand, the *Document* model features *denormalization* of data, to optimize the read performance of a database by adding redundant data or by grouping data. It also features horizontal scaling of the servers, since data can easily be balanced among several servers, without the speed penalty of performing a remote JOIN.

One of the main difficulties, when working with *NoSQL*, is to define how to *denormalize* the data, and when to store the data in *normalized* format.

One good habit is to model your data depending on the most current queries you will have to perform. For instance, you may embed sub-documents which will be very likely to be requested by your application most of the time. Note that most *NoSQL* engines feature a *projection* mechanism, which allows you to return only the needed fields for a query, leaving the sub-documents on the server if you do not need them at this time. The less frequent queries may be executed over separated collections, populated e.g. with consolidated information.

Since *NoSQL* databases have fewer hard-and-fast rules than their relational databases ancestors, you are more likely to tune your model, depending on your expectations. In practice, you may spend less time thinking about "how" to store the data than with a RDBMS, and are still able to *normalize* information later, if needed. *NoSQL* engines do not fear redundant information, as soon as you follow the rules of letting the client application take care of the whole data consistency (e.g. via one ORM).

As you may have stated, this *Document data Model* is much closer to the OOP paradigm than the classic relational scheme. Even a new family of frameworks did appear together with *NoSQL* adoption, named *Object Document Mapping* (ODM), which is what *Object-Relational Mapping* (ORM) (page 92) was for RDBMS.

In short, both approaches have benefits, which are to be weighted.

SQL	NoSQL
Ubiquitous SQL	Map OOP and complex types (e.g. arrays or nested documents)
Easy vertical scaling	Uncoupled data: horizontal scaling
Data size (avoid duplicates and with no schema)	Schema-less: cleaner evolution
Data is stored once, therefore consistent	Version management (e.g. <i>CouchDB</i>)
Complex ACID statements	Graph storage (e.g. <i>Redis</i>)
Aggregation functions (depends)	Map/Reduce or Aggregation functions (e.g. since <i>MongoDB 2.2</i>)

With *mORMot*, you can switch from a classic SQL engine into a trendy *MongoDB* server, just in one line of code, when initializing the data on the server side. You can switch from ORM to ODM at any time, even at runtime, e.g. for a demanding customer.

2.8. Domain-Driven Design

2.8.1. Definition

<http://domaindrivendesign.org..> gives the somewhat "official" definition of *Domain-Driven design* (DDD):

Over the last decade or two, a philosophy has developed as an undercurrent in the object community. The premise of domain-driven design is two-fold:

- *For most software projects, the primary focus should be on the domain and domain logic;*
- *Complex domain designs should be based on a model.*

Domain-driven design is not a technology or a methodology. It is a way of thinking and a set of priorities, aimed at accelerating software projects that have to deal with complicated domains.

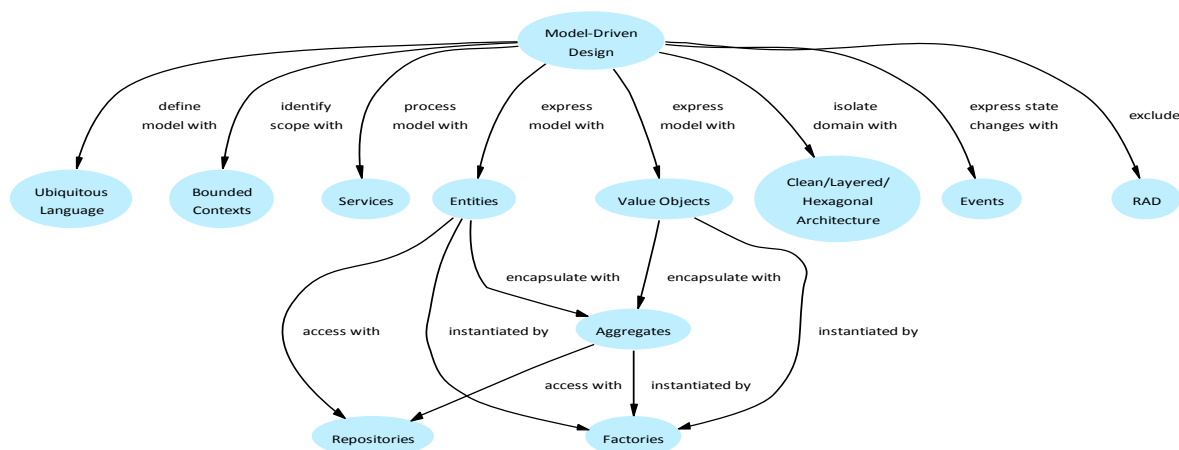

Of course, this particular architecture is customizable according to the needs of each project. We simply propose following an architecture that serves as a baseline to be modified or adapted by architects according to their needs and requirements.

2.8.2. Patterns

In respect to other kinds of *Multi-tier architecture* (page 88), DDD introduces some restrictive patterns, for a cleaner design:

- Focus on the *Domain* - i.e. a particular kind of knowledge;
- Define *Bounded contexts* within this domain;
- Create an evolving *Model* of the domain, ready-to-be consumed by applications;
- Identify some kind of objects - called *Value objects* or *Entity Objects / Aggregates*;
- Use an *Ubiquitous Language* in resulting model and code;
- Isolate the domain from other kind of concern (e.g. persistence should not be called from the domain layer - i.e. the domain should not be polluted by technical considerations, but rely on the *Factory* and *Repository* patterns);
- Publish the domain as well-defined uncoupled *Services*;
- Integrate the domain services with existing applications or legacy code.

The following diagram is a map of the patterns presented and the relationships between them. It is inspired from the one included in the Eric Evans's reference book, "*Domain-Driven Design*", Addison-Wesley, 2004 (and updated to take in account some points appeared since).

Domain-Driven Design - Building Blocks

You may recognize a lot of existing patterns you already met or implemented. What makes DDD unique is that those patterns have been organized around some clear concepts, thanks to decades of business software experiment.

2.8.3. Is DDD good for you?

Domain-Driven design is not to be used everywhere, and in every situation.

First of all, the following are prerequisite of using DDD:

- Identified and well-bounded domain (e.g. your business target should be clearly identified);
- You must have access to domain experts to establish a creative collaboration, in an iterative (may be *agile*) way;
- Skilled team, able to write clean code - note also that since DDD is more about code expressiveness than technology, it may not appear so "trendy" to youngest developers;
- You want your internal team to accumulate knowledge of the domain - therefore, outsourcing may be constrained to applications, not the core domain.

Then check that DDD is worth it, i.e. if:

- It helps you solving the problem area you are trying to address;
- It meets your strategic goals: DDD is to be used where you will get your business money, and make you distinctive from your competitors;
- You need to bring clarity, and need to solve inner complexity, e.g. modeling a lot of rules (you won't use DDD to build simple applications - in this case, RAD may be enough);
- Your business is exploring: your goal is identified, but you do not know how to accomplish it;
- Don't have all of these concerns, but at least one or two.

2.8.4. Introducing DDD

Perhaps DDD sounds more appealing to you now. In this case, our *mORMot* framework will provide all the bricks you need to implement it, focusing on your domain and letting the libraries do all the needed plumbing.

If you identified that DDD is not to be used now, you will always find with *mORMot* the tools you need, ready to switch to DDD when it will be necessary.

Legacy code and existing projects (page 77) will benefit from DDD patterns. Finding so-called seams, along with isolating your core domain, can be extremely valuable when using DDD techniques to refactor and tighten the highest value parts of your code. It is not mandatory to re-write your whole existing software with DDD patterns everywhere: once you have identified where your business strategy's core is, you can introduce DDD progressively in this area. Then, following continuous feedback, you will refine your code, adding regression tests, and isolating your domain code from end-user code.

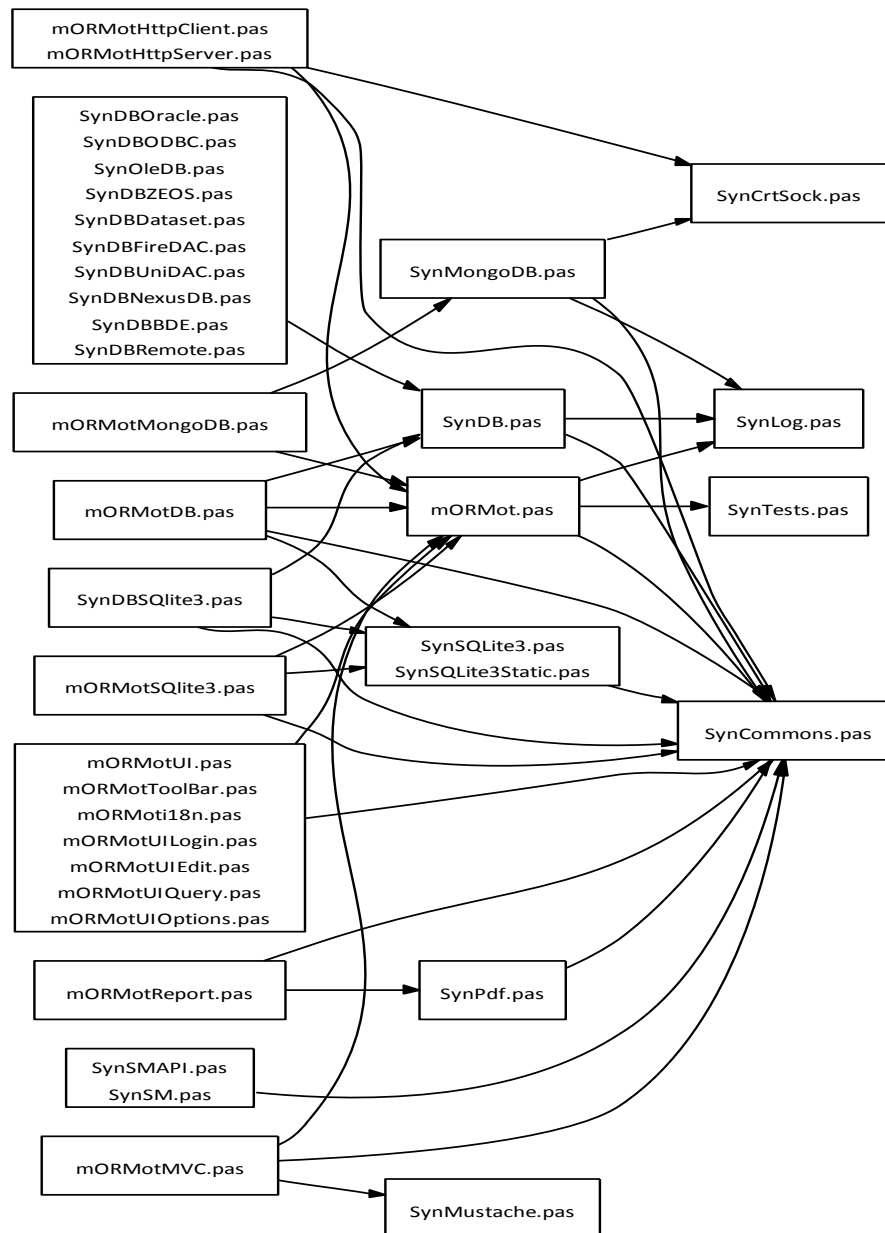

For a technical introduction about DDD and how *mORMot* can help you implement this design, see below (page 596).

With *mORMot*, your software solution will never be stuck in a dead-end. You'll be able to always adapt to your customers need, and maximize your ROI.

3. Enter new territory

3.1. Meet the mORMot

The *Synapse mORMot* framework consists in a huge number of units, so we will start by introducing them.

mORMot Source Code Main Units

3.2. Main units

The main units you have to be familiar with are the following:

Unit name	Description
SynCommons.pas SynLog.pas SynTests.pas	Common types, classes and functions
mORMot.pas	Main unit of the ORM / SOA framework
SynSQLite3.pas SynSQLite3Static.pas	<i>SQLite3</i> database engine
mORMotSQLite3.pas	Bridge between mORMot.pas and SynSQLite3.pas
SynDB.pas SynDB*.pas	Direct RDBMS access classes
mORMotDB.pas	ORM external SynDB.pas access, via <i>SQLite3</i> virtual tables
SynMongoDB.pas mORMotMongoDB.pas	Direct access to a <i>MongoDB</i> server
SynSM.pas SynSMAPI.pas	<i>SpiderMonkey</i> JavaScript engine
mORMotHttpClient.pas mORMotHttpServer.pas SynCrtSock.pas	RESTful HTTP/1.1 Client and Server
mORMotMVC.pas SynMustache.pas	MVC classes for writing Web Applications
mORMotUI*.pas	Grid and Forms User Interface generation
mORMotToolBar.pas	ORM ToolBar User Interface generation
mORMotReport.pas	Integrated Reporting engine

Other units are available in the framework source code repository, but are either expected by those files above (e.g. like SynDB*.pas database providers), or used only optionally in end-user cross-platform client applications (e.g. the CrossPlatform folder).

In the following pages, the features offered by those units will be presented.

Do not forget to take a look at all sample projects available in the SQLite3\Samples sub-folders - nothing is better than some simple code to look at.

Then detailed information will be available in the second part of this document - see below (page 644).

4. SynCommons unit

Adopt a mORMot

First of all, let us introduce some cross-cutting features, used everywhere in the *Synopse* source code. Even if you do not need to go deeply into the implementation details, it will help you not be disturbed with some classes and types you may encounter in the framework source, and its documentation.

It was a design choice to use some custom low-level types, classes and functions instead of calling the official *Delphi* RTL.

Benefits could be:

- Cross-platform and cross-compiler support (e.g. leverage specificities, about memory model or RTTI);
- Unicode support for all versions of *Delphi*, even before *Delphi* 2009, or with FPC;
- Optimized for process speed, multi-thread friendliness and re-usability;
- Sharing of most common features (e.g. for text/data processing);
- KISS and consistent design.

In order to use *Synopse mORMot framework*, you should better be familiar with some of those definitions.

First of all, a `Synopse.inc` include file is provided, and appears in most of the framework units:

```
{ $I Synopse.inc } // define HASINLINE USETYPEINFO CPU32 CPU64
```

It will define some conditionals, helping write portable and efficient code.

In the following next paragraphs, we'll comment some main features of the lowest-level part of the framework, mainly located in `SynCommons.pas`:

- Unicode and UTF-8;
- Currency type;
- *Dynamic array* wrappers (TDynArray and TDynArrayHashed);
- TDocVariant custom variant type for dynamic schema-less *object* or *array* storage.

Other shared features available in `SynTests.pas` and `SynLog.pas` will be detailed later, i.e. Testing and Logging - see below (page 627).

4.1. Unicode and UTF-8

Our *mORMot* Framework has 100% UNICODE compatibility, that is compilation under *Delphi* 2009 and up (including the latest available *Delphi* version). The code has been deeply rewritten and tested, in order to provide compatibility with the `String=UnicodeString` paradigm of these compilers. But the code will also handle safely Unicode for older versions, i.e. from *Delphi* 6 up to *Delphi* 2007.

From its core to its uppermost features, our framework is natively UTF-8, which is the de-facto character encoding for JSON, *SQLite3*, and most supported database engines. This allows our code to offer fast streaming/parsing in a SAX-like mode, avoiding any conversion between encodings from the storage layer to your business logic. We also needed to establish a secure way to use strings, in order to handle all versions of *Delphi* (even pre-Unicode versions, especially the *Delphi* 7 version we like so much), and provide compatibility with the *FreePascal Compiler*. This consistency allows to circumvent any RTL bug or limitation, and ease long-term support of your project.

Some string types have been defined, and used in the code for best cross-compiler efficiency:

- `RawUTF8` is used for every internal data usage, since both *SQLite3* and JSON do expect UTF-8 encoding;
- `WinAnsiString` where *WinAnsi*-encoded `AnsiString` (code page 1252) are needed;
- Generic string for *i18n* (e.g. in unit `mORMoti18n`), i.e. text ready to be used within the VCL, as either `AnsiString` (for *Delphi* 2 to 2007) or `UnicodeString` (for *Delphi* 2009 and later);
- `RawUnicode` in some technical places (e.g. direct `Win32 *W()` API call in *Delphi* 7) - note: this type is NOT compatible with *Delphi* 2009 and later `UnicodeString`;
- `RawByteString` for byte storage (e.g. for `FileFromString()` function);
- `SynUnicode` is the fastest available Unicode *native* string type, depending on the compiler used (i.e. `WideString` before *Delphi* 2009, and `UnicodeString` since);
- Some special conversion functions to be used for *Delphi* 2009+ `UnicodeString` (defined inside `{ifdef UNICODE}...{$endif}` blocks);
- Never use `AnsiString` directly, but one of the types above.

Note that `RawUTF8` is the preferred string type to be used in our framework when defining textual properties in a `TSQLRecord` and for all internal data processing. It is only when you're reaching the User Interface layer that you may convert explicitly the `RawUTF8` content into the generic VCL string type, using either the `Language.UTF8ToString` method (from `mORMoti18n.pas` unit) or the following function from `SynCommons.pas`:

```
/// convert any UTF-8 encoded String into a generic VCL Text
// - it's preferred to use TLanguageFile.UTF8ToString() in mORMoti18n.pas,
// which will handle full i18n of your application
// - it will work as is with Delphi 2009+ (direct unicode conversion)
// - under older version of Delphi (no unicode), it will use the
// current RTL codepage, as with WideString conversion (but without slow
// WideString usage)
function UTF8ToString(const Text: RawUTF8): string;
```

Of course, the `StringToUTF8` method or function are available to send back some text to the ORM layer.

A lot of dedicated conversion functions (including to/from numerical values) are included in `SynCommons.pas`. Those were optimized for speed and multi-thread capabilities, and to avoid implicit conversions involving a temporary string variable.

Warning during the compilation process are not allowed, especially under Unicode version of *Delphi* (e.g. *Delphi* 2010): all string conversion from the types above are made explicitly in the framework's code, to avoid any unattended data loss.

If you are using older version of Delphi, and have an existing code base involving a lot of `WideString` variables, you may take a look at the `SynFastWideString.pas` unit. Adding this unit in the top of your `.dpr` uses clauses will let all `WideString` process use the Delphi heap and its very efficient *FastMM4* memory manager, instead of the much slower BSTR Windows API. Performance gain can be more than 50 times, if your existing code uses a lot of `WideString` variables. Note that using this unit will break the compatibility with BSTR/COM/OLE kind of string, so is not to be used with COM objects. In all cases, if you need *Unicode* support with older versions of Delphi, consider using our `RawUTF8` type instead, which is much better integrated with our framework, and has less overhead.

4.2. Currency handling

Faster and safer way of comparing two currency values is certainly to map the variables to their internal `Int64` binary representation, as such:

```
function CompCurrency(var A,B: currency): Int64;  
var A64: Int64 absolute A;  
    B64: Int64 absolute B;  
begin  
  result := A64-B64;  
end;
```

This will avoid any rounding error during comparison (working with `*10000` integer values), and is likely to be faster than the default implementation, which uses the FPU (or SSE2 under *x64* architecture) instructions.

Some direct currency processing is available in the `SynCommons.pas` unit. It will by-pass the FPU use, and is therefore very fast.

There are some functions using the `Int64` binary representation (accessible either as `PInt64(@aCurrencyVar)^` or the absolute syntax):

- function `Curr64ToString(Value: Int64): string;`
- function `StrToCurr64(P: PUTF8Char): Int64;`
- function `Curr64ToStr(Value: Int64): RawUTF8;`
- function `Curr64ToPChar(Value: Int64; Dest: PUTF8Char): PtrInt;`
- function `StrCurr64(P: PAnsiChar; const Value: Int64): PAnsiChar;`

Using those functions can be *much* faster for textual conversion than using the standard `FloatToText()` implementation. They are validated with provided regression tests.

Of course, in normal code, it is certainly not worth using the `Int64` binary representation of currency, but rely on the default compiler/RTL implementation. In all cases, having optimized functions was a need for both speed and accuracy of our ORM data processing, and also for below (page 240).

Note that we discovered some issue in the FPC compiler, when currency is used when compiling from *x64-win64*: currency values comparison may be wrongly implemented using *x87* registers: we found out that using a *i386-win32* FPC compiler is a safer approach, even targetting *x64-win64* - at least for the trunk in 2019/11.

4.3. TDynArray dynamic array wrapper

Version 1.13 of the SynCommons.pas unit introduced two kinds of wrapper:

- Low-level RTTI functions for handling record types: RecordEquals, RecordSave, RecordSaveLength, RecordLoad;
- TDynArray and TDynArrayHashed objects, which are wrappers around any *dynamic array*.

With TDynArray, you can access any *dynamic array* (like TIntegerDynArray = array of integer) using TList-like properties and methods, e.g. Count, Add, Insert, Delete, Clear, IndexOf, Find, Sort and some new methods like LoadFromStream, SaveToStream, LoadFrom, SaveTo, Slice, Reverse, and AddArray. It includes e.g. fast binary serialization of any *dynamic array*, even containing strings or records - a CreateOrderedIndex method is also available to create individual index according to the *dynamic array* content. You can also serialize the array content into JSON, if you wish.

One benefit of *dynamic arrays* is that they are reference-counted, so they do not need any Create/try..finally...Free code, and are well handled by the *Delphi* compiler. For performance-critical tasks, dynamic array access is very optimized, since its whole content will be allocated at once, therefore reducing the memory fragmentation and being much more CPU cache friendly.

Dynamic arrays are no replacement to a TCollection nor a TList (which are the standard and efficient way of storing class instances, and are also handled as published properties since revision 1.13 of the framework), but they are very handy way of having a list of content or a dictionary at hand, with no previous class nor properties definition.

You can look at them like Python's list, tuples (via records handling) and dictionaries (via Find method, especially with the dedicated TDynArrayHashed wrapper), in pure *Delphi*. Our new methods (about searching and serialization) allow most usage of those script-level structures in your *Delphi* code.

In order to handle *dynamic arrays* in our ORM, some RTTI-based structure were designed for this task. Since *dynamic array of records* should be necessary, some low-level fast access to the record content, using the common RTTI, has also been implemented (much faster than the "new" enhanced RTTI available since *Delphi* 2010).

4.3.1. TList-like properties

Here is how you can have method-driven access to the *dynamic array*:

```
type
  TGroup: array of integer;
var
  Group: TGroup;
  GroupA: TDynArray;
  i, v: integer;
begin
  GroupA.Init(TypeInfo(TGroup), Group); // associate GroupA with Group
  for i := 0 to 1000 do
  begin
    v := i+1000; // need argument passed as a const variable
    GroupA.Add(v);
  end;
  v := 1500;
  if GroupA.IndexOf(v)<0 then // search by content
    ShowMessage('Error: 1500 not found!');
  for i := GroupA.Count-1 downto 0 do
```

```
if i and 3=0 then
  GroupA.Delete(i); // delete integer at index i
end;
```

This TDynArray wrapper will work also with array of string or array of record...

Records need only to be packed and have only not reference counted fields (byte, integer, double...) or string or variant reference-counted fields (there is no support of nested Interface yet). TDynArray is able to handle record within record, and even *dynamic arrays* within record.

Yes, you read well: it will handle a *dynamic array* of record, in which you can put some string or whatever data you need.

The IndexOf() method will search by content. That is e.g. for an array of record, all record fields content (including string properties) must match.

Note that TDynArray is just a wrapper around an existing *dynamic array* variable. In the code above, Add and Delete methods are modifying the content of the Group variable. You can therefore initialize a TDynArray wrapper on need, to access more efficiently any native *Delphi dynamic array*. TDynArray doesn't contain any data: the elements are stored in the *dynamic array* variable, not in the TDynArray instance.

4.3.2. Enhanced features

Some methods were defined in the TDynArray wrapper, which are not available in a plain TList - with those methods, we come closer to some native generics implementation:

- Now you can save and load a *dynamic array* content to or from a stream or a string (using LoadFromStream/SaveToStream or LoadFrom/SaveTo methods) - it will use a proprietary but very fast binary stream layout;
- And you can sort the *dynamic array* content by two means: either *in-place* (i.e. the array elements content is exchanged - use the Sort method in this case) or via an external integer *index look-up array* (using the CreateOrderedIndex method - in this case, you can have several orders to the same data);
- You can specify any custom comparison function, and there is a new Find method will can use fast binary search if available.

Here is how those new methods work:

```
var
  Test: RawByteString;
...
  Test := GroupA.SaveTo;
  GroupA.Clear;
  GroupA.LoadFrom(Test);
  GroupA.Compare := SortDynArrayInteger;
  GroupA.Sort;
  for i := 1 to GroupA.Count-1 do
    if Group[i]<Group[i-1] then
      ShowMessage('Error: unsorted!');
  v := 1500;
  if GroupA.Find(v)<0 then // fast binary search
    ShowMessage('Error: 1500 not found!');
```

Some unique methods like Slice, Reverse or AddArray are also available, and mimic well-known Python methods.

Still closer to the generic paradigm, working for *Delphi 6* up to the latest available *Delphi* version, without the need of the slow enhanced RTTI, nor the executable size overhead and compilation issues of generics...

4.3.3. Capacity handling via an external Count

One common speed issue with the default usage of TDynArray is that the internal memory buffer is reallocated when you change its length, just like a regular *Delphi dynamic array*.

That is, whenever you call Add or Delete methods, an internal call to SetLength(DynArrayVariable) is performed. This could be slow, because it always executes some extra code, including a call to ReallocMem.

In order not to suffer for this, you can define an external *Count* value, as an Integer variable.

In this case, the Length(DynArrayVariable) will be the memory capacity of the *dynamic array*, and the exact number of stored item will be available from this *Count* variable. A Count property is exposed by TDynArray, and will always reflect the number of items stored in the *dynamic array*. It will point either to the external Count variable, if defined; or it will reflect the Length(DynArrayVariable), just as usual. A Capacity property is also exposed by TDynArray, and will reflect the capacity of the *dynamic array*: in case of an external *Count* variable, it will reflect Length(DynArrayVariable).

As a result, adding or deleting items could be much faster.

```
var
  Group: TIntegerDynArray;
  GroupA: TDynArray;
  GroupCount, i, v: integer;
begin
  GroupA.Init(TypeInfo(TGroup), Group, @GroupCount);
  GroupA.Capacity := 1023; // reserve memory
  for i := 0 to 1000 do
  begin
    v := i+1000; // need argument passed as a const variable
    GroupA.Add(v); // faster than with no external GroupCount variable
  end;
  Check(GroupA.Count=1001);
  Check(GroupA.Capacity=1023);
  Check(GroupA.Capacity=length(Group));
```

4.3.4. JSON serialization

The TDynArray wrapper features some native JSON serialization abilities: TTextWriter. AddDynArrayJSON and TDynArray. LoadFromJSON methods are available for UTF-8 JSON serialization of *dynamic arrays*.

See below (page 304) for all details about this unique feature.

4.3.5. Daily use

The TTestLowLevelCommon._TDynArray and _TDynArrayHashed methods implement the automated unitary tests associated with these wrappers.

You'll find out there samples of *dynamic array* handling and more advanced features, with various kind of data (from plain TIntegerDynArray to records within records).

The TDynArrayHashed wrapper allow implementation of a dictionary using a *dynamic array* of record. For instance, the prepared statement cache is handling by the following code in SynSQLite3.pas:

```
TSQLStatementCache = record
  StatementSQL: RawUTF8;
  Statement: TSQLRequest;
end;
```

```
TSQLStatementCacheDynArray = array of TSQLStatementCache;
```

```
TSQLStatementCached = object
  Cache: TSQLStatementCacheDynArray;
  Count: integer;
  Caches: TDynArrayHashed;
  DB: TSQLite3DB;
  procedure Init(aDB: TSQLite3DB);
  function Prepare(const GenericSQL: RawUTF8): PSQLRequest;
  procedure ReleaseAllDBStatements;
end;
```

Those definitions will prepare a *dynamic array* storing a TSQLRequest and SQL statement association, with an external Count variable, for better speed.

It will be used as such in TSQLRestServerDB:

```
constructor TSQLRestServerDB.Create(aModel: TSQLModel; aDB: TSQLDataBase);
begin
  fStatementCache.Init(aDB);
  (...)
end;
```

The wrapper will be initialized in the object constructor:

```
procedure TSQLStatementCached.Init(aDB: TSQLite3DB);
begin
  Caches.Init(TypeInfo(TSQLStatementCacheDynArray), Cache, nil, nil, nil, @Count);
  DB := aDB;
end;
```

The TDynArrayHashed.Init method will recognize that the first TSQLStatementCache field is a RawUTF8, so will set by default an AnsiString hashing of this first field (we could specify a custom hash function or content hashing by overriding the default nil parameters to some custom functions).

So we can specify directly a GenericSQL variable as the first parameter of FindHashedForAdding, since this method will only access to the first field RawUTF8 content, and won't handle the whole record content. In fact, the FindHashedForAdding method will be used to make all the hashing, search, and new item adding if necessary - just in one step. Note that this method only prepare for adding, and code needs to explicitly set the StatementSQL content in case of an item creation:

```
function TSQLStatementCached.Prepare(const GenericSQL: RawUTF8): PSQLRequest;
var added: boolean;
begin
  with Cache[Caches.FindHashedForAdding(GenericSQL, added)] do begin
    if added then begin
      StatementSQL := GenericSQL; // need explicit set the content
      Statement.Prepare(DB, GenericSQL);
    end else begin
      Statement.Reset;
      Statement.BindReset;
    end;
    result := @Statement;
  end;
end;
```

The latest method of TSQLStatementCached will just loop for each statement, and close them: you can note that this code uses the dynamic array just as usual:

```
procedure TSQLStatementCached.ReleaseAllDBStatements;
var i: integer;
begin
  for i := 0 to Count-1 do
    Cache[i].Statement.Close; // close prepared statement
    Caches.Clear; // same as SetLength(Cache, 0) + Count := 0
  end;
```

The resulting code is definitively quick to execute, and easy to read/maintain.

4.3.6. TDynArrayHashed

If your purpose is to access a *dynamic array* using one of its fields as key, consider using `TDynArrayHashed`. This wrapper, inheriting from `TDynArray`, will store an hashed index of one field of the dynamic array record, for very efficient lookup. For a few dozen entries, it won't change the performance, but once you reach thousands of items, an index will be much faster - almost $O(1)$ instead of $O(n)$.

In respect to `TDynArray`, `TDynArrayHashed` instance lifetime should be consistent with the dynamic array itself, to ensure the hashed index is properly populated. You should also ensure that the dynamic array content is modified mainly via the `TDynArrayHashed.FindHashedForAdding`, `TDynArrayHashed.FindHashedAndUpdate` and `TDynArrayHashed.FindHashedAndDelete` methods, or explicitly call `TDynArrayHashed.ReHash` when the dynamic array content has been modified.

In practice, `TDynArrayHashed.FindHashed` will be much faster than a regular `TDynArray.Find` call.

4.3.7. TSynDictionary

One step further is available with the `TSynDictionary` class. It is a thread-safe dictionary to store some values from associated keys, as two separated dynamic arrays.

Each `TSynDictionary` instance will hold and store the associated dynamic arrays - this is not the case with `TDynArray` and `TDynArrayHashed`, which are only *wrappers* around an existing dynamic array variable.

One big advantage is that access to `TSynDictionary` methods are thread-safe by design: internally, a `TSynLock` will protect the keys, maintained by a *TDynArrayHashed* (page 111) instance, and the values by a `TDynArray`. Access to/from local variables will be made via explicit copy, for perfect thread safety.

For advanced use, the `TSynDictionary` offers JSON serialization and binary storage (with optional compression), and the ability to specify a timeout period in seconds, after which any call to `TSynDictionary.DeleteDeprecated` will delete older entries - which is very convenient to cache values, with optional persistence on disk. Just like your own in-process *Redis/MemCached* instance.

4.4. TDocVariant custom variant type

With revision 1.18 of the framework, we introduced two new custom types of variants:

- TDocVariant kind of variant;
- TBSONVariant kind of variant.

The second custom type (which handles *MongoDB*-specific extensions - like *ObjectID* or other specific types like dates or binary) will be presented later, when dealing with *MongoDB* support in *mORMot*, together with the BSON kind of content. BSON / *MongoDB* support is implemented in the *SynMongoDB.pas* unit.

We will now focus on TDocVariant itself, which is a generic container of JSON-like objects or arrays. This custom variant type is implemented in *SynCommons.pas* unit, so is ready to be used everywhere in your code, even without any link to the *mORMot* ORM kernel, or *MongoDB*.

4.4.1. TDocVariant documents

TDocVariant implements a custom variant type which can be used to store any JSON/BSON document-based content, i.e. either:

- Name/value pairs, for object-oriented documents (internally identified as *dvObject* sub-type);
- An array of values (including nested documents), for array-oriented documents (internally identified as *dvArray* sub-type);
- Any combination of the two, by nesting TDocVariant instances.

Here are the main features of this custom variant type:

- DOM approach of any *object* or *array* documents;
- Perfect storage for dynamic value-objects content, with a *schema-less* approach (as you may be used to in scripting languages like *Python* or *JavaScript*);
- Allow nested documents, with no depth limitation but the available memory;
- Assignment can be either *per-value* (default, safest but slower when containing a lot of nested data), or *per-reference* (immediate reference-counted assignment);
- Very fast JSON serialization / un-serialization with support of *MongoDB*-like extended syntax;
- Access to properties in code, via late-binding (including almost no speed penalty due to our VCL hack as detailed in *SDD # DI-2.2.3*);
- Direct access to the internal variant *names* and *values* arrays from code, by trans-typing into a TDocVariantData record;
- Instance life-time is managed by the compiler (like any other variant type), without the need to use interfaces or explicit *try..finally* blocks;
- Optimized to use as little memory and CPU resource as possible (in contrast to most other libraries, it does not allocate one *class* instance per node, but rely on pre-allocated arrays);
- Opened to extension of any content storage - for instance, it will perfectly integrate with BSON serialization and custom *MongoDB* types (*ObjectID*, *Decimal128*, *RegEx*...), to be used in conjunction with *MongoDB* servers;
- Perfectly integrated with our *TDynArray dynamic array wrapper* (page 107) and its JSON serialization - see below (page 304), as with the record serialization - see below (page 298);
- Designed to work with our *mORMot* ORM: any *TSQLRecord* instance containing such variant custom types as published properties will be recognized by the ORM core, and work as expected with any database back-end (storing the content as JSON in a TEXT column);
- Designed to work with our *mORMot* SOA: any interface-based service - see below (page 420) - is able to consume or publish such kind of content, as variant kind of parameters;

- Fully integrated with the *Delphi* IDE: any variant instance will be displayed as JSON in the IDE debugger, making it very convenient to work with.

To create instances of such variant, you can use some easy-to-remember functions:

- `_Obj()` `_ObjFast()` global functions to create a variant *object* document;
- `_Arr()` `_ArrFast()` global functions to create a variant *array* document;
- `_Json()` `_JsonFast()` `_JsonFmt()` `_JsonFastFmt()` global functions to create any variant *object* or *array* document from JSON, supplied either with standard or *MongoDB*-extended syntax.

You have two non excluding ways of using the `TDocVariant` storage:

- As regular variant variables, then using either late-binding or faster `_Safe()` to access its data;
- Directly as `TDocVariantData` variables, then later on returning a variant instance using `variant(aDocVariantData)`.

Note that you do not need to protect any stack-allocated `TDocVariantData` instance with a `try..finally`, since the compiler will do it for you. This record type has a lot of powerful methods, e.g. to apply *map/reduce* on the content, or do advanced searches or marshalling.

4.4.1.1. Variant object documents

The more straightforward is to use late-binding to set the properties of a new `TDocVariant` instance:

```
var V: variant;  
...  
TDocVariant.New(V); // or slightly slower V := TDocVariant.New;  
V.name := 'John';  
V.year := 1972;  
// now V contains {"name":"john","year":1982}
```

With `_Obj()`, an *object* variant instance will be initialized with data supplied two by two, as *Name,Value* pairs, e.g.

```
var V1,V2: variant; // stored as any variant  
...  
V1 := _Obj(['name','John','year',1972]);  
V2 := _Obj(['name','John','doc',_Obj(['one',1,'two',2.5])]); // with nested objects
```

Then you can convert those objects into JSON, by two means:

- Using the `VariantSaveJson()` function, which return directly one UTF-8 content;
- Or by trans-typing the variant instance into a string (this will be slower, but is possible).

```
writeln(VariantSaveJson(V1)); // explicit conversion into RawUTF8  
writeln(V1); // implicit conversion from variant into string  
// both commands will write '{"name":"john","year":1982}'  
writeln(VariantSaveJson(V2)); // explicit conversion into RawUTF8  
writeln(V2); // implicit conversion from variant into string  
// both commands will write '{"name":"john","doc":{"one":1,"two":2.5}}'
```

As a consequence, the *Delphi* IDE debugger is able to display such variant values as their JSON representation. That is, `V1` will be displayed as `'{"name":"john","year":1982}'` in the IDE debugger *Watch List* window, or in the *Evaluate/Modify* (F7) expression tool. This is pretty convenient, and much more user friendly than any class-based solution (which requires the installation of a specific design-time package in the IDE).

You can access to the object properties via late-binding, with any depth of nesting objects, in your code:

```
writeln('name=',V1.name,' year=',V1.year);  
// will write 'name=John year=1972'  
writeln('name=',V2.name,' doc.one=',V2.doc.one,' doc.two=',doc.two);
```

```
// will write 'name=John doc.one=1 doc.two=2.5'
V1.name := 'Mark';           // overwrite a property value
writeln(V1.name);           // will write 'Mark'
V1.age := 12;                // add a property to the object
writeln(V1.age);            // will write '12'
```

Note that the property names will be evaluated at runtime only, not at compile time. For instance, if you write `V1.nome` instead of `V1.name`, there will be no error at compilation, but an `EDocVariant` exception will be raised at execution (unless you set the `dvoReturnNullForUnknownProperty` option to `_Obj/_Arr/_Json/_JsonFmt` which will return a null variant for such undefined properties).

In addition to the property names, some pseudo-methods are available for such *object* variant instances:

```
writeln(V1.Count); // will write 3 i.e. the number of name/value pairs in the object document
writeln(V1.Kind); // will write 1 i.e. ord(dvObject)
for i := 0 to V2.Count-1 do
  writeln(V2.Name(i),'=',V2.Value(i));
// will write to the console:
// name=John
// doc={"one":1,"two":2.5}
// age=12
if V1.Exists('year') then
  writeln(V1.year);
V1.Add('key','value'); // add one property to the object
```

The variant values returned by late-binding are generated as `varByRef`, so it has two benefits:

- Much better performance, even if the nested objects are created *per-value* (see below);
- Allow nested calls of pseudo methods, as such:

```
var V: variant;
...
V := _Json('{arr:[1,2]}');
V.arr.Add(3); // will work, since V.arr is returned by reference (varByRef)
writeln(V); // will write '{"arr":[1,2,3]}'
V.arr.Delete(1);
writeln(V); // will write '{"arr":[1,3]}'
```

You may also trans-type your variant instance into a `TDocVariantData` record, and access directly to its internals.

For instance:

```
TDocVariantData(V1).AddValue('comment','Nice guy');
with TDocVariantData(V1) do // direct transtyping
  if Kind=dvObject then // direct access to the TDocVariantKind field
    for i := 0 to Count-1 do // direct access to the Count: integer field
      writeln(Names[i],'=',Values[i]); // direct access to the internal storage arrays
```

By definition, trans-typing via a `TDocVariantData` record is slightly faster than using late-binding.

But you must ensure that the variant instance is really a `TDocVariant` kind of data before transtyping e.g. by calling `_Safe(aVariant)^` function (or `DocVariantType.IsOfType(aVariant)` or `DocVariantData(aVariant)^`), which will work even for members returned as `varByRef` via late binding (e.g. `V2.doc`):

```
with _Safe(V1)^ do // note ^ to de-reference into TDocVariantData
  for ndx := 0 to Count-1 do // direct access to the Count: integer field
    writeln(Names[ndx],'=',Values[ndx]); // direct access to the internal storage arrays

writeln(V2.doc); // will write '{"name":"john","doc":{"one":1,"two":2.5}}'
if DocVariantType.IsOfType(V2.Doc) then // will be false, since V2.Doc is a varByRef variant
  writeln('never run'); // .. so TDocVariantData(V2.doc) will fail
with DocVariantData(V2.Doc)^ do // note ^ to de-reference into TDocVariantData
  for ndx := 0 to Count-1 do // direct access to the TDocVariantData methods
    writeln(Names[ndx],'=',Values[ndx]);
```

```
// will write to the console:
// one=1
// two=2.5
```

In practice, `_Safe(aVariant)^` may be preferred, since `DocVariantData(aVariant)^` will raise an `EDocVariant` exception if `aVariant` is not a `TDocVariant`, but `_Safe(aVariant)^` will return a "fake" void `DocVariant` instance, in which `Count=0` and `Kind=dbUndefined`.

The `TDocVariantData` type features some additional `U[]` `I[]` `B[]` `D[]` `O[]` `O_[]` `A[]` `A_[]` `_[]` properties, which could be used to have direct typed access to the data, as `RawUTF8`, `Int64/integer`, `Double`, or checking if the nested document is an `O[]` object or an `A[]` array.

You can also allocate directly the `TDocVariantData` instance on stack, if you do not need any variant-oriented access to the object, but just some local storage:

```
var Doc1,Doc2: TDocVariantData;
...
Doc1.Init; // needed for proper initialization
assert(Doc1.Kind=dvUndefined);
Doc1.AddValue('name','John'); // add some properties
Doc1.AddValue('birthyear',1972);
assert(Doc1.Kind=dvObject); // is now identified as an object
assert(Doc1.Value['name']='John'); // read access to the properties (also as varByRef)
assert(Doc1.Value['birthyear']=1972);
assert(Doc1.U['name']='John'); // slightly faster read access
assert(Doc1.I['birthyear']=1972);
writeln(Doc1.ToJSON); // will write '{"name":"John","birthyear":1972}'
Doc1.Value['name'] := 'Jonas'; // update one property
writeln(Doc1.ToJSON); // will write '{"name":"Jonas","birthyear":1972}'
Doc2.InitObject(['name','John','birthyear',1972],
  aOptions+[dvoReturnNullForUnknownProperty]); // initialization from name/value pairs
assert(Doc2.Kind=dvObject);
assert(Doc2.Count=2);
assert(Doc2.Names[0]='name');
assert(Doc2.Values[0]='John');
writeln(Doc2.ToJSON); // will write '{"name":"John","birthyear":1972}'
Doc2.Delete('name');
writeln(Doc2.ToJSON); // will write '{"birthyear":1972}'
assert(Doc2.U['name']='');
assert(Doc2.I['birthyear']=1972);
Doc2.U['name'] := 'Paul';
Doc2.I['birthyear'] := 1982;
writeln(Doc2.ToJSON); // will write '{"name":"Paul","birthyear":1982}'
```

You do not need to protect the stack-allocated `TDocVariantData` instances with a `try..finally`, since the compiler will do it for your. Take a look at all the methods and properties of `TDocVariantData`.

4.4.1.2. FPC restrictions

You should take note that with the *FreePascal* compiler, calling late-binding functions with arguments (like `Add` or `Delete`) would most probably fail to work as expected.

We have found out that the following code may trigger some random access violations:

```
doc.Add('text');
doc.Add(anotherdocvariant);
```

So you should rather access directly the underlying `TDocVariantData` instance:

```
TDocVariantData(doc).AddItem('text');
TDocVariantData(doc).AddItem(anotherdocvariant);
```

Or even better using `_Safe()`:

```
_Safe(doc)^.AddItem('text');
```

```
_Safe(doc)^.AddItem(anotherdocvariant);
```

In fact, late-binding functions arguments seem to work only for simple values (like integer or double), but not complex types (like string or other TDocVariantData), which generate some random GPF, especially when heaptrc paranoid memory checks are enabled.

As a result, direct access to TJSONVariantData instances - preferably via `_Safe()`, and not a variant variable, will be faster and less error-prone when using FPC.

4.4.1.3. Variant array documents

With `_Arr()`, an *array* variant instance will be initialized with data supplied as a list of *Value1, Value2, ..., e.g.*

```
var V1,V2: variant; // stored as any variant
...
V1 := _Arr(['John','Mark','Luke']);
V2 := _Obj(['name','John','array',_Arr(['one','two',2.5])]); // as nested array
```

Then you can convert those objects into JSON, by two means:

- Using the `VariantSaveJson()` function, which return directly one UTF-8 content;
- Or by trans-typing the variant instance into a string (this will be slower, but is possible).

```
writeln(VariantSaveJson(V1));
writeln(V1); // implicit conversion from variant into string
// both commands will write '["John","Mark","Luke"]'
writeln(VariantSaveJson(V2));
writeln(V2); // implicit conversion from variant into string
// both commands will write '{"name":"john","array":["one","two",2.5]}'
```

As a with any *object* document, the *Delphi* IDE debugger is able to display such *array* variant values as their JSON representation.

Late-binding is also available, with a special set of pseudo-methods:

```
writeln(V1._Count); // will write 3 i.e. the number of items in the array document
writeln(V1._Kind); // will write 2 i.e. ord(dvArray)
for i := 0 to V1._Count-1 do
  writeln(V1.Value(i),':',V2._(i)); // Value() or _() pseudo-methods
// will write in the console:
// John John
// Mark Mark
// Luke Luke
if V1.Exists('John') then // Exists() pseudo-method
  writeln('John found in array');
V1.Add('new item'); // add "new item" to the array
V1._ := 'another new item'; // add "another new item" to the array
writeln(V1); // will write '["John","Mark","Luke","new item","another new item"]'
V1.Delete(2);
V1.Delete(1);
writeln(V1); // will write '["John","Luke","another new item"]'
```

When using late-binding, the object properties or array items are retrieved as `varByRef`, so you can even run the pseudo-methods on any nested member:

```
V := _Json(['root',{'name':"Jim","year":1972}]);
V.Add(3.1415);
assert(V=['root',{'name':"Jim","year":1972},3.1415]);
V._(1).Delete('year'); // delete a property of the nested object
assert(V=['root',{'name':"Jim"},3.1415]);
V.Delete(1); // delete an item in the main array
assert(V=['root',3.1415]);
```

Of course, trans-typing into a TDocVariantData record is possible, and will be slightly faster than using late-binding. As usual, using `_Safe(aVariant)^` function is safer, especially when working on

varByRef members returned via late-binding.

As with an *object* document, you can also allocate directly the TDocVariantData instance on stack, if you do not need any variant-oriented access to the array:

```
var Doc: TDocVariantData;
...
Doc.Init; // needed for proper initialization - see also Doc.InitArray()
assert(Doc.Kind=dvUndefined); // this instance has no defined sub-type
Doc.AddItem('one'); // add some items to the array
Doc.AddItem(2);
assert(Doc.Kind=dvArray); // is now identified as an array
assert(Doc.Value[0]='one'); // direct read access to the items
assert(Doc.Values[0]='one'); // with index check
assert(Doc.Count=2);
writeln(Doc.ToJSON); // will write '["one",2]'
Doc.Delete(0);
assert(Doc.Count=1);
writeln(Doc.ToJSON); // will write '[2]'
```

You could use the A[] property to retrieve an object property as a TDocVariant array, or the A_[] property to add a missing array property to an object, for instance:

```
Doc.Clear; // reset the previous Doc content
writeln(Doc.A['test']); // will write 'null'
Doc.A_['test']^.AddItems([1,2]);
writeln(Doc.ToJSON); // will write '{"test":[1,2]}'
writeln(Doc.A['test']); // will write '[1,2]'
Doc.A_['test']^.AddItems([3,4]);
writeln(Doc.ToJSON); // will write '{"test":[1,2,3,4]}'
```

4.4.1.4. Create variant object or array documents from JSON

With _Json() or _JsonFmt(), either a *document* or *array* variant instance will be initialized with data supplied as JSON, e.g.

```
var V1,V2,V3,V4: variant; // stored as any variant
...
V1 := _Json('{"name":"john","year":1982}'); // strict JSON syntax
V2 := _Json('{name:"john",year:1982}'); // with MongoDB extended syntax for names
V3 := _Json('{"name":?,"year":?}',[1,['john',1982]]);
V4 := _JsonFmt('{%:?,%:?}",['name','year'],['john',1982]);
writeln(VariantSaveJSON(V1));
writeln(VariantSaveJSON(V2));
writeln(VariantSaveJSON(V3));
// all commands will write '{"name":"john","year":1982}'
```

Of course, you can nest objects or arrays as parameters to the _JsonFmt() function.

The supplied JSON can be either in strict JSON syntax, or with the *MongoDB* extended syntax, i.e. with unquoted property names. It could be pretty convenient and also less error-prone when typing in the *Delphi* code to forget about quotes around the property names of your JSON.

Note that TDocVariant implements an open interface for adding any custom extensions to JSON: for instance, if the SynMongoDB.pas unit is defined in your application, you will be able to create any *MongoDB* specific types in your JSON, like ObjectID(), NumberDecimal("..."), new Date() or even /regex/option.

As with any *object* or *array* document, the *Delphi* IDE debugger is able to display such variant values as their JSON representation.

4.4.1.5. Per-value or per-reference

By default, the variant instance created by `_Obj()` `_Arr()` `_Json()` `_JsonFmt()` will use a *copy-by-value* pattern. It means that when an instance is affected to another variable, a new variant document will be created, and all internal values will be copied. Just like a record type.

This will imply that if you modify any item of the copied variable, it won't change the original variable:

```
var V1,V2: variant;
...
V1 := _Obj(['name','John','year',1972]);
V2 := V1;           // create a new variant, and copy all values
V2.name := 'James'; // modifies V2.name, but not V1.name
writeln(V1.name, ' and ',V2.name);
// will write 'John and James'
```

As a result, your code will be perfectly safe to work with, since V1 and V2 will be uncoupled.

But one drawback is that passing such a value may be pretty slow, for instance, when you nest objects:

```
var V1,V2: variant;
...
V1 := _Obj(['name','John','year',1972]);
V2 := _Arr(['John','Mark','Luke']);
V1.names := V2; // here the whole V2 array will be re-allocated into V1.names
```

Such a behavior could be pretty time and resource consuming, in case of a huge document.

All `_Obj()` `_Arr()` `_Json()` `_JsonFmt()` functions have an optional `TDocVariantOptions` parameter, which allows to change the behavior of the created `TDocVariant` instance, especially setting `dvoValueCopiedByReference`.

This particular option will set the *copy-by-reference* pattern:

```
var V1,V2: variant;
...
V1 := _Obj(['name','John','year',1972],[dvoValueCopiedByReference]);
V2 := V1;           // creates a reference to the V1 instance
V2.name := 'James'; // modifies V2.name, but also V1.name
writeln(V1.name, ' and ',V2.name);
// will write 'James and James'
```

You may think that this behavior is somewhat weird for a variant type. But if you forget about *per-value* objects and consider those `TDocVariant` types as a *Delphi* class instance (which is a *per-reference* type), without the need of having a fixed schema nor handling manually the memory, it will probably start to make sense.

Note that a set of global functions have been defined, which allows direct creation of documents with *per-reference* instance lifetime, named `_ObjFast()` `_ArrFast()` `_JsonFast()` `_JsonFmtFast()`. Those are just wrappers around the corresponding `_Obj()` `_Arr()` `_Json()` `_JsonFmt()` functions, with the following `JSON_OPTIONS[true]` constant passed as options parameter:

```
const
  // some convenient TDocVariant options
  // - JSON_OPTIONS[false] is _Json() and _JsonFmt() functions default
  // - JSON_OPTIONS[true] are used by _JsonFast() and _JsonFastFmt() functions
  JSON_OPTIONS: array[Boolean] of TDocVariantOptions = (
    [dvoReturnNullForUnknownProperty],
    [dvoReturnNullForUnknownProperty,dvoValueCopiedByReference]);
```

When working with complex documents, e.g. with BSON / MongoDB documents, almost all content will be created in "fast" *per-reference* mode.

4.4.2. Advanced TDocVariant process

4.4.2.1. Number values options

By default, TDocVariantData will only recognize integer, Int64 and currency - see *Currency handling* (page 106) - as number values. Any floating point value which may not be translated to/from JSON textual representation safely will be stored as a JSON string, i.e. if it does match an integer or up to 4 fixed decimals, with 64-bit precision. We stated that JSON serialization should be conservative, i.e. serializing then unserializing (or the other way round) should return the very same value; parsing JSON is a matter of (difficult) choices - see http://seriot.ch/parsing_json.php#5.. - and we choose to be paranoid and not loose information by default.

You can use the `_JsonFastFloat()` wrapper or set the `dvoAllowDoubleValue` option to TDocVariantData, so that such floating-point numbers will be recognized and stored as double. In this case, only `varDouble` storage will be used for the variant values, i.e. 64-bit IEEE 754 double values, handling 5.0×10^{-324} .. 1.7×10^{308} range. With such floating-point values, you may loose precision and digits during the JSON serialization process: this is why it is not enabled by default.

Also note that some JSON engines do not support 64-bit integer numbers. For instance, JavaScript engines handle only up to 53-bit of information without precision loss (called the *significand* bits), due to their internal storage as a 8 bytes IEEE 754 container. In some cases, it is safest to use JSON string representation of such numbers, as is done with the `woIDAsIDstr` value of `TTextWriterWriteObjectOption` for safe serialization of `TSQLRecord.ID` ORM values.

If you want to work with high-precision floating point numbers, consider using `TDecimal128` values, as implemented in `SynMongoDB.pas`, which supports 128-bit high precision decimal, as defined by the *IEEE 754-2008 128-bit decimal floating point* standard, and handled in *MongoDB 3.4+*. Their conversion to/from text - therefore to/from JSON - won't loose nor round any digit, as soon as the value fits in its 128-bit storage.

4.4.2.2. Object or array document creation options

As stated above, a `TDocVariantOptions` parameter enables to define the behavior of a `TDocVariant` custom type for a given instance. Please refer to the documentation of this set of options to find out the available settings. Some are related to the memory model, other to case-sensitivity of the property names, other to the behavior expected in case of non-existing property, and so on...

Note that this setting is *local* to the given variant instance.

In fact, `TDocVariant` does not force you to stick to one memory model nor a set of global options, but you can use the best pattern depending on your exact process. You can even *mix* the options - i.e. including some objects as properties in an object created with other options - but in this case, the initial options of the nested object will remain. So you should better use this feature with caution.

You can use the `_Unique()` global function to force a variant instance to have an unique set of options, and all nested documents to become *by-value*, or `_UniqueFast()` for all nested documents to become *by-reference*.

```
// assuming V1={'name':'James','year':1972}' created by-reference
_Unique(V1);           // change options of V1 to be by-value
V2 := V1;              // creates a full copy of the V1 instance
V2.name := 'John';     // modifies V2.name, but not V1.name
writeln(V1.name);      // write 'James'
writeln(V2.name);      // write 'John'
V1 := _Arr(['root',V2]); // created as by-value by default, as V2 was
writeln(V1._Count);    // write 2
_UniqueFast(V1);       // change options of V1 to be by-reference
V2 := V1;
V1._(1).name := 'Jim';
```

```
writeln(V1);  
writeln(V2);  
// both commands will write '["root",{"name":"Jim","year":1972}]'
```

The easiest is to stick to one set of options in your code, i.e.:

- Either using the `_*`() global functions if your business code does send some `TDocVariant` instances to any other part of your logic, for further storage: in this case, the *by-value* pattern does make sense;
- Or using the `_*Fast`() global functions if the `TDocVariant` instances are local to a small part of your code, e.g. used as dynamic schema-less *Data Transfer Objects (DTO)*.

In all cases, be aware that, like any `class` type, the `const`, `var` and `out` specifiers of method parameters does not behave to the `TDocVariant` value, but to its reference.

4.4.2.3. Integration with other mORMot units

In fact, whenever a dynamic *schema-less* storage structure is needed, you may use a `TDocVariant` instance instead of `class` or record strong-typed types:

- Client-Server ORM - see below (page 130) - will support `TDocVariant` in any of the `TSQLRecord` variant published properties (and store them as JSON in a text column);
- Interface-based services - see below (page 420) - will support `TDocVariant` as variant parameters of any method, which make them as perfect *DTO*;
- Since JSON support is implemented with any `TDocVariant` value from the ground up, it makes a perfect fit for working with AJAX clients, in a script-like approach;
- If you use our `SynMongoDB.pas` `mORMotMongoDB.pas` units to access a *MongoDB* server, `TDocVariant` will be the native storage to create or access nested BSON arrays or objects documents - that is, it will allow proper ODM storage;
- Cross-cutting features (like logging or record / *dynamic array* enhancements) will also benefit from this `TDocVariant` custom type.

We are pretty convinced that when you will start playing with `TDocVariant`, you won't be able to live without it any more. It introduces the full power of late-binding and dynamic schema-less patterns to your application code, which can be pretty useful for prototyping or in Agile development. You do not need to use scripting engines like *Python* or *JavaScript*: *Delphi* is perfectly able to handle dynamic coding!

4.5. Cross-cutting functions

4.5.1. Iso8601 time and date

For date/time storage as text, the framework will use *ISO 8601* encoding. Dates could be encoded as `YYYY-MM-DD` or `YYYYMMDD`, time as `hh:mm:ss` or `hhmmss`, and combined date and time representations as `<date>T<time>`, i.e. `YYYY-MM-DDThh:mm:ss` or `YYYYMMDDThhmmss`.

The *lexicographical order* of the representation thus corresponds to chronological order, except for date representations involving negative years. This allows dates to be naturally sorted by, for example, file systems, or grid lists.

4.5.1.1. TDateTime and TDateTimeMS

In addition to the default `TDateTime` type, which will be serialized with a second resolution, you may use `TDateTimeMS`, which will include the milliseconds, i.e. `YYYY-MM-DDThh:mm:ss.sss` or `YYYYMMDDThhmmss.sss`:

```
type
  TDateTimeMS = type TDateTime;
```

This TDateTimeMS type is handled both during record - see below (page 298) - and dynamic array - see below (page 304) - JSON serialization, and by the framework ORM.

4.5.1.2. TTimeLog and TTimeLogBits

The SynCommons.pas unit defines a TTimeLog type, and some functions able to convert to/from regular TDateTime values:

```
type
  TTimeLog = type Int64;
```

This integer storage is encoded as a series of bits, which will map the TTimeLogBits record type, as defined in SynCommons.pas unit.

The resolution of such values is one second. In fact, it uses internally for computation an abstract "year" of 16 months of 32 days of 32 hours of 64 minutes of 64 seconds.

As a consequence, any date/time information can be retrieved from its internal bit-level representation:

- 0..5 bits will map *seconds*,
- 6..11 bits will map *minutes*,
- 12..16 bits will map *hours*,
- 17..21 bits will map *days* (minus one),
- 22..25 bits will map *months* (minus one),
- 26..40 bits will map *years*.

The *ISO 8601* standard allows millisecond resolution, encoded as hh:mm:ss.sss or hhmmss.sss. Our TTimeLog/TTimeLogBits integer encoding uses a second time resolution, and a 64-bit integer storage, so is not able to handle such precision. You could use TDateTimeMS or TUnixMSTime values instead, if milliseconds are required.

Note that since TTimeLog type is bit-oriented, you can't just use *add* or *subtract* two TTimeLog values when doing such date/time computation: use a TDateTime temporary conversion in such case. See for instance how the TSQLRest.ServerTimestamp property is computed:

```
function TSQLRest.GetServerTimestamp: TTimeLog;
begin
  PTimeLogBits(@result)^.From(Now+fServerTimestampOffset);
end;

procedure TSQLRest.SetServerTimestamp(const Value: TTimeLog);
begin
  fServerTimestampOffset := PTimeLogBits(@Value)^.ToDateTime-Now;
end;
```

But if you simply want to *compare* TTimeLog kind of date/time, it is safe to directly compare their Int64 underlying value, since timestamps will be stored in increasing order, with a resolution of one second.

Due to compiler limitation in older versions of *Delphi*, direct typecast of a TTimeLog or Int64 variable into a TTimeLogBits record (as with TTimeLogBits(aTimeLog).ToDateTime) could lead to an internal compiler error. In order to circumvent this bug, you will have to use a pointer typecast, e.g. as in TimeLogBits(@Value)^.ToDateTime above.

But in most case, you should better use the following functions to manage such timestamps:

```
function TimeLogNow: TTimeLog;
function TimeLogNowUTC: TTimeLog;
```

```
function TimeLogFromDateTime(DateTime: TDateTime): TTimeLog;  
function TimeLogToDateTime(const Timestamp: TTimeLog): TDateTime; overload;  
function Iso8601ToTimeLog(const S: RawByteString): TTimeLog;
```

See below (page 136) for additional information about this TTimeLog storage, and how it is handled by the framework ORM, via the additional TModTime and TCreateTime types.

4.5.1.3. TUnixTime and TUnixMSTime

You may consider the TUnixTime type, which holds a 64-bit encoded number of *seconds* since the Unix Epoch, i.e. 1970-01-01 00:00:00 UTC:

```
type  
  TUnixTime = type Int64;
```

You can convert such values:

- to/from TTimeLog values using TTimeLogBits.ToUnixTime and TTimeLogBits.FromUnixTime methods;
- to/from TDateTime values using UnixTimeToDateTime/DateTimeToUnixTime functions;
- using UnixTimeUTC to return the current timestamp, calling very fast OS API.

An alternative TUnixMSTime type is also available, which stores the date/time as a 64-bit encoded number of *milliseconds* since the Unix Epoch, i.e. 1970-01-01 00:00:00 UTC. Milliseconds resolution may be handy in some cases, especially when TTimeLog second resolution is not enough, and you want a more standard encoding than Delphi's TDateTime.

You may consider using TUnixTime and TUnixMSTime especially if the timestamp is likely to be handled by third-party clients following this C/C#/Java/JavaScript encoding. In the Delphi world, TDateTime, TDateTimeMS or TTimeLog types could be preferred.

4.5.2. Time Zones

One common problem when handling dates and times, is that common time is shown and entered as *local*, whereas the computer should better use non-geographic information - especially on a Client-Server architecture, where both ends may not be on the same physical region.

A *time zone* is a region that observes a uniform standard time for legal, commercial, and social purposes. Time zones tend to follow the boundaries of countries and their subdivisions because it is convenient for areas in close commercial or other communication to keep the same time. Most of the time zones on land are offset from *Coordinated Universal Time* (UTC) by a whole number of hours, or minutes. Even worse, some countries use daylight saving time for part of the year, typically by changing clocks by an hour, twice every year.

The main rule is that any date and time stored should be stored in UTC, or with an explicit Zone identifier (i.e. an explicit offset to the UTC value). Our framework expects this behavior: every date/time value stored and handled by the ORM, SOA, or any other part of it, is expected to be UTC-encoded. At presentation layer (e.g. the User Interface), conversion to/from local times should take place, so that the end-user is provided with friendly clock-wall compatible timing.

As you may guess, handling time zones is a complex task, which should be managed by the Operating System itself. Since this cultural material is constantly involving, it is updated as part of the OS.

In practice, current local time could be converted from UTC from the current system-wide time zone. One of the only parameters you have to set when installing an Operating System is to pickup the keyboard layout... and the current time zone to be used. But in a client-server environment, you may have to manage several time zones on the server side: so you can't rely on this global setting.

One sad - but predictable - disappointment is that there is no common way of encoding time zone information. Under *Windows*, the registry contains a list of time zones, and the associated time bias data. Most POSIX systems (including *Linux* and Mac OSX) do rely on the IANA database, also called *tzdata* - you may have noticed that this particular package is often updated with your system. Both zone identifiers do not map, so our framework needed something to be shared on all systems.

The `SynCommons.pas` unit features the `TSynTimeZone` class, which is able to retrieve the information from the *Windows* registry into memory via `TSynTimeZone.LoadFromRegistry`, or into a compressed file via `TSynTimeZone.SaveToFile`. Later on, this file could be reloaded on any system, including any *Linux* flavor, via `TSynTimeZone.LoadFromFile`, and returns the very same results. The compressed file is pretty small, thanks to its optimized layout, and use of our SynLZ compression algorithm: the full information is stored in a 7 KB file - the same flattened information as JSON is around 130 KB, and you may compare with the official <http://www.iana.org..> content, which weighted as a 280KB tar.gz... Of course, *tzdata* stores potentially a lot more information than we need.

In practice, you may use `TSynTimeZone.Default`, which will return an instance read from the current version of the registry under *Windows*, and will attempt to load the information named after the executable file name (appended as a `.tz` extension) on other Operating Systems.

You may therefore write:

```
aLocalTime := TSynTimeZone.Default.NowToLocal(aTimeZoneID);
```

Similarly, you may use `TSynTimeZone.UtcToLocal` or `TSynTimeZone.LocalToUtc` methods, with the proper TZ identifier.

You will have to create the needed `.tz` compressed file under a *Windows* machine, then provide this file together with any *Linux* server executable, in its very same folder. On a Cloud-like system, you may store this information in a centralized server, e.g. via a dedicated service - see below (page 420) - generated from a single reference *Windows* system via `TSynTimeZone.SaveToBuffer`, and later on use `TSynTimeZone.LoadFromBuffer` to decode it from all your cloud nodes. The main benefit is that the time information will stay consistent whatever system it runs on, as you may expect.

Your User Interface could retrieve the IDs and ready to be displayed text from `TSynTimeZone.Ids` and `TSynTimeZone.Displays` properties, as plain `TStrings` instance, which index will follow the `TSynTimeZone.Zone[]` internal information.

As a nice side effect, the `TSynTimeZone` binary internal storage has been found out to be very efficient, and much faster than a manual reading of the *Windows* registry. Complex local time calculation could be done on the server side, with no fear of breaking down your processing performances.

4.5.3. Safe locks for multi-thread applications

4.5.3.1. Protect your resources

Once your application is multi-threaded, concurrent data access should be protected. Otherwise, a "race condition" issue may appear: for instance, if two threads modify a variable at the same time (e.g. decrease a counter), values may become incoherent and unsafe to use. The most known symptom is the "deadlock", by which the whole application appears to be blocked and unresponsive. On a server system, which is expected to run 24/7 with no maintenance, such an issue is to be avoided.

In Delphi, protection of a resource (which may be an object, or any variable) is usually done via *Critical Sections*. A *critical section* is an object used to make sure, that some part of the code is executed only by one thread at a time. A *critical section* needs to be created/initialized before it can be used and be

released when it is not needed anymore. Then, some code is protected using *Enter/Leave* methods, which will *lock* its execution: in practice, only a single thread will own the *critical section*, so only a single thread will be able to execute this code section, and other threads will wait until the lock is released. For best performance, the protected sections should be as small as possible - otherwise the benefit of using threads may be voided, since any other thread will wait for the thread owning the *critical section* to release the lock.

4.5.3.2. Fixing TRTLCriticalSection

In practice, you may use a `TCriticalSection` class, or the lower-level `TRTLCriticalSection` record, which is perhaps to be preferred, since it will use less memory, and could easily be included as a (protected) field to any class definition.

Let's say we want to protect any access to the variables `a` and `b`. Here's how to do it with the critical sections approach:

```
var CS: TRTLCriticalSection;  
    a, b: integer;  
// set before the threads start  
InitializeCriticalSection(CS);  
// in each TThread.Execute:  
EnterCriticalSection(CS);  
try // protect the lock via a try ... finally block  
    // from now on, you can safely make changes to the variables  
    inc(a);  
    inc(b);  
finally  
    // end of safe block  
    LeaveCriticalSection(CS);  
end;  
// when the threads stop  
DeleteCriticalSection(CS);
```

In newest versions of Delphi, you may use a `TMonitor` class, which will let the lock be owned by any Delphi `TObject`. Before XE5, there was some performance issue, and even now, this Java-inspired feature may not be the best approach, since it is tied to a single object, and is not compatible with older versions of Delphi (or FPC).

Eric Grange reported some years ago - see <https://www.delphitools.info/2011/11/30/fixing-tcriticalsection..> - that `TRTLCriticalSection` (along with `TMonitor`) suffers from a severe design flaw in which entering/leaving different *critical sections* can end up serializing your threads, and the whole can even end up performing worse than if your threads had been serialized. This is because it's a small, dynamically allocated object, so several `TRTLCriticalSection` memory can end up in the same CPU cache line, and when that happens, you'll have cache conflicts aplenty between the cores running the threads.

The fix proposed by Eric is dead simple:

```
type  
    TFixedCriticalSection = class(TCriticalSection)  
    private  
        FDummy: array [0..95] of Byte;  
    end;
```

4.5.3.3. Introducing TSynLocker

Since we wanted to use a `TRTLCriticalSection` record instead of a `TCriticalSection` class instance, we defined a `TSynLocker` record in `SynCommons.pas`:

```
TSynLocker = record
```

```
private
  fSection: TRTLCriticalSection;
public
  Padding: array[0..6] of TVarData;
  procedure Init;
  procedure Done;
  procedure Lock;
  procedure Unlock;
end;
```

As you can see, the `Padding[]` array will ensure that the CPU cache-line issue won't affect our object.

TSynLocker use is close to TRTLCriticalSection, with some method-oriented behavior:

```
var safe: TSynLocker;
    a, b: integer;
// set before the threads start
safe.Init;
// in each TThread.Execute:
safe.Lock
try // protect the lock via a try ... finally block
  // from now on, you can safely make changes to the variables
  inc(a);
  inc(b);
finally
  // end of safe block
  safe.Unlock;
end;
// when the threads stop
safe.Done;
```

If your purpose is to protect a method execution, you may use the `TSynLocker.ProtectMethod` function or explicit `Lock/Unlock`, as such:

```
type
  TMyClass = class
  protected
    fSafe: TSynLocker;
    fField: integer;
  public
    constructor Create;
    destructor Destroy; override;
    procedure UseLockUnlock;
    procedure UseProtectMethod;
  end;

{ TMyClass }

constructor TMyClass.Create;
begin
  fSafe.Init; // we need to initialize the lock
end;

destructor TMyClass.Destroy;
begin
  fSafe.Done; // finalize the lock
  inherited;
end;

procedure TMyClass.UseLockUnlock;
begin
  fSafe.Lock;
  try
    // now we can safely access any protected field from multiple threads
    inc(fField);
  finally
    fSafe.Unlock;
```

```

end;
end;

procedure TMyClass.UseProtectMethod;
begin
  fSafe.ProtectMethod; // calls fSafe.Lock and return IUnknown Local instance
  // now we can safely access any protected field from multiple threads
  inc(fField);
  // here fSafe.Unlock will be called when IUnknown is released
end;

```

4.5.3.4. Inheriting from T*Locked

For your own classes definition, you may inherit from some classes providing a TSynLocker instance, as defined in SynCommons.pas:

```

TSynPersistentLocked = class(TSynPersistent)
...
  property Safe: TSynLocker read fSafe;
end;
TInterfacedObjectLocked = class(TInterfacedObjectWithCustomCreate)
...
  property Safe: TSynLocker read fSafe;
end;
TObjectListLocked = class(TObjectList)
...
  property Safe: TSynLocker read fSafe;
end;
TRawUTF8ListHashedLocked = class(TRawUTF8ListHashed)
...
  property Safe: TSynLocker read fSafe;
end;

```

All those classes will initialize and finalize their owned Safe instance, in their constructor/destructor.

So, we may have written our class as such:

```

type
  TMyClass = class(TSynPersistentLocked)
  protected
    fField: integer;
  public
    procedure UseLockUnlock;
    procedure UseProtectMethod;
  end;

{ TMyClass }

procedure TMyClass.UseLockUnlock;
begin
  fSafe.Lock;
  try
    // now we can safely access any protected field from multiple threads
    inc(fField);
  finally
    fSafe.Unlock;
  end;
end;

procedure TMyClass.UseProtectMethod;
begin
  fSafe.ProtectMethod; // calls fSafe.Lock and return IUnknown Local instance
  // now we can safely access any protected field from multiple threads
  inc(fField);
end;

```

```
// here fSafe.Unlock will be called when IUnknown is released  
end;
```

As you can see, the `Safe: TSynLocker` instance will be defined and handled at `TSynPersistentLocked` parent level.

4.5.3.5. Injecting TAutoLocker instances

Inheriting from a `TSynPersistentLocked` class (or one of its sibling) only gives you access to a single `TSynLocker` per instance. If your class inherits from `TSynAutoCreateFields`, you may create one or several `TAutoLocker` published properties, which will be auto-created with the instance:

```
type  
  TMyClass = class(TSynAutoCreateFields)  
    protected  
      fLock: TAutoLocker;  
      fField: integer;  
    public  
      function FieldValue: integer;  
    published  
      property Lock: TAutoLocker read fLock;  
    end;  
  
  { TMyClass }  
  
function TMyClass.FieldValue: integer;  
begin  
  fLock.ProtectMethod;  
  result := fField;  
  inc(fField);  
end;  
  
var c: TMyClass;  
begin  
  c := TMyClass.Create;  
  Assert(c.FieldValue=0);  
  Assert(c.FieldValue=1);  
  c.Free;  
end.
```

In practice, `TSynAutoCreateFields` is a very powerful way of defining Value objects, i.e. objects containing nested objects or even arrays of objects. You may use its ability to create the needed `TAutoLocker` instances in an automated way. But be aware that if you serialize such an instance into JSON, its nested `TAutoLocker` properties will be serialized as void properties - which may not be the expected result.

4.5.3.6. Injecting IAutoLocker instances

If your class inherits from `TInjectableObject`, you may define the following:

```
type  
  TMyClass = class(TInjectableObject)  
    private  
      fLock: IAutoLocker;  
      fField: integer;  
    public  
      function FieldValue: integer;  
    published  
      property Lock: IAutoLocker read fLock write fLock;  
    end;  
  
  { TMyClass }
```

```
function TMyClass.FieldValue: integer;
begin
  Lock.ProtectMethod;
  result := fField;
  inc(fField);
end;

var c: TMyClass;
begin
  c := TMyClass.CreateInjected([],[],[]);
  Assert(c.FieldValue=0);
  Assert(c.FieldValue=1);
  c.Free;
end;
```

Here we use dependency resolution - see below (page 418) - to let the `TMyClass.CreateInjected` constructor scan its published properties, and therefore search for a provider of `IAutoLocker`. Since `IAutoLocker` is globally registered to be resolved with `TAutoLocker`, our class will initialize its `fLock` field with a new instance. Now we could use `Lock.ProtectMethod` to use the associated `TAutoLocker`'s `TSynLocker` critical section, as usual.

Of course, this may sounds more complicated than manual `TSynLocker` handling, but if you are writing an interface-based service - see below (page 420), your class may already inherit from `TInjectableObject` for its own dependency resolution, so this trick may be very convenient.

4.5.3.7. Safe locked storage in `TSynLocker`

When we fixed the potential CPU cache-line issue, do you remember that we added a padding binary buffer to the `TSynLocker` definition? Since we do not want to waste resource, `TSynLocker` gives easy access to its internal data, and allow to directly handle those values. Since it is stored as 7 slots of variant values, you could store any kind of data, including complex `TDocVariant` document or array.

Our class may use this feature, and store its integer field value in the internal slot 0:

```
type
  TMyClass = class(TSynPersistentLocked)
  public
    procedure UseInternalIncrement;
    function FieldValue: integer;
  end;

{ TMyClass }

function TMyClass.FieldValue: integer;
begin // value read will also be protected by the mutex
  result := fSafe.LockedInt64[0];
end;

procedure TMyClass.UseInternalIncrement;
begin // this dedicated method will ensure an atomic increase
  fSafe.LockedInt64Increment(0,1);
end;
```

Please note that we used the `TSynLocker.LockedInt64Increment()` method, since the following will not be safe:

```
procedure TMyClass.UseInternalIncrement;
begin
  fSafe.LockedInt64[0] := fSafe.LockedInt64[0]+1;
end;
```

In the above line, two locks are acquired (one per `LockedInt64` property call), so another thread may modify the value in-between, and the increment may not be as accurate as expected.

`TSynLocker` offers some dedicated properties and methods to handle this safe storage. Those expect an `Index` value, from 0..6 range:

```
property Locked[Index: integer]: Variant read GetVariant write SetVariant;  
property LockedInt64[Index: integer]: Int64 read GetInt64 write SetInt64;  
property LockedPointer[Index: integer]: Pointer read GetPointer write SetPointer;  
property LockedUTF8[Index: integer]: RawUTF8 read GetUTF8 write SetUTF8;  
function LockedInt64Increment(Index: integer; const Increment: Int64): Int64;  
function LockedExchange(Index: integer; const Value: variant): variant;  
function LockedPointerExchange(Index: integer; Value: pointer): pointer;
```

You may store a pointer or a reference to a `TObject` instance, if necessary.

Having such a tool-set of thread-safe methods does make sense, in the context of our framework, which offers multi-thread server abilities - see below (page 336).

4.5.3.8. Thread-safe `TSynDictionary`

Remember that the `TSynDictionary` (page 111) class is thread-safe. In fact, the `TSynDictionary` methods are protected by a `TSynLocker` instance, and internal `Count` or `TimeOuts` values are actually stored within its 7 locked storage slots.

You may consider defining `TSynDictionary` instances in your business logic, or in the public API layer of your services, with proper thread safety - see below (page 363).

5. Object-Relational Mapping

Adopt a mORMot

The ORM part of the framework - see *Object-Relational Mapping (ORM)* (page 92) - is mainly implemented in the `mORMot.pas` unit. Then it will use other units (like `mORMotSQLite3.pas`, `mORMotDB.pas`, `SynSQLite3.pas` or `SynDB.pas`) to access to the various database back-ends.

Generic access to the data is implemented by defining high-level objects as *Delphi* classes, descendant from a main `TSQLRecord` class.

In our Client-Server ORM, those `TSQLRecord` classes can be used for at least three main purposes:

- To store and retrieve data from any database engine - for most common usage, you can forget about writing SQL queries: CRUD data access statements (`SELECT` / `INSERT` / `UPDATE` / `DELETE`) are all created on the fly by the *Object-relational mapping (ORM)* core of *mORMot* - see below (page 240) - a NoSQL engine like *MongoDB* can even be accessed the same way - see below (page 288);
- To have business logic objects accessible for both the Client and Server side, in a RESTful approach - see below (page 342);
- To fill a grid content with the proper field type (e.g. grid column names are retrieved from property names after translation, enumerations are displayed as plain text, or `boolean` as a checkbox); to create menus and reports directly from the field definition; to have edition window generated in an automated way - see below (page 2523).

Our ORM engine has genuine advanced features like *convention over configuration*, integrated security, local or remote access, REST JSON publishing (for AJAX or mobile clients), direct access to the database (by-passing slow `DB.pas` unit), content in-memory cache, optional audit-trail (change tracking), and integration with other parts of the framework (like SOA, logging, authentication...).

5.1. TSQLRecord fields definition

All the framework ORM process relies on the TSQLRecord class. This abstract TSQLRecord class features a lot of built-in methods, convenient to do most of the ORM process in a generic way, at record level.

It first defines a *primary key* field, defined as ID: TID, i.e. as Int64 in mORMot.pas:

```
type
  TID = type Int64;
  ...
  TSQLRecord = class(TObject)
  ...
    property ID: TID read GetID write fID;
  ...
```

In fact, our ORM relies on a Int64 primary key, matching the *SQLite3* ID/RowID primary key.

You may be disappointed by this limitation, which is needed by the *SQLite3*'s implementation of Virtual Tables - see below (page 226). We won't debate about a composite primary key (i.e. several fields), which is not a good idea for an ORM. In your previous RDBMS data modeling, you may be used to define a TEXT primary key, or even a GUID primary key: those kinds of keys are somewhat less efficient than an INTEGER, especially for ORM internals, since they are not monotonic. You can always define a secondary key, as string or TGUID field, if needed - using stored AS_UNIQUE attribute as explained below.

All published properties of the TSQLRecord descendant classes are then accessed via RTTI in a Client-Server RESTful architecture.

For example, a database Baby Table is defined in *Delphi* code as:

```
/// some enumeration
// - will be written as 'Female' or 'Male' in our UI Grid
// - will be stored as its ordinal value, i.e. 0 for sFemale, 1 for sMale
// - as you can see, ladies come first, here
TSex = (sFemale, sMale);

/// table used for the Babies queries
TSQLBaby = class(TSQLRecord)
private
  fName: RawUTF8;
  fAddress: RawUTF8;
  fBirthDate: TDateTime;
  fSex: TSex;
published
  property Name: RawUTF8 read fName write fName;
  property Address: RawUTF8 read fAddress write fAddress;
  property BirthDate: TDateTime read fBirthDate write fBirthDate;
  property Sex: TSex read fSex write fSex;
end;
```

By adding this TSQLBaby class to a TSQLModel instance, common for both Client and Server, the corresponding *Baby* table is created by the Framework in the database engine (*SQLite3* natively or any external database). All SQL work ('CREATE TABLE ...') is done by the framework. Just code in Pascal, and all is done for you. Even the needed indexes will be created by the ORM. And you won't miss any ' or ; in your SQL query any more.

The following published properties types are handled by the ORM, and will be converted as specified to database content (in *SQLite3*, an *INTEGER* is an *Int64*, *FLOAT* is a double, *TEXT* is an UTF-8 encoded text):

Delphi	SQLite3	Remarks
byte	INTEGER	
word	INTEGER	
integer	INTEGER	
cardinal	INTEGER	
Int64	INTEGER	
boolean	INTEGER	0 is false, anything else is true
enumeration	INTEGER	store the ordinal value of the enumerated item(i.e. starting at 0 for the first element)
set	INTEGER	each bit corresponding to an enumerated item (therefore a set of up to 64 elements can be stored in such a field)
single	FLOAT	
double	FLOAT	
extended	FLOAT	stored as double (precision lost)
currency	FLOAT	safely converted to/from currency type with fixed decimals, without rounding error
RawUTF8	TEXT	this is the preferred field type for storing some textual content in the ORM
WinAnsiString	TEXT	<i>WinAnsi</i> char-set (code page 1252) in <i>Delphi</i>
RawUnicode	TEXT	<i>UCS2</i> char-set in <i>Delphi</i> , as <i>AnsiString</i>
WideString	TEXT	<i>UCS2</i> char-set, as COM <i>BSTR</i> type (Unicode in all version of <i>Delphi</i>)
SynUnicode	TEXT	Will be either <i>WideString</i> before <i>Delphi</i> 2009, or <i>UnicodeString</i> later
string	TEXT	Not to be used before <i>Delphi</i> 2009 (unless you may loose some data during conversion) - <i>RawUTF8</i> is preferred in all cases
TDateTime	TEXT	ISO 8601 encoded date time, with second resolution
TDateTimeMS	TEXT	ISO 8601 encoded date time, with millisecond resolution
TTimeLog	INTEGER	as proprietary fast <i>Int64</i> date time
TModTime	INTEGER	the server date time will be stored when a record is modified (as proprietary fast <i>Int64</i>)

TCreateTime	INTEGER	the server date time will be stored when a record is created (as proprietary fast Int64)
TUnixTime	INTEGER	timestamp stored as second-based Unix Time (i.e. the 64-bit number of seconds since 1970-01-01 00:00:00 UTC)
TUnixMSTime	INTEGER	timestamp stored as millisecond-based Unix Time (i.e. the 64-bit number of milliseconds since 1970-01-01 00:00:00 UTC)
TSQLRecord	INTEGER	32-bit RowID pointing to another record (warning: the field value contains pointer(RowID), not a valid object instance - the record content must be retrieved with late-binding via its ID using a PtrInt(Field) typecast or the Field.ID method), or by using e.g. CreateJoined() - 64-bit under Win64
TID	INTEGER	64-bit RowID pointing to another record, but without any information about the corresponding table
TSQLRecordMany	nothing	data is stored in a separate <i>pivot</i> table; this is a particular case of TSQLRecord: it won't contain pointer(RowID), but an instance)
TRecordReference TRecordReferenceToBeDeleted	INTEGER	able to join any row on any table of the model, by storing both ID and TSQLRecord class type in a RecordRef-like Int64 value, with automatic reset to 0 (for TRecordReference) or row deletion (for TRecordReferenceToBeDeleted) when the pointed record is deleted
TSessionUserID	INTEGER	64-bit RowID of the TSQLAuthUser currently logged with the active session
TPersistent	TEXT	JSON object (ObjectToJSON)
TCollection	TEXT	JSON array of objects (ObjectToJSON)
TObjectList	TEXT	JSON array of objects (ObjectToJSON) - see TJSONSerializer. RegisterClassForJSON below (page 310)
TStrings	TEXT	JSON array of string (ObjectToJSON)
TRawUTF8List	TEXT	JSON array of string (ObjectToJSON)
any TObject	TEXT	See TJSONSerializer. RegisterCustomSerializer below (page 307)
TSQLRawBlob	BLOB	This type is an alias to RawByteString
<i>dynamic arrays</i>	BLOB	in the TDynArray.SaveTo binary format
variant	TEXT	numerical or text in JSON, or TDocVariant custom variant type (page 112) for JSON objects or arrays
TNullableInteger	INTEGER	Nullable Int64 value - see below (page 142)
TNullableBoolean	INTEGER	Nullable boolean (0/1/NULL) value - see below (page 142)

TNullableFloat	FLOAT	<i>Nullable</i> double value - see below (page 142)
TNullableCurrency	FLOAT	<i>Nullable</i> currency value - see below (page 142)
TNullableDateTime	TEXT	<i>Nullable</i> ISO 8601 encoded date time - see below (page 142)
TNullableTimeLog	INTEGER	<i>Nullable</i> TTimeLog value - see below (page 142)
TNullableUTF8Text	TEXT	<i>Nullable</i> Unicode text value - see below (page 142)
record	TEXT	JSON string or object, directly handled since <i>Delphi</i> XE5, or as defined in code by overriding TSQLRecord. InternalRegisterCustomProperties for prior versions
TRecordVersion	INTEGER	64-bit revision number, which will be monotonically updated each time the object is modified, to allow remote synchronization - see below (page 180)

5.1.1. Property Attributes

Some additional attributes may be added to the published field definitions:

- If the property is marked as stored `AS_UNIQUE` (i.e. stored `false`), it will be created as `UNIQUE` in the database (i.e. a SQL index will be created and uniqueness of the value will be checked at insert/update);
- For a dynamic array field, the index number can be used for the `TSQLRecord`.
`DynArray(DynArrayFieldIndex)` method to create a `TDynArray` wrapper mapping the dynamic array data;
- For a `RawUTF8` / `string` / `WideString` / `WinAnsiString` field of an "external" class - i.e. a `TEXT` field stored in a remote `SynDB.pas`-based database - see below (page 269), the index number will be used to define the maximum character size of this field, when creating the corresponding column in the database (`SQLite3` or `PostgreSQL` does not have any such size expectations).

For instance, the following class definition will create an index for its `SerialNumber` property (up to 30 characters long if stored in an external database), and will expect a link to a model of diaper (`TSQLDiaperModel`) and the baby which used it (`TSQLBaby`). An `ID` / `RowID` column will be always available (from `TSQLRecord`), so in this case, you will be able to make a fast lookup for a particular diaper from either its internal *mORMot* ID, or its official unique serial number:

```
/// table used for the Diaper queries
TSQLDiaper = class(TSQLRecord)
private
  fSerialNumber: RawUTF8;
  fModel: TSQLDiaperModel;
  fBaby: TSQLBaby;
published
  property SerialNumber: RawUTF8
    index 30
    read fSerialNumber write fSerialNumber
    stored AS_UNIQUE;
  property Model: TSQLDiaperModel read fModel write fModel;
  property Baby: TSQLBaby read fBaby write fBaby;
end;
```

Note that `TTNullableUTF8Text` kind of property will follow the same index `###` attribute interpretation.

5.1.2. Text fields

In practice, the generic string type is handled (as `UnicodeString` under *Delphi* 2009 and later), but you may loose some content if you're working with pre-Unicode version of *Delphi* (in which `string` = `AnsiString` with the current system code page). So we won't recommend its usage.

The natural *Delphi* type to be used for `TEXT` storage in our framework is `RawUTF8` as introduced for *Unicode and UTF-8* (page 105). All business process should better use `RawUTF8` variables and methods (you have all necessary functions in `SynCommons.pas`), then you should explicitly convert the `RawUTF8` content into a string using `U2S` / `S2U` from `mORMoti18n.pas` or `StringToUTF8` / `UTF8ToString` which will handle proper char-set conversion according to the current `i18n` settings. On Unicode version of *Delphi* (starting with *Delphi* 2009), you can directly assign a `string` / `UnicodeString` value to / from a `RawUTF8`, but this implicit conversion will be slightly slower than our `StringToUTF8` / `UTF8ToString` functions. With pre-Unicode version of *Delphi* (up to *Delphi* 2007), such direct assignation will probably loose data for all non ASCII 7 bit characters, so an explicit call to `StringToUTF8` / `UTF8ToString` functions is required.

You will find in `SynCommons.pas` unit all low-level RawUTF8 processing functions and classes, to be used instead of any `SysUtils.pas` functions. The mORMot core implementation about RawUTF8 is very optimized for speed and multi-threading, so it is recommended not to use `string` in your code, unless you access to the VCL / User Interface layer.

Having such a dedicated RawUTF8 type will also ensure that you are not leaking your domain from its business layer to the presentation layer, as defined with *Multi-tier architecture* (page 88):

Strings in Domain Driven Design n-Tier Architecture

For additional information about UTF-8 handling in the framework, see *Unicode and UTF-8* (page 105).

5.1.3. Date and time fields

Delphi `TDateTime` and `TDateTimeMS` properties will be stored as ISO 8601 text in the database, with seconds and milliseconds resolution. See *Iso8601 time and date* (page 120) for details about this text encoding.

As alternatives, `TTimeLog` / `TModTime` / `TCreateTime` offer a proprietary fast Int64 date time format, which will map the `TTimeLogBits` record type, as defined in `SynCommons.pas` unit.

This format will be very fast for comparing dates or convert into/from text, and will be stored as INTEGER in the database, therefore more efficiently than plain ISO 8601 text as for `TDateTime` fields.

In practice, `TModTime` and `TCreateTime` values are inter-exchangeable with `TTimeLog`. They are just handled with a special care by the ORM, so that their associated field value will be updated with the current UTC timestamp, for every `TSQLRecord` modification (for `TModTime`), or at entry creation (for `TCreateTime`). The time value stored is in fact the UTC timestamp, as returned from the current REST Server: in fact, when any REST client perform a connection, it will retrieve any time offset from the REST Server, which will be used to store a consistent time value across all Clients.

You may also define a `TUnixTime` property, which will store the number of seconds since 1970-01-01 00:00:00 UTC as INTEGER in the database, and serialized as 64-bit JSON number - or `TUnixMSTime` if you expect milliseconds resolution. This encoding has the benefit of being handled by *SQLite3* date/time functions, and interoperable with most third-party languages.

5.1.4. TSessionUserID field

If you define a `TSessionUserID` published property, this field will be automatically filled at creation or modification of the `TSQLRecord` with the current `TSQLAuthUser.ID` value of the active session. If no

session has been initialized from the client side, 0 will be stored.

By design, and similar to TModTime fields, you should use the ORM PUT/POST CRUD methods to compute this field value: manual SQL statements (like UPDATE Table SET Column=0) won't set its content. Also, it is up to the client to fill the TSessionUserID fields before sending their content to the server - the Delphi and cross-platform ORM clients will perform this assignment.

5.1.5. Enumeration fields

Enumerations should be mapped as INTEGER, i.e. via ord(aEnumValue) or TEnum(aIntegerValue).

Enumeration sets should be mapped as INTEGER, with byte/word/integer type, according to the number of elements in the set: for instance, byte(aSetValue) for up to 8 elements, word(aSetValue) for up to 16 elements, and integer(aSetValue) for up to 32 elements in the set.

5.1.6. Floating point and Currency fields

For standard floating-point values, the framework natively handles the double and currency kind of variables.

In fact, double is the native type handled by most database providers - it is also native to the SSE set of opcodes of newer CPUs (as handled by *Delphi* XE 2 in 64-bit mode). Lack of extended should not be problematic (if it is mandatory, a dedicated set of mathematical classes should be preferred to a database), and could be implemented with the expected precision via a TEXT field (or a BLOB mapped by a dynamic array).

The currency type is the standard *Delphi* type to be used when storing and handling monetary values, native to the x87 FPU - when it comes to money, a dedicated type is worth the cost in a "rich man's world". It will avoid any rounding problems, assuming exact 4 decimals precision. It is able to safely store numbers in the range -922337203685477.5808 .. 922337203685477.5807. Should be enough for your pocket change.

As stated by the official *Delphi* documentation:

Currency is a fixed-point data type that minimizes rounding errors in monetary calculations. On the Win32 platform, it is stored as a scaled 64-bit integer with the four least significant digits implicitly representing decimal places. When mixed with other real types in assignments and expressions, Currency values are automatically divided or multiplied by 10000.

In fact, this type matches the corresponding OLE and .Net implementation of currency. It is still implemented the same in the *Win64* platform (since XE 2). The Int64 binary representation of the currency type (i.e. value*10000 as accessible via a typecast like PInt64(@aCurrencyValue)^) is a safe and fast implementation pattern.

In our framework, we tried to avoid any unnecessary conversion to float values when dealing with currency values. Some dedicated functions have been implemented - see *Currency handling* (page 106) - for fast and secure access to currency published properties via RTTI, especially when converting values to or from JSON text. Using the Int64 binary representation can be not only faster, but also safer: you will avoid any rounding problem which may be introduced by the conversion to a float type. For all database process, especially with external engines, the SynDB.pas units will try to avoid any conversion to/from double for the dedicated FtCurrency columns.

Rounding issues are a nightmare to track in production - it sounds safe to have a framework handling natively a currency type from the ground up.

5.1.7. TSQLRecord fields

It is worth saying that TSQLRecord published properties are not by default class instances, as with regular *Delphi* code. After running TSQLRecord.Create() or CreateAndFillPrepare() constructors, you should never call aMyRecord.AnotherRecord.Property directly, or you will raise an *Access Violation*.

In fact, TSQLRecord published properties definition is used to define "one to many" or "one to one" relationships between tables. As a consequence, the nested AnotherRecord property won't be a true class instance, but one ID trans-typed as TSQLRecord.

Only exception to this rule is TSQLRecordMany kind of published properties, which, by design, are true instances, needed to access the pivot table data of "many to many" relationship. The ORM will *auto-instantiate* all TSQLRecordMany published properties, then release them at Destroy - so you do not need to maintain their life time.

Note that you may use e.g. TSQLRecord.CreateJoined() constructor to *auto-instantiate* and load all TSQLRecord published properties at once, then release them at Destroy. - see below (page 153).

The ORM will automatically perform the following optimizations for TSQLRecord published fields:

- An *index* will be created on the database, for the corresponding column;
- When a referenced record is deleted, the ORM will detect it and automatically set all published properties pointing to this record to 0.

In fact, the ORM won't define a ON DELETE SET DEFAULT foreign key via SQL: this feature won't be implemented at RDBMS level, but emulated *at ORM level*.

See below (page 151) for more details about how to work with TSQLRecord published properties.

5.1.8. TID fields

TSQLRecord published properties do match a class instance pointer, so are 32-bit (at least for *Win32/Linux32* executables). Since the TSQLRecord.ID field is declared as TID = Int64, we may loose information if the stored ID is greater than 2,147,483,647 (i.e. a signed 32-bit value).

You can define a published property as TID to store any value of our primary key, i.e. up to 9,223,372,036,854,775,808. Note that in this case, there is no information about the joined table.

As a consequence, the ORM will perform the following optimizations for TID fields:

- An *index* will be created on the database, for the corresponding column;
- When a referenced record is deleted, the ORM *won't do anything*, since it has no information about the table to track - this is the main difference with TSQLRecord published property.

You can optionally specify the associated table, using a custom TID type for the published property definition. In this case, you will sub-class TID, using *tableNameID* as naming convention.

For instance, if you define:

```
type
  TSQLRecordClientID = type TID;
  TSQLRecordClientToBeDeletedID = type TID;

  TSQLOrder = class(TSQLRecord)
  ...
  property Client: TID
    read fClient write fClient;
  property OrderedBy: TSQLRecordClientID
    read fOrderedBy write fOrderedBy;
```

```
property OrderedByCascade: TSQLRecordClientToBeDeletedID
  read fOrderedByCascade write fOrderedByCascade;
...
```

Those three published fields will be able to store a Int64 foreign key, and the ORM will ensure a corresponding *index* is created on the database, to speedup search on their values.

But their type - TID, TSQLRecordClientID, or TSQLRecordClientToBeDeletedID - will define how the deletion process will be processed.

By using the generic TID type, the first Client property won't have any reference to any table, so no deletion tracking will take place.

On the other hand, *following the type naming convention*, the others OrderedBy and OrderedByCascade properties will be associated with the TSQLRecordClient table of the data model. In fact, the ORM will retrieve the 'TSQLRecordClientID' or 'TSQLRecordClientToBeDeletedID' type names, and search for a TSQLRecord associated by trimming *[ToBeDeleted]ID, which is TSQLRecordClient in this case.

As a result, the ORM will be able to track any TSQLRecordClient deletion: for any row pointing to the deleted record, it will ensure that this OrderedBy property will be reset to 0, or that the row containing the OrderedByCascade property will be deleted. Note that the framework won't define a ON DELETE SET DEFAULT or ON DELETE CASCADE foreign key via SQL, but emulate them *at ORM level*.

5.1.9. TRecordReference and TRecordReferenceToBeDeleted

TSQLRecord or TID published properties are associated with a single TSQLRecord joined table. You could use TRecordReference or TRecordReferenceToBeDeleted published properties to store a reference to any record on any table of the data model.

In fact, such properties will store in a Int64 value a reference to both a TSQLRecord class (therefore defining a table), and one ID (to define the row).

You could later on use e.g. TSQLRest.Retrieve(Reference) to get a record content in one step.

One **important note** is to remember that the table reference is stored as an index to the TSQLRecord class in the associated TSQLModel.

As a consequence, for such TRecordReference* properties to work as expected, you should ensure:

- That the order of TSQLRecord classes in the TSQLModel **do not change** after any model modification: otherwise, all previously stored TRecordReference* values may point to a wrong record;
- That both Client and Server side **share the same model** - at least for the TSQLRecord classes which are used with TRecordReference*.

Depending on the type, the ORM will track the deletion of the pointed record:

- TRecordReference fields will be reset to 0 - emulating ON DELETE SET DEFAULT foreign key SQL declaration;
- TRecordReferenceToBeDeleted will delete the whole record - emulating ON DELETE CASCADE foreign key SQL declaration.

Just like with TSQLRecord or TSQLRecordClassName[ToBeDeleted]ID fields, this deletion tracking is not defined at RDBMS level, but emulated *at ORM level*.

In order to work easily with TRecordReference values (which are in fact plain Int64 values), you could transtype them into the RecordRef() record, and access the stored information via a set of helper methods. See below (page 2517) for an example of use of such TRecordReference in a data model, e.g. the AssociatedRecord property of TSQLAuditTrail.

5.1.10. TSQLRecord, TID, TRecordReference deletion tracking

To sum up all possible foreign key reference available by the framework, check out this table:

Type Definition	Index	Tables	Deletion Tracking	Emulated SQL
TSQLRecord	Yes	One	Field reset to 0	ON DELETE SET DEFAULT
TID	Yes	No	None	None
TClassNameID	Yes	One	Field reset to 0	ON DELETE SET DEFAULT
TClassNameToBeDeletedID	Yes	One	Row deleted	ON DELETE CASCADE
TRecordReference	Yes	All	Field reset to 0	ON DELETE SET DEFAULT
TRecordReferenceToBeDeleted	Yes	All	Row deleted	ON DELETE CASCADE

It is worth saying that this deletion tracking is not defined at RDBMS level, but *at ORM level*.

As a consequence, it will work with any kind of databases, including *NoSQL and Object-Document Mapping (ODM)* (page 96). In fact, RDBMS engines do not allow defining such ON DELETE trigger on several tables, whereas *mORMot* handles such composite references as expected for TRecordReference.

Since this is not a database level tracking, but only from a *mORMot* server, if you still use the database directly from legacy code, ensure that you will take care of this tracking, perhaps by using a SOA service instead of direct SQL statements.

5.1.11. Variant fields

The ORM will store variant fields as TEXT in the database, serialized as JSON.

At loading, it will check their content:

- If some custom variant types are registered (e.g. *MongoDB* custom objects), they will be recognized as such (with extended syntax, if applying);
- It will create a *TDocVariant custom variant type* (page 112) instance if the stored TEXT is a JSON object or array;
- It will create a numerical value (integer or double) if the stored text has the corresponding layout;
- Otherwise, it will create a string value.

Since all data is stored as TEXT in the column, your queries shall ensure that any SQL WHERE statement handles it as expected (e.g. with a conversion to number before comparison). Even if *SQLite3* is able to affect a column type for each row (i.e. store a variant as in *Delphi* code), we did not use this feature, since we wanted our framework to work with all databases - and *SQLite3* is quite alone having this feature.

At JSON level, variant fields will be transmitted as JSON text or number, depending on the stored value.

If you use a *MongoDB* external NoSQL database - see below (page 288), such variant field will not be stored as JSON text, but as true BSON documents. So you will be able to apply all the advanced search and indexing abilities of this database engine, if needed.

5.1.12. Record fields

Since *Delphi* XE5, you can define and work directly with published record properties of TSQLRecord:

```
TSQLMyRecord = class(TSQLRecordPeople)
protected
  fGUID: TGUID;
published
  property GUID: TGUID read fGUID write fGUID index 38;
end;
```

The record will be serialized as JSON - here TGUID will be serialized as a JSON string - then will be stored as TEXT column in the database.

We specified an index 38 attribute to state that this column will contain up to 38 characters, when stored on an external database - see below (page 269).

Published properties of *records* are handled by our code, but *Delphi* doesn't create the corresponding RTTI for such properties before *Delphi* XE5.

So record published properties, as defined in the above class definition, won't work directly for older versions of *Delphi*, or *FreePascal*.

You could use a *dynamic array* with only one element, in order to handle records within your TSQLRecord class definition - see below (page 161). But it may be confusing.

If you want to work with such properties before *Delphi* XE5, you can override the TSQLRecord.InternalRegisterCustomProperties() virtual method of a given table, to explicitly define a record property.

For instance, to register a GUID property mapping a TSQLMyRecord.fGUID: TGUID field:

```
type
  TSQLMyRecord = class(TSQLRecord)
  protected
    fGUID: TGUID;
    class procedure InternalRegisterCustomProperties(Props: TSQLRecordProperties); override;
  public
    property GUID: TGUID read fGUID write fGUID;
  end;

{ TSQLMyRecord }

class procedure TSQLMyRecord.InternalRegisterCustomProperties(
  Props: TSQLRecordProperties);
begin
  Props.RegisterCustomPropertyFromTypeName(self, 'TGUID', 'GUID',
    @TSQLRecordCustomProps(nil).fGUID, [aIsUnique], 38);
end;
```

You may call Props.RegisterCustomPropertyFromRTTI(), supplying the TypeInfo() pointer, for a record containing reference-counted fields like string, variant or nested dynamic arrays. Of course, any custom JSON serialization of the given record type - see below (page 298) - will be supported.

Those custom record registration methods will define either:

- TEXT serialization, for RegisterCustomPropertyFromRTTI() or RegisterCustomPropertyFromTypeName();
- BLOB serialization, for RegisterCustomRTTIRecordProperty() or RegisterCustomFixedSizeRecordProperty().

5.1.13. BLOB fields

In fact, several kind of properties will be stored as BLOB in the database backend:

- TSQLRawBlob properties are how you store your binary data, e.g. images or documents;
- *dynamic arrays* (saved in the TDynArray.SaveTo binary format);

- record which were explicitly registered as BLOB columns.

By default, both *dynamic arrays* and BLOB *record* content will be retrieved from the database, encoded as Base64 text.

But TSQLRawBlob properties will be transmitted as RESTful separate resources, as required by the REST scheme. For instance, it means that a first request will retrieve all "simple" fields as JSON, then some other requests are needed to retrieve each BLOB fields as a binary buffer. As a result, TSQLRawBlob won't be transmitted by default, to spare transmission bandwidth and resources.

You can change this default behavior, by setting:

- Either TSQLRestClientURI.ForceBlobTransfert: boolean property, to force the transfert of all BLOBs of all the tables of the data model - this is what is done e.g. for the *SynFile* main demo - see later in this document;
- Or via TSQLRestClientURI.TSQLRestClientURI.ForceBlobTransfertTable[] property, for a specified table of the model.

5.1.14. TNullable* fields for NULL storage

In *Delphi*, nullable types do not exist, as they do for instance in C#, via the `int?` kind of definition. But at SQL and JSON levels, the NULL values do exist and are expected to be available from our ORM.

In *SQLite3* itself, NULL is handled as stated in http://www.sqlite.org/lang_expr.html.. (see e.g. IS and IS NOT operators).

It is worth noting that NULL handling is not consistent among all existing database engines, e.g. when you are comparing NULL with non NULL values... so we recommend using it with care in any database statements, or only with proper (unit) testing, when you switch from one database engine to another.

By default, in the *mORMot* ORM/SQL code, NULL will appear only in case of a BLOB storage with a size of 0 bytes. Otherwise, you should not see it as a value, in most used types - see *TSQLRecord fields definition* (page 131).

Null-oriented value types have been implemented in our framework, since the object pascal language does not allow defining a nullable type (yet). We choose to store those values as variant, with a set of TNullable* dedicated types, as defined in *mORMot.pas*:

```
type
  TNullableInteger = type variant;
  TNullableBoolean = type variant;
  TNullableFloat = type variant;
  TNullableCurrency = type variant;
  TNullableDateTime = type variant;
  TNullableTimeLog = type variant;
  TNullableUTF8Text = type variant;
```

In order to define a NULLable column of such types, you could use them as types for your TSQLRecord class definition:

```
type
  TSQLNullableRecord = class(TSQLRecord)
  protected
    fInt: TNullableInteger;
    fBool: TNullableBoolean;
    fFlt: TNullableFloat;
    fCurr: TNullableCurrency;
    fDate: TNullableDateTime;
    fTimestamp: TNullableTimeLog;
    fCLOB: TNullableUTF8Text;
    fText: TNullableUTF8Text;
```

```
published
  property Int: TNullableInteger read fInt write fInt;
  property Bool: TNullableBoolean read fBool write fBool;
  property Flt: TNullableFloat read fFlt write fFlt;
  property Curr: TNullableCurrency read fCurr write fCurr;
  property Date: TNullableDateTime read fDate write fDate;
  property Timestamp: TNullableTimeLog read fTimestamp write fTimestamp;
  property CLOB: TNullableUTF8Text read fCLOB write fCLOB;
  property Text: TNullableUTF8Text index 32 read fText write fText;
end;
```

Such a class will let the ORM handle SQL NULL values as expected, i.e. returning a null variant value, or an integer/number/text value if there is something stored. Of course, the corresponding column in the database will have the expected data type, e.g. a NULLABLE INTEGER for TNullableInteger property.

Note that TNullableUTF8Text is defined as a RawUTF8 usual field - see *Property Attributes* (page 135). That is, without any size limitation by default (as for the CLOB property), or with an explicit size limitation using the index ### attribute (as for Text property, which will be converted as a VARCHAR(32) SQL column).

You could use the following wrapper functions to create a TNullable* value from any non-nullable standard Delphi value:

```
function NullableInteger(const Value: Int64): TNullableInteger;
function NullableBoolean(Value: boolean): TNullableBoolean;
function NullableFloat(const Value: double): TNullableFloat;
function NullableCurrency(const Value: currency): TNullableCurrency;
function NullableDateTime(const Value: TDateTime): TNullableDateTime;
function NullableTimeLog(const Value: TTimeLog): TNullableTimeLog;
function NullableUTF8Text(const Value: RawUTF8): TNullableUTF8Text;
```

Some corresponding constants do match the expected null value for each kind, with strong typing (to be used for FPC compatibility, which does not allow direct assignment of a plain null: variant to a TNullable* = type variant property):

```
var
  NullableIntegerNull: TNullableInteger absolute NullVarData;
  NullableBooleanNull: TNullableBoolean absolute NullVarData;
  ...
```

You could check for a TNullable* value to contain null, using the following functions:

```
function NullableIntegerIsEmptyOrNull(const V: TNullableInteger): Boolean;
function NullableBooleanIsEmptyOrNull(const V: TNullableBoolean): Boolean;
...
```

Or retrieve a Delphi non-nullable value in one step, using the corresponding wrappers:

```
function NullableIntegerToValue(const V: TNullableInteger; out Value: Int64): Boolean;
function NullableBooleanToValue(const V: TNullableBoolean; out Value: Boolean): Boolean;
...
function NullableIntegerToValue(const V: TNullableInteger): Int64;
function NullableBooleanToValue(const V: TNullableBoolean; out Value: Boolean): Boolean;
...
```

Those Nullable*ToValue() functions are mandatory for use under FPC, which does not allow mixing plain variant values and specialized TNullable* = type variant values.

Thanks to those types, and their corresponding wrapper functions, you have at hand everything needed to safely store some nullable values into your application database, with proper handling on Delphi side.

5.2. Working with Objects

To access a particular record, the following code can be used to handle CRUD statements (*Create Retrieve Update Delete* actions are implemented via *Add/Update/Delete/Retrieve* methods), following the RESTful pattern - see below (page 312), and using the ID primary key as resource identifier:

```
procedure Test(Client: TSQLRest); // we will use CRUD operations on a REST instance
var Baby: TSQLBaby; // store a record
    ID: TID; // store a reference to a record
begin
    // create and save a new record, since Smith, Jr was just born
    Baby := TSQLBaby.Create;
    try
        Baby.Name := 'Smith';
        Baby.Address := 'New York City';
        Baby.BirthDate := Date;
        Baby.Sex := sMale;
        ID := Client.Add(Baby, true);
    finally
        Baby.Free; // manage memory as usual
    end;
    // update record data
    Baby := TSQLBaby.Create(Client, ID); // retrieve from ID
    try
        assert(Baby.Name='Smith');
        Baby.Name := 'Smeeth';
        Client.Update(Baby);
    finally
        Baby.Free;
    end;
    // retrieve record data
    Baby := TSQLBaby.Create;
    try
        Client.Retrieve(ID, Baby);
        // we may have written: Baby := TSQLBaby.Create(Client, ID);
        assert(Baby.Name='Smeeth');
    finally
        Baby.Free;
    end;
    // delete the created record
    Client.Delete(TSQLBaby, ID);
end;
```

Of course, you can have a TSQLBaby instance alive during a longer time. The same TSQLBaby instance can be used to access several record content, and call Retrieve / Add / Delete / Update methods on purpose.

No SQL statement to write, nothing to care about database engine expectations (e.g. for date or numbers processing): just accessing objects via high-level methods. It could even work with NoSQL databases, like a fast TObjectList or MongoDB. This is the magic of ORM.

To be honest, the REST pattern does not match directly the CRUD operations exactly. We had to tied a little bit the REST verbs - as defined below (page 312) - to fit our ORM purpose. But all you have to know is that those *Add/Update/Delete/Retrieve* methods are able to define the full persistence lifetime of your precious objects.

5.3. Queries

5.3.1. Return a list of objects

You can query your table with the FillPrepare or CreateAndFillPrepare methods, for instance all

babies with balls and a name starting with the letter 'A':

```
var aMale: TSQLBaby;  
...  
aMale := TSQLBaby.CreateAndFillPrepare(Client,  
  'Name LIKE ? AND Sex = ?', ['A%', ord(sMale)]);  
try  
  while aMale.FillOne do  
    DoSomethingWith(aMale);  
finally  
  aMale.Free;  
end;
```

This request loops through all matching records, accessing each row content via a TSQLBaby instance.

The mORMot engine will create a SQL statement with the appropriate SELECT query, retrieve all data as JSON, transmit it between the Client and the Server (if any), then convert the values into properties of our TSQLBaby object instance. Internally, the [CreateAnd]FillPrepare / FillOne methods use a list of records, retrieved as JSON from the Server, and parsed in memory one row a time (using an internal TSQLTableJSON instance).

Note that there is an optional aCustomFieldsCSV parameter available in all FillPrepare / CreateAndFillPrepare methods, by which you may specify a CSV list of field names to be retrieved. It may save some remote bandwidth, if not all record fields values are needed in the loop. Note that you should use this aCustomFieldsCSV parameter only to retrieve some data, and that the other fields will remain untouched (i.e. void in case of CreateAndFillPrepare): any later call to Update should lead into a data loss, since the method will know that it has been called during a FillPrepare / CreateAndFillPrepare process, and only the retrieved filled will be updated on the server side.

You could also create a TObjectList, or - even better for newer versions of *Delphi* supporting the generics syntax - a TObjectList<T> instance to retrieve all values of a table:

```
var aList: TObjectList<TSQLBaby>;  
  aMale: TSQLBaby;  
...  
aList := Client.RetrieveList<TSQLBaby>(  
  'Name LIKE ? AND Sex = ?', ['A%', ord(sMale)]);  
try  
  for aMale in aList do  
    DoSomethingWith(aMale);  
finally  
  aList.Free;  
end;
```

Note that this method will use more memory and resources than a *FillPrepare call followed by a while ...FillOne do loop, since the later will only allocate one instance of the TSQLRecord, then fill the properties of this single instance directly from the returned JSON content, one at a time. For huge lists, or in multi-threaded environment, it may make a difference.

But the generics syntax can make cleaner code, or more integrated with your business logic.

5.3.2. Query parameters

For safer and faster database process, the WHERE clause of the request expects some parameters to be specified. They are bound in the ? appearance order in the WHERE clause of the [CreateAnd]FillPrepare query method.

Standard simple kind of parameters (RawUTF8, integer, double, currency..) can be bound directly - as in the sample code above for Name or Sex properties. The first parameter will be bound as 'A%' RawUTF8 TEXT, and the second as the 1 INTEGER value.

Any `TDateTime` bound parameter shall better be specified using `DateToSQL()`, `DateTimeToSQL()` or `TimeLogToSQL()` functions, as such:

```
aRec.CreateAndFillPrepare(Client, 'Datum=?', [DateToSQL(EncodeDate(2012,5,4))]);
aRec.CreateAndFillPrepare(Client, 'Datum>=?', [DateToSQL(2012,5,4)]);
aRec.CreateAndFillPrepare(Client, 'Datum<=?', [DateTimeToSQL(Now)]);
aRec.CreateAndFillPrepare(Client, 'Datum<=?', [TimeLogToSQL(Client.ServerTimestamp)]);
```

For `TTimeLog` / `TModTime` / `TCreateTime` / `TUnixTime` / `TUnixMSTime` kind of properties, please use the underlying `Int64` value as bound parameter.

As stated previously, BLOB (i.e. `sftBlob` or `TSQLRawBlob`) properties are handled separately, via dedicated `RetrieveBlob` and `UpdateBlob` method calls (or their global `RetrieveBlobFields` / `UpdateBlobFields` twins). In fact, BLOB data is expected to be potentially big (more than a few MB). But you can specify a small BLOB content using an explicit conversion to the corresponding TEXT format, by calling `BinToBase64WithMagic()` overloaded functions when preparing an UPDATE query, or by defining a `TByteDynArray` published field instead of `TSQLRawBlob`.

See also `ForceBlobTransfert` and `ForceBlobTransfertTable[]` properties of `TSQLRestClientURI`.

Note that there was a *breaking change* about the `TSQLRecord.Create` / `FillPrepare` / `CreateAndFillPrepare` and `TSQLRest.OneFieldValue` / `MultiFieldValues` methods: for historical reasons, they expected parameters to be marked as % in the SQL WHERE clause, and inlined via `:(...):` as stated below (page 148) - since revision 1.17 of the framework, those methods expect parameters marked as ? and with no `:(...):`. Due to this *breaking change*, user code review is necessary if you want to upgrade the engine from 1.16 or previous. In all cases, using ? is less confusing for new users, and more close to the usual way of preparing database queries - e.g. as stated below (page 240). Both `TSQLRestClient.ExecuteFmt` / `ListFmt` methods are not affected by this change, since they are just wrappers to the `FormatUTF8()` function.

For the most complex codes, you may want to prepare ahead the WHERE clause of the ORM request. You may use the overloaded `FormatUTF8()` function as such:

```
var where: RawUTF8;
begin
  where := FormatUTF8('id=?', [], [SomeID]);
  if add_active then
    where := FormatUTF8('% and active=?', [where], [ActiveFlag]);
  if add_date_ini then
    where := FormatUTF8('% and date_ini>=?', [where], [DateToSQL(Date-2)]);
  ...
end;
```

Then the request will be easy to create, and fast to execute, thanks to prepared statements in the framework database layer.

5.3.3. Introducing TSQLTableJSON

As we stated above, `[CreateAnd]FillPrepare` / `FillOne` methods are implemented via an internal `TSQLTableJSON` instance.

In short, `TSQLTableJSON` will expect some JSON content as input, will parse it in rows and columns, associate it with one or more optional `TSQLRecord` class types, then will let you access the data via its `Get*` methods.

You can use this `TSQLTableJSON` class as in the following example:

```
procedure WriteBabiesStartingWith(const Letters: RawUTF8; Sex: TSex);
var aList: TSQLTableJSON;
    Row: integer;
begin
```

```

aList := Client.MultiFieldValues(TSQLBaby, 'ID, BirthDate',
'Name LIKE ? AND Sex = ?', [Letters+'%', ord(Sex)]);
if aList=nil then
  raise Exception.Create('Impossible to retrieve data from Server');
try
  for Row := 1 to aList.RowCount do
    writeln('ID=', aList.GetAsInteger(Row, 0), ' BirthDate=', aList.Get(Row, 1));
  finally
    aList.Free;
  end;
end;

```

For a record with a huge number of fields, specifying the needed fields could save some bandwidth. In the above sample code, the ID column has a field index of 0 (so is retrieved via `aList.GetAsInteger(Row, 0)`) and the BirthDate column has a field index of 1 (so is retrieved as a `PUTF8Char` via `aList.Get(Row, 1)`). All data rows are processed via a loop using the `RowCount` property count - first data row is indexed as 1, since the row 0 will contain the column names.

The `TSQLTable` class has some methods dedicated to direct cursor handling, as such:

```

procedure WriteBabiesStartingWith(const Letters: RawUTF8; Sex: TSex);
var aList: TSQLTableJSON;
begin
  aList := Client.MultiFieldValues(TSQLBaby, 'ID, BirthDate',
'Name LIKE ? AND Sex = ?', [Letters+'%', ord(Sex)]);
  try
    while aList.Step do
      writeln('ID=', aList.Field(0), ' BirthDate=', aList.Field(1));
    finally
      aList.Free;
    end;
  end;
end;

```

By using the `TSQLTable.Step` method, you do not need to check that `aList<>nil`, since it will return false if `aList` is not assigned. And you do not need to access the `RowCount` property, nor specify the current row number.

We may have used not the field index, but the field name, within the loop:

```

writeln('ID=', aList.Field('ID'), ' BirthDate=', aList.Field('BirthDate'));

```

You can also access the field values using late-binding and a local variant, which gives some perfectly readable code:

```

procedure WriteBabiesStartingWith(const Letters: RawUTF8; Sex: TSex);
var baby: variant;
begin
  with Client.MultiFieldValues(TSQLBaby, 'ID, BirthDate',
'Name LIKE ? AND Sex = ?', [Letters+'%', ord(Sex)]) do
    try
      while Step(false, @baby) do
        writeln('ID=', baby.ID, ' BirthDate=', baby.BirthDate);
      finally
        Free;
      end;
    end;
  end;
end;

```

In the above code, late-binding will search for the "ID" and "BirthDate" fields at runtime. But the ability to write `baby.ID` and `baby.BirthDate` is very readable. Using a `with ... do` statement makes the code shorter, but should be avoided if it leads into confusion, e.g. in case of more complex process within the loop.

See also the following methods of `TSQLRest`: `OneFieldValue`, `OneFieldValues`, `MultiFieldValue`, `MultiFieldValues` which are able to retrieve either a `TSQLTableJSON`, or a *dynamic array* of integer or `RawUTF8`. And also `List` and `ListFmt` methods of `TSQLRestClient`, if you want to make a JOIN

against multiple tables at once.

A TSQLTableJSON content can be associated to a TGrid in order to produce an User Interface taking advantage of the column types, as retrieved from the associated TSQLRecord RTTI. The TSQLTableToGrid class is able to associate any TSQLTable to a standard TDrawGrid, with some enhancements: themed drawing, handle Unicode, column types (e.g. boolean are displayed as check-boxes, dates as text, etc...), column auto size, column sort, incremental key lookup, optional hide IDs, selection...

5.3.4. Note about query parameters

(this paragraph is not mandatory to be read at first, so you can skip it if you do not need to know about the mORMot internals - just remember that ? bound parameters are inlined as :(...): in the JSON transmitted content so can be set directly as such in any WHERE clause)

If you consider the first sample code:

```
aMale := TSQLBaby.CreateAndFillPrepare(Client,  
  'Name LIKE ? AND Sex = ?', ['A%', ord(sMale)]);
```

This will execute a SQL statement, with an ORM-generated SELECT, and a WHERE clause using two parameters bound at execution, containing 'A%' RawUTF8 text and 1 integer value.

In fact, from the SQL point of view, the CreateAndFillPrepare() method as called here is exactly the same as:

```
aMale := TSQLBaby.CreateAndFillPrepare(Client,  
  'Name LIKE :(''A%'') : AND Sex = :(1):');
```

or

```
aMale := TSQLBaby.CreateAndFillPrepare(Client,  
  'Name LIKE :(%): AND Sex = :(%):', [''A%''], ord(sMale), []]);
```

or

```
aMale := TSQLBaby.CreateAndFillPrepare(Client,  
  FormatUTF8('Name LIKE :(%): AND Sex = :(%):', [''A%''], ord(sMale))]);
```

First point is that the 'A' letter has been embraced with quotes, as expected per the SQL syntax. In fact, Name LIKE :(%): AND Sex = :(%):, [''A%''], ord(sMale) is expected to be a valid WHERE clause of a SQL statement.

Note we used single quotes, but we may have used double quotes (") inside the :(:): statements. In fact, SQLite3 expects single quotes in its raw SQL statements, whereas our prepared statements :(:): will handle both single ' and double " quotes. Just to avoid any confusion, we'll always show single quotes in the documentation. But you can safely use double quotes within :(:): statements, which could be more convenient than single quotes, which should be doubled within a pascal constant string ''.

The only not-obvious syntax in the above code is the :(%): used for defining prepared parameters in the format string.

In fact, the format string will produce the following WHERE clause parameter as plain text:

```
aMale := TSQLBaby.CreateAndFillPrepare(Client,  
  'Name LIKE :(''A%'') : AND Sex = :(1):');
```

So that the following SQL query will be executed by the database engine, after translation by the ORM magic:

```
SELECT * FROM Baby WHERE Name LIKE ? AND Sex = ?;
```

With the first ? parameter bound with 'A%' value, and the second with 1.

In fact, when the framework finds some `:():` in the SQL statement string, it will prepare a SQL statement, and will bound the parameters before execution (in our case, text A and integer 1), reusing any previous matching prepared SQL statement. See below (page 213) for more details about this mechanism.

To be clear, without any prepared statement, you could have used:

```
aMale := TSQLBaby.CreateAndFillPrepare(Client,  
  'Name LIKE % AND Sex = %', ['A%', ord(sMale)], []);
```

or

```
aMale := TSQLBaby.CreateAndFillPrepare(Client,  
  FormatUTF8('Name LIKE % AND Sex = %', ['A%', ord(sMale)]));
```

which will produce the same as:

```
aMale := TSQLBaby.CreateAndFillPrepare(Client,  
  'Name LIKE 'A%' AND Sex = 1');
```

So that the following SQL statement will be executed:

```
SELECT * FROM Baby WHERE Name LIKE 'A%' AND Sex = 1;
```

Note that we prepared the SQL WHERE clause, so that we could use the same request statement for all females with name starting with the character 'D':

```
aFemale := TSQLBaby.CreateAndFillPrepare(Client,  
  'Name LIKE :(:%): AND Sex = :(:%):', ['D%', ord(sFemale)]);
```

Using a prepared statement will speed up the database engine, because the SQL query will have to be parsed and optimized only once.

The second query method, i.e.

```
alist := Client.MultiFieldValues(TSQLBaby, 'ID, BirthDate',  
  'Name LIKE ? AND Sex = ?', [Letters+'%', ord(Sex)]);
```

is the same as this code:

```
alist := Client.MultiFieldValues(TSQLBaby, 'ID, BirthDate',  
  'Name LIKE :(:%): AND Sex = :(:%):', [QuotedStr(Letters+'%'), ord(Sex)], []);
```

or

```
alist := Client.MultiFieldValues(TSQLBaby, 'ID, BirthDate',  
  FormatUTF8('Name LIKE :(:%): AND Sex = :(:%):', [QuotedStr(Letters+'%'), ord(Sex)]));
```

In both cases, the parameters will be inlined, in order to prepare the statements, and improve execution speed.

We used the `QuotedStr` standard function to embrace the `Letters` parameter with quotes, as expected per the SQL syntax.

Of course, using '?' and bounds parameters is much easier than '%' and manual `:(%):` in-lining with a `QuotedStr()` function call. In your client code, you should better use '?' - but if you find some `:(%):` in the framework source code and when a WHERE clause is expected within the transmitted JSON content, you won't be surprised.

5.4. Automatic TSQLRecord memory handling

Working with objects is pretty powerful, but requires to handle manually the created instances life

time, via try .. finally blocks. Most of the time, the TSQLRecord life time will be very short: we allocate one instance on a local variable, then release it when it goes out of scope.

If we take again the TSQLBaby sample, we may write:

```
function NewMaleBaby(Client: TSQLRest; const Name,Address: RawUTF8): TID;
var Baby: TSQLBaby; // store a record
begin
  Baby := TSQLBaby.Create;
  try
    Baby.Name := Name;
    Baby.Address := Address;
    Baby.BirthDate := Date;
    Baby.Sex := sMale;
    result := Client.Add(Baby,true);
  finally
    Baby.Free;
  end;
end;
```

To ease this pretty usual pattern, the framework offers some kind of automatic memory management at TSQLRecord level:

```
function NewMaleBaby(Client: TSQLRest; const Name,Address: RawUTF8): TID;
var Baby: TSQLBaby; // store a record
begin
  TSQLBaby.AutoFree(Baby); // no try..finally needed!
  Baby.Name := Name;
  Baby.Address := Address;
  Baby.BirthDate := Date;
  Baby.Sex := sMale;
  result := Client.Add(Baby,true);
end; // Local Baby instance will be released here
```

It may also be useful for queries.

Instead of writing:

```
var aMale: TSQLBaby;
...
aMale := TSQLBaby.CreateAndFillPrepare(Client,
  'Name LIKE ? AND Sex = ?',[A%,ord(sMale)]);
try
  while aMale.FillOne do
    DoSomethingWith(aMale);
finally
  aMale.Free;
end;
```

We may write:

```
var aMale: TSQLBaby;
...
TSQLBaby.AutoFree(aMale,Client,'Name LIKE ? AND Sex = ?',[A%,ord(sMale)]);
while aMale.FillOne do
  DoSomethingWith(aMale);
```

Without the need to write the try ... finally block.

See the TSQLRecord.AutoFree() overloaded methods in mORMot.pas for the several use cases, and the associated TAutoFree / IAutoFree types as defined in SynCommons.pas. Note that you can handle several local variables in a single TSQLRecord.AutoFree() or TAutoFree.Create() initialization.

Be aware that it does not introduce some kind of magic garbage collector, as available in C# or Java. It is not even similar to the ARC memory model used by *Apple* and the *Delphi NextGen* compiler. It is just some syntactic sugar creating a local hidden IAutoFree interface, which will be released at the end of

the local method by the compiler, and also release all associated class instances. So the local class instances should stay in the local scope, and should not be sent and stored in another process: in such cases, you may encounter access violation issues.

Due to an issue (feature?) in the FPC implementation of interfaces - see <http://bugs.freepascal.org/view.php?id=26602..> - the above code will not work directly. You should assign the result of this method to a local `IAutoFree` variable, as such:

```
var aMale: TSQLBaby;  
    auto: IAutoFree;  
...  
    auto := TSQLBaby.AutoFree(aMale,Client,'Name LIKE ? AND Sex = ?',['A%',ord(sMale)]);  
    while aMale.FillOne do  
        DoSomethingWith(aMale);
```

One alternative may be to use a `with` statement, which prevents the need of defining a local variable:

```
var aMale: TSQLBaby;  
...  
    with TAutoFree.One(aMale,TSQLBaby.CreateAndFillPrepare(Client,  
        'Name LIKE ? AND Sex = ?',['A%',ord(sMale)])) do  
        while aMale.FillOne do  
            DoSomethingWith(aMale);
```

Or use one of the `TSQLRecord.AutoFree` overloaded class methods:

```
var aMale: TSQLBaby;  
...  
    with TSQLBaby.AutoFree(aMale,Client,'Name LIKE ? AND Sex = ?',['A%',ord(sMale)]) do  
        while aMale.FillOne do  
            DoSomethingWith(aMale);
```

If you want your code to cross-compile with both Delphi and FPC, consider this expectation of the FPC compiler.

5.5. Objects relationship: cardinality

All previous code is fine if your application requires "flat" data. But most of the time, you'll need to define master/child relationship, perhaps over several levels. In data modeling, the *cardinality* of one data table with respect to another data table is a critical aspect of database design. Relationships between data tables define *cardinality* when explaining how each table links to another.

In the relational model, tables can have the following *cardinality*, i.e. can be related as any of:

- "One to one".
- "Many to one" (rev. "One to many");
- "Many to many" (or "has many").

Our *mORMot framework* handles all those kinds of *cardinality*.

5.5.1. "One to one" or "One to many"

5.5.1.1. TSQLRecord published properties are IDs, not instance

In order to handle "One to one" or "One to many" relationship between tables (i.e. normalized Master/Detail in a classical RDBMS approach), you could define `TSQLRecord` published properties in the object definition.

For instance, you could declare classes as such:

```
TSQLMyFileInfo = class(TSQLRecord)
```

```
private
  FMyFileDate: TDateTime;
  FMyFileSize: Int64;
published
  property MyFileDate: TDateTime read FMyFileDate write FMyFileDate;
  property MyFileSize: Int64 read FMyFileSize write FMyFileSize;
end;

TSQLMyFile = class(TSQLRecord)
private
  FSecondOne: TSQLMyFileInfo;
  FFirstOne: TSQLMyFileInfo;
  FMyFileName: RawUTF8;
published
  property MyFileName: RawUTF8 read FMyFileName write FMyFileName;
  property FirstOne: TSQLMyFileInfo read FFirstOne write FFirstOne;
  property SecondOne: TSQLMyFileInfo read FSecondOne write FSecondOne;
end;
```

As stated by *TSQLRecord fields definition* (page 131), TSQLRecord published properties do not contain an instance of the TSQLRecord class. They will instead contain pointer(RowID), and will be stored as an INTEGER in the database.

So the main rule is to *never use directly such published properties*, as if they were regular class instance: otherwise you'll have an unexpected *access violation* error.

5.5.1.2. Transtyping IDs

When creating such records, use temporary instances for each detail object, as such:

```
var One, Two: TSQLMyFileInfo;
    MyFile: TSQLMyFile;
begin
  One := TSQLMyFileInfo.Create;
  Two := TSQLMyFileInfo.Create;
  MyFile := TSQLMyFile.Create;
  try
    One.MyFileDate := ....
    One.MyFileSize := ...
    MyFile.FirstOne := TSQLMyFileInfo(MyDataBase.Add(One,True)); // add One and store ID in
    MyFile.FirstOne
    Two.MyFileDate := ....
    Two.MyFileSize := ...
    MyFile.SecondOne:= TSQLMyFileInfo(MyDataBase.Add(Two,True)); // add Two and store ID in
    MyFile.SecondOne
    MyDataBase.Add(MyFile,true);
  finally
    MyFile.Free;
    Two.Free;
    One.Free;
  end;
end;
```

Note that you those two assignments are the same:

```
MyFile.FirstOne := TSQLMyFileInfo(MyDataBase.Add(One,True));
MyFile.FirstOne := pointer(MyDataBase.Add(One,True));
```

Or you may have added the One row first:

```
MyDataBase.Add(One,true);
```

then assigned it to the MyFile record on one of the following expressions:

```
MyFile.FirstOne := TSQLMyFileInfo(One.ID);
MyFile.FirstOne := pointer(One.ID);
MyFile.FirstOne := One.AsTSQLRecord;
```

The first two statements, using a class/pointer type cast will work only in 32-bit (since ID is an integer). Using `TSQLRecord.AsTSQLRecord` property will work on all platforms, including 64-bit, and is perhaps easier to deal with in your code.

When accessing the detail objects, you should not access directly to `FirstOne` or `SecondOne` properties (there are not class instances, but integer IDs), then use instead the `TSQLRecord.Create(aClient: TSQLRest; aPublishedRecord: TSQLRecord; ForUpdate: boolean=false)` overloaded constructor, as such:

```
var One: TSQLMyFileInfo;
    MyFile: TSQLMyFile;
begin
  MyFile := TSQLMyFile.Create(Client,aMyFileID);
  try
    // here MyFile.FirstOne.MyFileDate will trigger an access violation
    One := TSQLMyFileInfo.Create(Client,MyFile.FirstOne);
    try
      // here you can access One.MyFileDate or One.MyFileSize
    finally
      One.Free;
    end;
  finally
    MyFile.Free;
  end;
end;
```

Or with a with statement:

```
var MyFile: TSQLMyFile;
begin
  MyFile := TSQLMyFile.Create(Client,aMyFileID);
  try
    // here MyFile.FirstOne.MyFileDate will trigger an access violation
    with TSQLMyFileInfo.Create(Client,MyFile.FirstOne) do
      try
        // here you can access MyFileDate or MyFileSize
      finally
        Free;
      end;
    finally
      MyFile.Free;
    end;
  end;
```

Mapping a `TSQLRecord` field into an integer ID is a bit difficult to learn at first. It was the only way we found out in order to define a "one to one" or "one to many" relationship within the class definition, without any property attribute features of the *Delphi* compiler (only introduced in newer versions). The main drawback is that the compiler won't be able to identify at compile time some potential GPF issues at run time. This is up to the developer to write correct code, when dealing with `TSQLRecord` properties. Using `AsTSQLRecord` property and overloaded `TSQLRecord.Create(aPublishedRecord)` constructor will help a lot.

5.5.1.3. Automatic instantiation and JOINed query

Having to manage at hand all nested `TSQLRecord` instances can be annoying, and error-prone.

As an alternative, if you want to retrieve a whole `TSQLRecord` instance including its nested `TSQLRecord` published properties, you can use either of those two constructors:

- `TSQLRecord.CreateJoined(aClient,aID);`
- `TSQLRecord.CreateAndFillPrepareJoined()`, followed by a `while FillOne do loop`.

Both constructors:

- Will *auto-instantiate* all TSQLRecord published properties;
- Then the ORM core will retrieve all properties, included nested TSQLRecord via a SELECT LEFT JOIN . . . statement;
- Then the nested TSQLRecord will be released at Destroy of the main instance (to avoid any unexpected memory leak).

So you can safely write:

```
var MyFile: TSQLMyFile;  
begin  
  MyFile := TSQLMyFile.CreateJoined(Client, aMyFileID);  
  try  
    // here MyFile.FirstOne and MyFile.SecondOne are true instances  
    // and have already retrieved from the database by the constructor  
    // so you can safely access MyFile.FirstOne.MyFileDate or MyFile.SecondOne.MyFileSize here!  
  finally  
    MyFile.Free; // will release also MyFile.FirstOne and MyFile.SecondOne  
  end;  
end;
```

Note that this will work as expected when retrieving some data from the database, but, in the current implementation of the ORM, any Update() call will manage only the main TSQLRecord properties, and the nested TSQLRecord properties ID, not the nested properties values. For instance, in code above, aClient.Update(MyFile) will update the TSQLMyFile table, but won't reflect any modification to MyFile.FirstOne or MyFile.SecondOne properties. This limitation may be removed in the future - you may ask explicitly for this feature request.

5.5.2. "Has many" and "has many through"

As [http://en.wikipedia.org/wiki/Many-to-many_\(data_model\)](http://en.wikipedia.org/wiki/Many-to-many_(data_model)).. wrote:

In systems analysis, a many-to-many relationship is a type of cardinality that refers to the relationship between two entities (see also Entity-Relationship Model) A and B in which A may contain a parent row for which there are many children in B and vice versa. For instance, think of A as Authors, and B as Books. An Author can write several Books, and a Book can be written by several Authors. Because most database management systems only support one-to-many relationships, it is necessary to implement such relationships physically via a third and fourth junction table, say, AB with two one-to-many relationships A -> AB and B -> AB. In this case the logical primary key for AB is formed from the two foreign keys (i.e. copies of the primary keys of A and B).

From the record point of view, and to follow the ORM vocabulary (in Ruby on Rails, Python, or other *ActiveRecord* clones), we could speak of "has many" relationship. In the classic RDBMS implementation, a pivot table is created, containing two references to both related records. Additional information can be stored within this pivot table. It could be used, for instance, to store association time or corresponding permissions of the relationship. This is called a "has many through" relationship.

In fact, there are several families of ORM design, when implementing the "many to many" cardinality:

- Map collections into JOINed query from the ORM (i.e. pivot tables are abstracted from object lists or collections by the framework, to implement "has many" relationship, but you will have to define lazy loading and won't have "has many through" relationship at hand);
- Explicitly handle pivot tables as ORM classes, and provide methods to access to them (it will allow both "has many" and "has many through" relationship).
- Store collections within the ORM classes property (data sharding).

In the *mORMot framework*, we did not implement the 1st implementation pattern, but the 2nd and

3rd:

- You can map the DB with dedicated `TSQLRecordMany` classes, which allows some true pivot table to be available (that is the 2nd family), introducing true "has many through" cardinality;
- But for most applications, it sounds definitively more easy to use `TCollection` (of `TPersistent` classes) or *dynamic arrays* within one `TSQLRecord` class, and data sharding (i.e. the 3rd family).

Up to now, there is no explicit *Lazy Loading* feature in our ORM. There is no native handling of `TSQLRecord` collections or lists (as they do appear in the first family of ORMs). This could sound like a limitation, but it allows to manage exactly the data to be retrieved from the server in your code, and maintain bandwidth and memory use as low as possible. Use of a pivot table (via the `TSQLRecordMany` kind of records) allows tuned access to the data, and implements optimal *lazy loading* feature. Note that the only case when some `TSQLRecord` instances are automatically created by the ORM is for those `TSQLRecordMany` published properties.

5.5.2.1. Shared nothing architecture (or sharding)

5.5.2.1.1. Embedding all needed data within the record

Defining a pivot table is a classic and powerful use of relational database, and unleash its power (especially when linked data is huge).

But it is not easy nor natural to properly handle it, since it introduces some dependencies from the DB layer into the business model. For instance, it does introduce some additional requirements, like constraints / integrity checking and tables/classes inter-dependency.

Furthermore, in real life, we do not have such a separated storage, but we store all details within the main data. So for a *Domain-Driven Design* (page 99), which tries to map the real objects of its own domain, such a pivot table is breaking the business logic. With today's computer power, we can safely implement a centralized way of storing data into our data repository.

Let us quote what *wikipedia* states at http://en.wikipedia.org/wiki/Shared_nothing_architecture..

A shared nothing architecture (SN) is a distributed computing architecture in which each node is independent and self-sufficient, and there is no single point of contention across the system. People typically contrast SN with systems that keep a large amount of centrally-stored state information, whether in a database, an application server, or any other similar single point of contention.

As we stated in *TSQLRecord fields definition* (page 131), in our ORM, high-level types like dynamic arrays or `TPersistent` / `TCollection` properties are stored as BLOB or TEXT inside the main data row. There is no external linked table, no *Master/Detail* to maintain. In fact, each `TSQLRecord` instance content could be made self-contained in our ORM.

In particular, you may consider using our *TDocVariant custom variant type* (page 112) stored in a variant published property. It will allow to store any complex document, of nested objects or objects. They will be efficiently stored and transmitted as JSON.

When the server starts to have an increasing number of clients, such a data layout could be a major benefit. In fact, the so-called *sharding*, or horizontal partitioning of data, is a proven solution for web-scale databases, such as those in use by social networking sites. How does *EBay* or *Facebook* scale with so many users? Just by *sharding*.

A simple but very efficient *sharding* mechanism could therefore be implemented with our ORM. In-memory databases, or *SQLite3* are good candidate for light speed data process. Even *SQLite* could scale very well in most cases, when properly used - see below (page 199).

Storing detailed data in BLOB or in TEXT as JSON could first sounds a wrong idea. It does break one widely accepted principle of the RDBMS architecture. But even *Google* had to break this dogma. And when *MySQL* or any similar widely used databases try to implement sharding, it does need a lot of effort. Others, like the NoSQL *MongoDB*, are better candidates: they are not tight to the SQL/RDBMS flat scheme.

Finally, this implementation pattern fits much better with a *Domain-Driven* design. See below (page 596).

Therefore, on second thought, having at hand a *shared nothing architecture* could be a great advantage. Our ORM is already ready to break the table-oriented of SQL. Let us go one step further.

5.5.2.1.2. Nesting objects and arrays

The "*has many*" and "*has many through*" relationship we just described does follow the classic process of rows association in a relational database, using a pivot table. This does make sense if you have some DB background, but it is sometimes not worth it.

One drawback of this approach is that the data is split into several tables, and you should carefully take care of data integrity to ensure for instance that when you delete a record, all references to it are also deleted in the associated tables. Our ORM engine will take care of it, but could fail sometimes, especially if you play directly with the tables via SQL, instead of using high-level methods like `FillMany*` or `DestGetJoined`.

Another potential issue is that one business logical unit is split into several tables, therefore into several diverse `TSQLRecord` and `TSQLRecordMany` classes. From the ORM point of view, this could be confusing.

Starting with the revision 1.13 of the framework, *dynamic arrays*, `TStrings` and `TCollection` can be used as published properties in the `TSQLRecord` class definition. This won't be strong enough to implement all possible "Has many" architectures, but could be used in most case, when you need to add a list of records within a particular record, and when this list won't have to be referenced as a stand-alone table.

Dynamic arrays will be stored as BLOB fields in the database, retrieved with *Base64* encoding in the JSON transmitted stream, then serialized using the `TDynArray` wrapper. Therefore, only *Delphi* clients will be able to use this field content: you'll loose the AJAX capability of the ORM, at the benefit of better integration with object pascal code. Some dedicated SQL functions have been added to the *SQLite* engine, like `IntegerDynArrayContains`, to search inside this BLOB field content from the WHERE clause of any search (see below (page 161)). Those functions are available from AJAX queries.

`TPersistent` / `TStrings` and `TCollection` / `TObjectList` will be stored as TEXT fields in the database, following the `ObjectToJSON` function format: you can even serialize any `TObject` class, via a previous call to the `TJSONSerializer`. `RegisterCustomSerializer` class method - see below (page 307) - or `TObjectList` list of instances, if they are previously registered by `TJSONSerializer`. `RegisterClassForJSON` - see below (page 310). This format contains only valid JSON arrays or objects: so it could be un-serialized via an AJAX application, for instance.

About this (trolling?) subject, and why/when you should use plain *Delphi* objects or arrays instead of classic Master/Detail DB relationship, please read "*Objects, not tables*" and "*ORM is not DB*" paragraphs below.

5.5.2.1.2.1. TDocVariant and variant fields

5.5.2.1.2.1.1. Schemaless storage via a variant

As we just wrote, a first-class candidate for *data sharding* in a TSQLRecord is our *TDocVariant custom variant type* (page 112).

You may define:

```
TSQLRecordData = class(TSQLRecord)
private
  fName: RawUTF8;
  fData: variant;
public
published
  property Name: RawUTF8 read fName write fName stored AS_UNIQUE;
  property Data: variant read fData write fData;
end;
```

Here, we defined two indexed keys, ready to access any data record:

- Via the ID: TID property defined at TSQLRecord level, which will map the *SQLite3* RowID primary key;
- Via the Name: RawUTF8 property, which will be marked to be indexed by setting the "stored AS_UNIQUE" attribute.

Then, any kind of data may be stored in the Data: variant published property. In the database, it will be stored as JSON UTF-8 text, ready to be retrieved from any client, including AJAX / HTML5 applications. *Delphi* clients or servers will access those data via *late-binding*, from its TDocVariant instance.

You just reproduced the *schema-less* approach of the NoSQL database engines, in a few lines of code! Thanks to the *mORMot's* below (page 296) design, your applications are able to store any kind of document, and easily access to them via HTTP.

The documents stored in such a database can have varying sets of fields, with different types for each field. One could have the following objects in a single collection of our Data: variant rows:

```
{ name : "Joe", x : 3.3, y : [1,2,3] }
{ name : "Kate", x : "abc" }
{ q : 456 }
```

Of course, when using the database for real problems, the data does have a fairly consistent structure. Something like the following will be more common, e.g. for a table persisting *student* objects:

```
{ name : "Joe", age : 30, interests : "football" }
{ name : "Kate", age : 25 }
```

Generally, there is a direct analogy between this *schema-less* style and dynamically typed languages. Constructs such as those above are easy to represent in *PHP*, *Python* and *Ruby*. And, thanks to our TDocVariant *late-binding* magic, even our good *Delphi* is able to handle those structures in our code. What we are trying to do here is make this mapping to the database natural, like:

```
var aRec: TSQLRecordData;
    aID: TID;
begin
  // initialization of one record
  aRec := TSQLRecordData.Create;
  aRec.Name := 'Joe'; // one unique key
  aRec.data := _JSONFast('{name:"Joe",age:30}'); // create a TDocVariant
  // or we can use this overloaded constructor for simple fields
  aRec := TSQLRecordData.Create(['Joe',_ObjFast(['name','Joe','age',30])]);
  // now we can play with the data, e.g. via late-binding:
  writeln(aRec.Name); // will write 'Joe'
  writeln(aRec.Data); // will write '{"name":"Joe","age":30}' (auto-converted to JSON string)
  aRec.Data.age := aRec.Data.age+1; // one year older
```

```
aRec.Data.interests := 'football'; // add a property to the schema
aID := aClient.Add(aRec,true); // will store {"name":"Joe","age":31,"interests":"footbal"}
aRec.Free;
// now we can retrieve the data either via the aID created integer, or via Name='Joe'
end;
```

One of the great benefits of these dynamic objects is that schema migrations become very easy. With a traditional RDBMS, releases of code might contain data migration scripts. Further, each release should have a reverse migration script in case a rollback is necessary. ALTER TABLE operations can be very slow and result in scheduled downtime.

With a *schema-less* organization of the data, 90% of the time adjustments to the database become transparent and automatic. For example, if we wish to add GPA to the *student* objects, we add the attribute, re-save, and all is well - if we look up an existing student and reference GPA, we just get back null. Further, if we roll back our code, the new GPA fields in the existing objects are unlikely to cause problems if our code was well written.

In fact, *SQLite3* is so efficient about its indexes B-TREE storage, that such a structure may be used as a credible alternative to much heavier *NoSQL* engines, like *MongoDB* or *CouchDB*.

With the possibility to add some "regular" fields, e.g. plain numbers (like ahead-computed aggregation values), or text (like a summary or description field), you can still use any needed fast SQL query, without the complexity of *map/reduce* algorithm used by the *NoSQL* paradigm. You could even use the *Full Text Search* - FTS3/FTS4/FTS5, see below (page 215) - or RTREE extension advanced features of *SQLite3* to perform your queries. Then, thanks to *mORMot*'s ability to access any external database engine, you are able to perform a JOINed query of your *schema-less* data with some data stored e.g. in an Oracle, PostgreSQL or MS SQL enterprise database. Or switch later to a true *MongoDB* storage, in just one line of code - see below (page 288).

5.5.2.1.2.1.2. JSON operations from SQL code

As we stated, any variant field will be serialized as JSON, then stored as plain TEXT in the database. In order to make a complex query on the stored JSON, you could retrieve it in your end-user code, then use the corresponding TDocVariant instance to perform the search on its content. Of course, all this has a noticeable performance cost, especially when the data tend to grow.

The natural way of solving those performance issue is to add some "regular" RDBMS fields, with a proper index, then perform the requests on those fields. But sometimes, you may need to do some addition query, perhaps in conjunction with "regular" field lookup, on the JSON data stored itself.

In order to avoid the slowest conversion to the ORM client side, we defined some SQL functions, dedicated to JSON process.

The first is `JsonGet()`, and is able to extract any value from the TEXT field, mapping a variant:

<code>JsonGet(ArrColumn,0)</code>	returns a property value by index, from a JSON array
<code>JsonGet(ObjColumn,'PropName')</code>	returns a property value by name, from a JSON object
<code>JsonGet(ObjColumn,'Obj1.Obj2.Prop')</code>	returns a property value by path, including nested JSON objects
<code>JsonGet(ObjColumn,'Prop1,Prop2')</code>	extract properties by name, from a JSON object

<code>JsonGet(ObjColumn, 'Prop1,Obj1.Prop')</code>	extract properties by name (including nested JSON objects), from a JSON object
<code>JsonGet(ObjColumn, 'Prop*')</code>	extract properties by wildchar name, from a JSON object
<code>JsonGet(ObjColumn, 'Prop*,Obj1.P*')</code>	extract properties by wildchar name (including nested JSON objects), from a JSON object

If no value does match, this function will return the SQL NULL. If the matching value is a simple JSON text or number, it will be returned as a TEXT, INTEGER or DOUBLE value, ready to be passed as a result column or any WHERE clause. If the returned value is a nested JSON object or array, it will be returned as TEXT, serialized as JSON; as a consequence, you may use it as the source of another `JsonGet()` function, or even able to gather the results via the `CONCAT()` aggregate function.

The comma-separated syntax allowed in the property name parameter (e.g. 'Prop1,Prop2,Prop3'), will search for several properties at once in a single object, returning a JSON object of all matching values - e.g. `'{"Prop2": "Value2", "Prop3": 123}'` if the Prop1 property did not appear in the stored JSON object.

If you end the property name with a * character, it will return a JSON object, with all matching properties. Any nested object will have its property names be flattened as `{"Obj1.Prop": ...}`, within the returned JSON object.

Note that the comma-separated syntax also allows such wildchar search, so that e.g.

```
JsonGet(ObjColumn, 'owner') = {"login": "smith", "id": 123456} as TEXT
JsonGet(ObjColumn, 'owner.login') = "smith" as TEXT
JsonGet(ObjColumn, 'owner.id') = 123456 as INTEGER
JsonGet(ObjColumn, 'owner.name') = NULL
JsonGet(ObjColumn, 'owner.login,owner.id') = {"owner.login": "smith", "owner.id": 123456} as TEXT
JsonGet(ObjColumn, 'owner.I*') = {"owner.id": 123456} as TEXT
JsonGet(ObjColumn, 'owner.*') = {"owner.login": "smith", "owner.id": 123456} as TEXT
JsonGet(ObjColumn, 'unknown.*') = NULL
```

Another function, named `JsonHas()` is similar to `JsonGet()`, but will return TRUE or FALSE depending if the supplied property (specified by name or index) do exist. It may be faster to use `JsonHas()` than `JsonGet()` e.g. in a WHERE clause, when you do not want to process this property value, but only return data rows containing needed information.

```
JsonHas(ObjColumn, 'owner') = true
JsonHas(ObjColumn, 'owner.login') = true
JsonHas(ObjColumn, 'owner.name') = false
JsonHas(ObjColumn, 'owner.i*') = true
JsonHas(ObjColumn, 'owner.n*') = false
```

Since the process will take place within the *SQLite3* engine itself, and since they use a SAX-like fast approach (without any temporary memory allocation during its search), those JSON functions could be pretty efficient, and proudly compare to some dedicated NoSQL engines.

5.5.2.1.2.2. Dynamic arrays fields

5.5.2.1.2.2.1. Dynamic arrays from Delphi Code

For instance, here is how the regression tests included in the framework define a `TSQLRecord` class with some additional *dynamic arrays* fields:

```
TFV = packed record
  Major, Minor, Release, Build: integer;
  Main, Detailed: string;
```

```
end;
TFVs = array of TFV;
TSQLRecordPeopleArray = class(TSQLRecordPeople)
private
  fInts: TIntegerDynArray;
  fCurrency: TCurrencyDynArray;
  fFileVersion: TFVs;
  fUTF8: RawUTF8;
published
  property UTF8: RawUTF8 read fUTF8 write fUTF8;
  property Ints: TIntegerDynArray index 1 read fInts write fInts;
  property Currency: TCurrencyDynArray index 2 read fCurrency write fCurrency;
  property FileVersion: TFVs index 3 read fFileVersion write fFileVersion;
end;
```

This TSQLRecordPeopleArray class inherits from TSQLRecordPeople, so it will add some new UTF8, Ints, Currency and FileVersion fields to this root class fields (FirstName, LastName, Data, YearOfBirth, YearOfDeath).

Some content is added to the PeopleArray table, with the following code:

```
var V: TSQLRecordPeople;
    VA: TSQLRecordPeopleArray;
    FV: TFV;
(...)
V2.FillPrepare(Client, 'LastName=(:'Dali')');
n := 0;
while V2.FillOne do
begin
  VA.FillFrom(V2); // fast copy some content from TSQLRecordPeople
```

The FillPrepare / FillOne method are used to loop through all People table rows with a LastName column value equal to 'Dali' (with a prepared statement thanks to : () :), then initialize a TSQLRecordPeopleArray instance with those values, using a FillFrom method call.

```
inc(n);
if n and 31=0 then
begin
  VA.UTF8 := '';
  VA.DynArray('Ints').Add(n);
  Curr := n*0.01;
  VA.DynArray(2).Add(Curr);
  FV.Major := n;
  FV.Minor := n+2000;
  FV.Release := n+3000;
  FV.Build := n+4000;
  str(n, FV.Main);
  str(n+1000, FV.Detailed);
  VA.DynArray('FileVersion').Add(FV);
end else
  str(n, VA.fUTF8);
```

The n variable is used to follow the PeopleArray number, and will most of the time set its textual converted value in the UTF8 column, and once per 32 rows, will add one item to both VA and FV *dynamic array* fields.

We could have used normal access to VVA and FV *dynamic arrays*, as such:

```
SetLength(VA.Ints, length(VA.Ints)+1);
VA.Ints[high(VA.Ints)] := n;
```

But the DynArray method is used instead, to allow direct access to the *dynamic array* via a TDynArray wrapper. Those two lines behave therefore the same as this code:

```
VA.DynArray('Ints').Add(n);
```

Note that the DynArray method can be used via two overloaded set of parameters: either the field

name ('Ints'), or an index value, as was defined in the class definition. So we could have written:

```
VA.DynArray(1).Add(n);
```

since the Ints published property has been defined as such:

```
property Ints: TIntegerDynArray
  index 1
  read fInts write fInts;
```

Similarly, the following line will add a currency value to the Currency field:

```
VA.DynArray(2).Add(Curr);
```

And a more complex TFF record is added to the FileVersion field *dynamic array* with just one line:

```
VA.DynArray('FileVersion').Add(FV);
```

Of course, using the DynArray method is a bit slower than direct SetLength / Ints[] use. Using DynArray with an index should be also a bit faster than using DynArray with a textual field name (like 'Ints'), with the benefit of perhaps less keyboard errors at typing the property name. But if you need to fast add a lot of items to a *dynamic array*, you could use a custom TDynArray wrapper with an associated external Count value, or direct access to its content (like SetLength + Ints[])

Then the FillPrepare / FillOne loop ends with the following line:

```
Check(Client.Add(VA,true)=n);
end;
```

This will add the VA fields content into the database, creating a new row in the PeopleArray table, with an ID following the value of the n variable. All *dynamic array* fields will be serialized as BLOB into the database table.

5.5.2.1.2.2.2. Dynamic arrays from SQL code

In order to access the BLOB content of the dynamic arrays directly from SQL statements, some new SQL functions have been defined in TSQLDataBase, named after their native simple types:

- ByteDynArrayContains(BlobField,I64);
- WordDynArrayContains(BlobField,I64);
- IntegerDynArrayContains(BlobField,I64);
- CardinalDynArrayContains(BlobField,I64);
- CurrencyDynArrayContains(BlobField,I64) - in this case, I64 is not the currency value directly converted into an Int64 value (i.e. not Int64(aCurrency)), but the binary mapping of the currency value, i.e. aCurrency*10000 or PInt64(@aCurrency)^;
- Int64DynArrayContains(BlobField,I64);
- RawUTF8DynArrayContainsCase(BlobField,'Text');
- RawUTF8DynArrayContainsNoCase(BlobField,'Text').

Those functions allow direct access to the BLOB content like this:

```
for i := 1 to n shr 5 do
begin
  k := i shl 5;
  aClient.OneFieldValues(TSQLRecordPeopleArray,'ID',
    FormatUTF8('IntegerDynArrayContains(Ints,?)',[k]),IDs);
  Check(length(IDs)=n+1-32*i);
  for j := 0 to high(IDs) do
    Check(IDs[j]=k+j);
  end;
```

In the above code, the WHERE clause of the OneFieldValues method will use the dedicated IntegerDynArrayContains SQL function to retrieve all records containing the specified integer

value k in its Ints BLOB column. With such a function, all the process is performed Server-side, with no slow data transmission nor JSON/Base64 serialization.

For instance, using such a SQL function, you are able to store multiple TSQLRecord. ID field values into one TIntegerDynArray property column, and have direct search ability inside the SQL statement. This could be a very handy way of implementing "one to many" or "many to many" relationship, without the need of a pivot table.

Those functions were implemented to be very efficient for speed. They won't create any temporary dynamic array during the search, but will access directly to the BLOB raw memory content, as returned by the *SQLite* engine. The RawUTF8DynArrayContainsCase / RawUTF8DynArrayContainsNoCase functions also will search directly inside the BLOB. With huge number of requests, this could be slower than using a TSQLRecordMany pivot table, since the search won't use any index, and will have to read all BLOB field during the request. But, in practice, those functions behave nicely with a relative small amount of data (up to about 50,000 rows). Don't forget that BLOB column access are very optimized in *SQLite3*.

For more complex dynamic array content handling, you'll have either to create your own SQL function using the TSQLDataBase. RegisterSQLFunction method and an associated TSQLDataBaseSQLFunction class, or via a dedicated Service or a stored procedure - see below (page 364) on how to implement it.

5.5.2.1.2.3. TPersistent/TCollection fields

For instance, here is the way regression tests included in the framework define a TSQLRecord class with some additional TPersistent, TCollection or TRawUTF8List fields (TRawUTF8List is just a TStringList-like component, dedicated to handle RawUTF8 kind of string):

```

TSQLRecordPeopleObject = class(TSQLRecordPeople)
private
  fPersistent: TCollTst;
  fUTF8: TRawUTF8List;
public
  constructor Create; override;
  destructor Destroy; override;
published
  property UTF8: TRawUTF8List read fUTF8;
  property Persistent: TCollTst read fPersistent;
end;
  
```

In order to avoid any memory leak or access violation, it is mandatory to initialize then release all internal property instances in the overridden constructor and destructor of the class:

```

constructor TSQLRecordPeopleObject.Create;
begin
  inherited;
  fPersistent := TCollTst.Create;
  fUTF8 := TRawUTF8List.Create;
end;

destructor TSQLRecordPeopleObject.Destroy;
begin
  inherited;
  FreeAndNil(fPersistent);
  FreeAndNil(fUTF8);
end;
  
```

Here is how the regression tests are performed:

```

var V0: TSQLRecordPeopleObject;
(...)
  
```

```
if Client.TransactionBegin(TSQLRecordPeopleObject) then
try
  V2.FillPrepare(Client, 'LastName=?', ['Morse']);
  n := 0;
  while V2.FillOne do
  begin
    V0.FillFrom(V2); // fast copy some content from TSQLRecordPeople
    inc(n);
    V0.Persistent.One.Color := n+100;
    V0.Persistent.One.Length := n;
    V0.Persistent.One.Name := Int32ToUtf8(n);
    if n and 31=0 then
    begin
      V0.UTF8.Add(V0.Persistent.One.Name);
      with V0.Persistent.Coll.Add do
      begin
        Color := n+1000;
        Length := n*2;
        Name := Int32ToUtf8(n*3);
      end;
    end;
    Check(Client.Add(V0,true)=n);
  end;
  Client.Commit;
except
  Client.Rollback; // in case of error
end;
```

This will add 1000 rows to the PeopleObject table.

First of all, the adding is nested inside a transaction call, to speed up SQL INSERT statements, via TransactionBegin and Commit methods. Please note that the TransactionBegin method returns a boolean value, and should be checked in a multi-threaded or Client-Server environment (in this part of the test suit, content is accessed in the same thread, so checking the result is not mandatory, but shown here for accuracy). In the current implementation of the framework, transactions should not be nested. The typical transaction usage should be the following:

```
if Client.TransactionBegin(TSQLRecordPeopleObject) then
try
  //... modify the database content, raise exceptions on error
  Client.Commit;
except
  Client.Rollback; // in case of error
end;
```

In a Client-Server environment with multiple Clients connected at the same time, you can use the dedicated TSQLRestClientURI.TransactionBeginRetry method:

```
if Client.TransactionBeginRetry(TSQLRecordPeopleObject,20) then
  ...
```

Note that the transactions are handled according to the corresponding client session: the client should make the transaction block as short as possible (e.g. using a batch command), since any write attempt by other clients will wait for the transaction to be released (with either a commit or rollback).

The fields inherited from the TSQLRecord class are retrieved via FillPrepare / FillOne method calls, for columns with the LastName matching 'Morse'. One TPersistent property instance values are set (V0.Persistent.One), then, for every 32 rows, a new item is added to the V0.Persistent.Coll collection.

Here is the data sent for instance to the Server, when the item with ID=32 is added:

```
{"FirstName":"Samuel Finley Breese31",
"LastName":"Morse",
"YearOfBirth":1791,
```

```
"YearOfDeath":1872,
"UTF8":["32"],
"Persistent":{"One":{"Color":132,"Length":32,"Name":"32"},"Coll":[{"Color":1032,"Length":64,"Name":
:"96"}]}}
}
```

Up to revision 1.15 of the framework, the transmitted JSON content was not a true JSON object, but sent as RawUTF8 TEXT values (i.e. every double-quote (") character is escaped as - e.g. "UTF8":["32]"). Starting with revision 1.16 of the framework, the transmitted data is a true JSON object, to allow better integration with an AJAX client. That is, UTF8 field is transmitted as a valid JSON array of string, and Persistent as a valid JSON object with nested objects and arrays.

When all 1000 rows were added to the database file, the following loop is called once with direct connection to the DB engine, once with a remote client connection (with all available connection protocols):

```
for i := 1 to n do
begin
  V0.ClearProperties;
  Client.Retrieve(i,V0);
  Check(V0.ID=i);
  Check(V0.LastName='Morse');
  Check(V0.UTF8.Count=i shr 5);
  for j := 0 to V0.UTF8.Count-1 do
    Check(GetInteger(pointer(V0.UTF8[j]))=(j+1) shl 5);
  Check(V0.Persistent.One.Length=i);
  Check(V0.Persistent.One.Color=i+100);
  Check(GetInteger(pointer(V0.Persistent.One.Name))=i);
  Check(V0.Persistent.Coll.Count=i shr 5);
  for j := 0 to V0.Persistent.Coll.Count-1 do
    with V0.Persistent.Coll[j] do
      begin
        k := (j+1) shl 5;
        Check(Color=k+1000);
        Check(Length=k*2);
        Check(GetInteger(pointer(Name))=k*3);
      end;
    end;
end;
```

All the magic is made in the Client.Retrieve(i,V0) method. Data is retrieved from the database as TEXT values, then un-serialized from JSON arrays or objects into the internal TRawUTF8List and TPersistent instances.

When the ID=33 row is retrieved, the following JSON content is received from the server:

```
{"ID":33,
"FirstName":"Samuel Finley Breese32",
"LastName":"Morse",
"YearOfBirth":1791,
"YearOfDeath":1872,
"UTF8":["\32"],
"Persistent":{"\One":{"\Color":133,"\Length":33,"\Name":"33"},"Coll":[{"\Color":1032,"\L
ength":64,"\Name":"96"}]}}
```

In contradiction with POST content, this defines no valid nested JSON objects nor arrays, but UTF8 and Persistent fields transmitted as JSON strings. This is a known limitation of the framework, due to the fact that it is much faster to retrieve directly the text from the database than process for this operation. For an AJAX application, this won't be difficult to use a temporary string property, and evaluate the JSON content from it, in order to replace the property with a corresponding object content. Implementation may change in the future.

5.5.2.1.2.4. Any TObject, including TObjectList

Not only `TPersistent`, `TCollection` and `TSQLRecord` types can be serialized by writing all published properties. The ORM core of *mORMot* uses `ObjectToJSON()` and `JSONToObject()` (aka `TJSONSerializer.WriteObject`) functions to process proper JSON serialization.

You have two methods to register JSON serialization for any kind of class:

- Custom serialization via read and write callbacks - see `TJSONSerializer.RegisterCustomSerializer` below (page 307);
- `TObjectList` instances, after a proper call to `TJSONSerializer.RegisterClassForJSON` below (page 310).

In the database, such kind of objects will be stored as TEXT (serialized as JSON), and transmitted as regular JSON objects or arrays when working in Client-Server mode.

5.5.2.1.2.5. Sharding on NoSQL engines

This "Shared nothing architecture" matches perfectly with the *NoSQL and Object-Document Mapping (ODM)* (page 96) design.

In fact, *mORMot*'s integration with *MongoDB* has been optimized so that any of those high-level properties (like dynamic arrays, variants and *TDocVariant*, or any class) will be stored as BSON documents on the *MongoDB* server.

If those types are able to be serialized as JSON - which is the case for simple types, variants and for any dynamic array / record custom types - see below (page 304), then the *mORMotDB.pas* unit will store this data as BSON objects or arrays on the server side, and not as BLOB or JSON text (as with SQL back-ends). You will be able to query by name any nested sub-document or sub-array, in the *MongoDB* collection.

As such, *data sharing* with *mORMot* will benefit of RDBMS back-end, as a reliable and proven solution, but also of the latest *NoSQL* technology.

5.5.2.2. ORM implementation via pivot table

Data sharding just feels natural, from the ORM point of view.

But defining a pivot table is a classic and powerful use of relational database, and will unleash its power:

- When data is huge, you can query only for the needed data, without having to load the whole content (it is something similar to *lazy loading* in ORM terminology);
- In a master/detail data model, sometimes it can be handy to access directly to the detail records, e.g. for data consolidation;
- And, last but not least, the pivot table is the natural way of storing data associated with "has many through" relationship (e.g. association time or corresponding permissions).

5.5.2.2.1. Introducing TSQLRecordMany

A dedicated class, inheriting from the standard `TSQLRecord` class (which is the base of all objects stored in our ORM), has been created, named `TSQLRecordMany`. This table will turn the "many to many" relationship into two "one to many" relationships pointing in opposite directions. It shall contain at least two `TSQLRecord` (i.e. `INTEGER`) published properties, named "Source" and "Dest" (name is mandatory, because the ORM will share for exact matches). The first pointing to the source record (the one with a `TSQLRecordMany` published property) and the second to the destination record.

For instance:

```

TSQLDest = class(TSQLRecord);
TSQLSource = class;
TSQLDestPivot = class(TSQLRecordMany)
private
  fSource: TSQLSource;
  fDest: TSQLDest;
  fTime: TDateTime;
published
  property Source: TSQLSource read fSource; // map Source column
  property Dest: TSQLDest read fDest; // map Dest column
  property AssociationTime: TDateTime read fTime write fTime;
end;
TSQLSource = class(TSQLRecordSigned)
private
  fDestList: TSQLDestPivot;
published
  property SignatureTime;
  property Signature;
  property DestList: TSQLDestPivot read fDestList;
end;
TSQLDest = class(TSQLRecordSigned)
published
  property SignatureTime;
  property Signature;
end;

```

When a TSQLRecordMany published property exists in a TSQLRecord, it is initialized automatically during TSQLRecord.Create constructor execution into a real class instance. Note that the default behavior for a TSQLRecord published property is to contain an INTEGER value which is the ID of the corresponding record - creating a "one to one" or "many to one" relationship. But TSQLRecordMany is a special case. So don't be confused! :)

This TSQLRecordMany instance is indeed available to access directly the pivot table records, via FillMany then FillRow, FillOne and FillRewind methods to loop through records, or FillManyFromDest / DestGetJoined for most advanced usage.

Here is how the regression tests are written in the SynSelfTests unit:

```

procedure TestMany(aClient: TSQLRestClient);
var MS: TSQLSource;
    MD, MD2: TSQLDest;
    i: integer;
    sID, dID: array[1..100] of Integer;
    res: TIntegerDynArray;
begin
  MS := TSQLSource.Create;
  MD := TSQLDest.Create;
  try
    MD.fSignatureTime := TimeLogNow;
    MS.fSignatureTime := MD.fSignatureTime;
    Check(MS.DestList<>nil);
    Check(MS.DestList.InheritsFrom(TSQLRecordMany));
    aClient.TransactionBegin(TSQLSource); // faster process

```

This code will create two TSQLSource / TSQLDest instances, then will begin a transaction (for faster database engine process, since there will be multiple records added at once). Note that during TSQLSource.Create execution, the presence of a TSQLRecordMany field is detected, and the DestList property is filled with an instance of TSQLDestPivot. This DestList property is therefore able to be directly used via the "has-many" dedicated methods, like ManyAdd.

```

  for i := 1 to high(dID) do
  begin
    MD.fSignature := FormatUTF8('% %',[aClient.ClassName,i]);
    dID[i] := aClient.Add(MD,true);
    Check(dID[i]>0);

```

```
end;
```

This will just add some rows to the Dest table.

```
for i := 1 to high(sID) do begin
  MS.fSignature := FormatUTF8('% %',[aClient.ClassName,i]);
  sID[i] := aClient.Add(MS,True);
  Check(sID[i]>0);
  MS.DestList.AssociationTime := i;
  Check(MS.DestList.ManyAdd(aClient,sID[i],dID[i])); // associate both lists
  Check(not MS.DestList.ManyAdd(aClient,sID[i],dID[i],true)); // no dup
end;
aClient.Commit;
```

This will create some Source rows, and will call the ManyAdd method of the auto-created DestList instance to associate a Dest item to the Source item. The AssociationTime field of the DestList instance is set, to implement a "has many through" relationship.

Then the transaction is committed to the database.

```
for i := 1 to high(dID) do
begin
  Check(MS.DestList.SourceGet(aClient,dID[i],res));
  if not Check(length(res)=1) then
    Check(res[0]=sID[i]);
  Check(MS.DestList.ManySelect(aClient,sID[i],dID[i]));
  Check(MS.DestList.AssociationTime=i);
end;
```

This code will validate the association of Source and Dest tables, using the dedicated SourceGet method to retrieve all Source items IDs associated to the specified Dest ID, i.e. one item, matching the sID[] values. It will also check for the AssociationTime as set for the "has many through" relationship.

```
for i := 1 to high(sID) do
begin
  Check(MS.DestList.DestGet(aClient,sID[i],res));
  if Check(length(res)=1) then
    continue; // avoid GPF
  Check(res[0]=dID[i]);
```

The DestGet method retrieves all Dest items IDs associated to the specified Source ID, i.e. one item, matching the dID[] values.

```
Check(MS.DestList.FillMany(aClient,sID[i])=1);
```

This will fill prepare the DestList instance with all pivot table instances matching the specified Source ID. It should return only one item.

```
Check(MS.DestList.FillOne);
Check(Integer(MS.DestList.Source)=sID[i]);
Check(Integer(MS.DestList.Dest)=dID[i]);
Check(MS.DestList.AssociationTime=i);
Check(not MS.DestList.FillOne);
```

Those lines will fill the first (and unique) prepared item, and check that Source, Dest and AssociationTime properties match the expected values. Then the next call to FillOne should fail, since only one prepared row is expected for this Source ID.

```
Check(MS.DestList.DestGetJoined(aClient,'',sID[i],res));
if not Check(length(res)=1) then
  Check(res[0]=dID[i]);
```

This will retrieve all Dest items IDs associated to the specified Source ID, with no additional WHERE condition.

```
Check(MS.DestList.DestGetJoined(aClient,'Dest.SignatureTime=(0):',sID[i],res));
```

```
Check(length(res)=0);
```

This will retrieve all Dest items IDs associated to the specified Source ID, with an additional always invalid WHERE condition. It should always return no item in the res array, since SignatureTime is never equal to 0.

```
Check(MS.DestList.DestGetJoined(aClient,  
  FormatUTF8('Dest.SignatureTime=?',[MD.SignatureTime]),sID[i],res));  
if Check(length(res)=1) then  
  continue; // avoid GPF  
Check(res[0]=dID[i]);
```

This will retrieve all Dest items IDs associated to the specified Source ID, with an additional WHERE condition, matching the expected value. It should therefore return one item.

Note the call of the global FormatUTF8() function to get the WHERE clause. You may have written instead:

```
Check(MS.DestList.DestGetJoined(aClient,  
  'Dest.SignatureTime=(' + Int64ToUTF8(MD.SignatureTime) + '):',sID[i],res));
```

But in this case, using manual inlined :(..): values is less convenient than the '?' calling convention, especially for string (RawUTF8) values.

```
MD2 := MS.DestList.DestGetJoined(aClient,  
  FormatUTF8('Dest.SignatureTime=?',[MD.SignatureTime]),sID[i]) as TSQLADest;  
if Check(MD2<>nil) then  
  continue;  
try  
  Check(MD2.FillOne);  
  Check(MD2.ID=dID[i]);  
  Check(MD2.Signature=FormatUTF8('% %',[aClient.ClassName,i]));  
finally  
  MD2.Free;  
end;  
end;
```

This overloaded DestGetJoined method will return into MD2 a TSQLADest instance, prepared with all the Dest record content associated to the specified Source ID, with an additional WHERE condition, matching the expected value. Then FillOne will retrieve the first (and unique) matching Dest record, and checks for its values.

```
aClient.TransactionBegin(TSQLADests); // faster process  
for i := 1 to high(sID) shr 2 do  
  Check(MS.DestList.ManyDelete(aClient,sID[i*4],dID[i*4]));  
aClient.Commit;  
for i := 1 to high(sID) do  
  if i and 3<>0 then  
    begin  
      Check(MS.DestList.ManySelect(aClient,sID[i],dID[i]));  
      Check(MS.DestList.AssociationTime=i);  
    end else  
      Check(not MS.DestList.ManySelect(aClient,sID[i],dID[i]));
```

This code will delete one association per four, and ensure that ManySelect will retrieve only expected associations.

```
finally  
  MD.Free;  
  MS.Free;  
end;
```

This will release associated memory, and also the instance of TSQLDestPivot created in the DestList property.

5.5.2.2.2. Automatic JOIN query

All those methods (`ManySelect`, `DestGetJoined...`) are used to retrieve the relations between tables from the pivot table point of view. This saves bandwidth, and can be used in most simple cases, but it is not the only way to perform requests on many-to-many relationships. And you may have several `TSQLRecordMany` instances in the same main record - in this case, those methods won't help you.

It is very common, in the SQL world, to create a JOINed request at the main "*Source*" table level, and combine records from two or more tables in a database. It creates a set that can be saved as a table or used as is. A JOIN is a means for combining fields from two or more tables by using values common to each. Writing such JOINed statements is not so easy by hand, especially because you'll have to work with several tables, and have to specify the exact fields to be retrieved; if you have several pivot tables, it may start to be a nightmare. Let's see how our ORM will handle it.

A dedicated `FillPrepareMany` method has been added to the `TSQLRecord` class, in conjunction with a new constructor named `CreateAndFillPrepareMany`. This particular method will:

- Instantiate all `Dest` properties of each `TSQLRecordMany` instances - so that the JOINed request will be able to populate directly those values;
- Create the appropriate `SELECT` statement, with an optional `WHERE` clause.

Here is the test included in our regression suite, working with the same database:

```
Check(MS.FillPrepareMany(aClient,  
'DestList.Dest.SignatureTime<>% and id>=? and DestList.AssociationTime<>0 '+  
'and SignatureTime=DestList.Dest.SignatureTime '+  
'and DestList.Dest.Signature<>"DestList.AssociationTime"', [0], [sID[1]]));
```

Of course, the only useful parameter here is `id>=?` which is used to retrieve the just added relationships in the pivot table. All other conditions will always be true, but it will help testing the generated SQL.

Our *mORMot* will generate the following SQL statement:

```
select A.ID AID,A.SignatureTime A00,A.Signature A01,  
       B.ID BID,B.AssociationTime B02,  
       C.ID CID,C.SignatureTime C00,C.Signature C01  
from ASource A,ADests B,ADest C  
where B.Source=A.ID and B.Dest=C.ID  
      and (C.SignatureTime<>0 and A.id>=: (1): and B.AssociationTime<>0  
      and A.SignatureTime=C.SignatureTime and C.Signature<>"DestList.AssociationTime")
```

You can notice the following:

- All declared `TSQLRecordMany` instances (renamed B in our case) are included in the statement, with all corresponding `Dest` instances (renamed as C);
- Fields are aliased with short unique identifiers (AID, A01, BID, B02...), for all *simple* properties of every classes;
- The JOIN clause is created (`B.Source=A.ID and B.Dest=C.ID`);
- Our manual `WHERE` clause has been translated into proper SQL, including the table internal aliases (A,B,C) - in fact, `DestList.Dest` has been replaced by C, the main ID property has been declared properly as A.ID, and the "`DestList.AssociationTime`" text remained untouched, because it was bounded with quotes.

That is, our ORM did make all the dirty work for you! You can use *Delphi*-level conditions in your query, and the engine will transparently convert them into a valid SQL statement. Benefit of this will become clear in case of multiple pivot tables, which are likely to occur in real-world applications.

After the statement has been prepared, you can use the standard `FillOne` method to loop through all

returned rows of data, and access to the JOINED columns within the *Delphi* objects instances:

```
Check(MS.FillTable.RowCount=length(sID));  
for i := 1 to high(sID) do begin  
  MS.FillOne;  
  Check(MS.fID=sID[i]);  
  Check(MS.SignatureTime=MD.fSignatureTime);  
  Check(MS.DestList.AssociationTime=i);  
  Check(MS.DestList.Dest.fID=dID[i]);  
  Check(MS.DestList.Dest.SignatureTime=MD.fSignatureTime);  
  Check(MS.DestList.Dest.Signature=FormatUTF8('% %',[aClient.ClassName,i]));  
end;  
MS.FillClose;
```

Note that in our case, an explicit call to `FillClose` has been added in order to release all `Dest` instances created in `FillPrepareMany`. This call is not mandatory if you call `MS.Free` directly, but it is required if the same `MS` instance is about to use some regular many-to-many methods, like `MS.DestList.ManySelect()` - it will prevent any GPF exception to occur with code expecting the `Dest` property not to be an instance, but a pointer(`DestID`) value.

5.6. ORM Data Model

5.6.1. Creating an ORM Model

The `TSQLModel` class centralizes all `TSQLRecord` inherited classes used by an application, both database-related and business-logic related.

In order to follow the MVC pattern, the `TSQLModel` instance is to be used when you have to deal at table level. For instance, do not try to use low-level `TSQLDataBase.GetTableNames` or `TSQLDataBase.GetFieldNames` methods in your code. In fact, the tables declared in the Model may not be available in the *SQLite3* database schema, but may have been defined as `TSQLRestStorageInMemory` instance via the `TSQLRestServer.StaticDataCreate` method, or being external tables - see below (page 240). You could even have a mORMot server running without any *SQLite3* engine at all, but pure in-memory tables!

Each `TSQLModel` instance is in fact associated with a `TSQLRest` instance. An `Owner` property gives access to the current running client or server `TSQLRest` instance associated with this model.

By design, models are used on both Client and Server sides. It is therefore a good practice to use a common unit to define all `TSQLRecord` types, and have a common function to create the related `TSQLModel` class.

For instance, here is the corresponding function as defined in the first samples available in the source code repository (`unit SampleData.pas`):

```
function CreateSampleModel: TSQLModel;  
begin  
  result := TSQLModel.Create([TSQLSampleRecord]);  
end;
```

For a more complex model including link to User Interface, see below (page 505).

5.6.2. Several Models

In practice, a same `TSQLRecord` can be used in several models: this is typically the case for `TSQLAuthUser` tables, or if client and server instances are running in the same process. So, for accessing the model properties, you have two structures available:

Class	Description
<code>TSQLModelRecordProperties</code>	Model-specific ORM parameters, like dedicated SQL auto-generation and external DB settings. Access these instances from <code>TSQLModel.TableProps[]</code> array
<code>TSQLRecordProperties</code>	Low-level table properties, as retrieved from below (page 504) by the ORM kernel of <i>mORMot</i> . Access these instances from <code>TSQLModel.TableProps[].Props</code>

So you may use code like this:

```
var i: integer;  
    ModelProps: TSQLModelRecordProperties;  
    Props: TSQLRecordProperties;  
begin  
  ...  
  for i := 0 to high(Model.TableProps) do begin
```

```
ModelProps := Model.TableProps[i];  
// now you can access ModelProps.ExternalDB.TableName ...  
Props := ModelProps.Props;  
// now you can use Props.SQLTableName or Props.Fields[]  
end;  
end;
```

5.6.3. Filtering and Validating

According to the n-Tier architecture - see *Multi-tier architecture* (page 88) - data filtering and validation should be implemented in the business logic, not in the User Interface.

If you were used to develop RAD database application using *Delphi*, you may have to change a bit your habits here. Data filtering and validation should be implemented not in the User Interface, but in pure *Delphi* code.

In order to make this easy, a dedicated set of classes are available in the `SynCommons.pas` unit, and allow to define both filtering (transformation) and validation. They all will be children of any of those both classes:

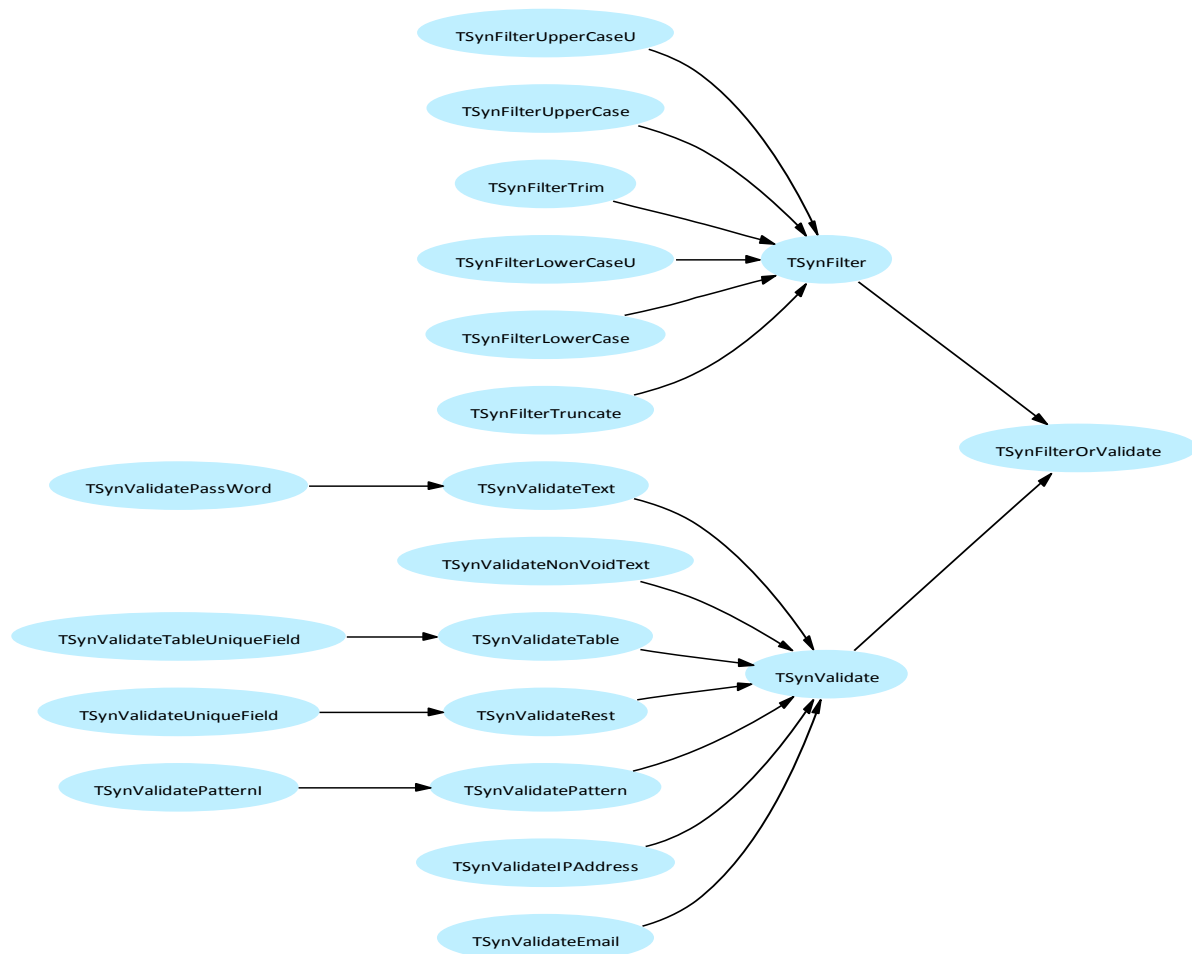

Filtering and Validation classes hierarchy

TSQLRecord field content *filtering* is handled in the TSQLRecord. Filter virtual method, or via some TSQLFilter classes. They will *transform* the object fields following some rules, e.g. forcing uppercase/lowercase, or trimming text spaces.

TSQLRecord field content *validation* is handled in the TSQLRecord. Validate virtual method, or via some TSQLValidate classes. Here the object fields will be checked against a set of rules, and report any invalid content.

Some "standard" classes are already defined in the `SynCommons.pas` and `mORMot.pas` units, covering most common usage:

Default filters and Validation classes hierarchy

You have powerful validation classes for IP Address, Email (with TLD+domain name), simple *regex* pattern, textual validation, strong password validation...

Note that some database-related validation is existing, like `TSynValidateUniqueField` which inherits from `TSynValidateRest`.

Of course, the `mORMotUIEdit` unit handles `TSQLRecord` automated filtering (using `TSQLFilter` classes) and validation (via the `TSQLValidate` classes).

The field validation process is run in `TSQLRecord`. `Validate` and not in `mORMotUIEdit` itself (to have a better multi-tier architecture).

To initialize it, you can add some filters/validators to your `TSQLModel` creation function:

```

function CreateFileModel(Owner: TSQLRest): TSQLModel;
begin
  result := TSQLModel.Create(Owner,
    @FileTabs, length(FileTabs), sizeof(FileTabs[0]), [],
    TypeInfo(TFileAction), TypeInfo(TFileEvent), 'synfile');
  TSQLFile.AddFilterOrValidate('Name', TSQLFilterLowerCase);
  TSQLUser.AddFilterOrValidate('Email', TSQLValidateEmail);
end;

```

As an alternative, you can override the following method:

```

TSQLRecordAuthInfo = class(TSQLRecord)
protected

```

```
class procedure InternalDefineModel(Props: TSQLRecordProperties); override;
...

class procedure TSQLRecordAuthInfo.InternalDefineModel(
  Props: TSQLRecordProperties);
begin
  AddFilterNotVoidText(['Logon','HashedPassword']);
end;
```

It does make sense to define this behavior within the TSQLRecord definition, so that it will be shared by all models.

If you want to perform some text field length validation or filter at ORM level, you may use TSQLRecordProperties's SetMaxLengthValidatorForTextFields() or SetMaxLengthFilterForTextFields() method, or at model level:

```
function CreateModel: TSQLModel;
begin
  result := TSQLModel.Create([TSQLMyRecord1,TSQLMyRecord2]);
  result.SetMaxLengthValidatorForAllTextFields(true); // "index n" is in UTF-8 bytes
end;
```

In order to perform the filtering (transformation) of some content, you'll have to call the aRecord.Filter() method, and aRecord.Validate() to test for valid content.

For instance, this is how mORMotUIEdit.pas unit filters and validates the user interface input:

```
procedure TRecordEditForm.BtnSaveClick(Sender: TObject);
(...)
// perform all registered filtering
Rec.Filter(ModifiedFields);
// perform content validation
FieldIndex := -1;
ErrMsg := Rec.Validate(Client,ModifiedFields,@FieldIndex);
if ErrMsg<>'' then begin
  // invalid field content -> show message, focus component and abort saving
  if cardinal(FieldIndex)<cardinal(length(fFieldComponents)) then begin
    C := fFieldComponents[FieldIndex];
    C.SetFocus;
    Application.ProcessMessages;
    ShowMessage(ErrMsg,format(sInvalidFieldN,[fFieldCaption[FieldIndex]]),true);
  end else
    ShowMessage(ErrMsg,format(sInvalidFieldN,['?']),true);
  end else
  // close window on success
  ModalResult := mrOk;
end;
```

It is up to your code to filter and validate the record content. By default, the mORMot CRUD operations won't call the registered filters or validators.

5.7. ORM Cache

Here is the definition of "cache", as stated by Wikipedia:

In computer engineering, a cache is a component that transparently stores data so that future requests for that data can be served faster. The data that is stored within a cache might be values that have been computed earlier or duplicates of original values that are stored elsewhere. If requested data is contained in the cache (cache hit), this request can be served by simply reading the cache, which is comparatively faster. Otherwise (cache miss), the data has to be recomputed or fetched from its original storage location, which is comparatively slower. Hence, the greater the number of requests that can be served from the cache, the faster the overall system performance becomes.

To be cost efficient and to enable an efficient use of data, caches are relatively small. Nevertheless, caches have proven themselves in many areas of computing because access patterns in typical computer applications have locality of reference. References exhibit temporal locality if data is requested again that has been recently requested already. References exhibit spatial locality if data is requested that is physically stored close to data that has been requested already.

In our ORM framework, since performance was one of our goals since the beginning, cache has been implemented at four levels:

- Statement cache for implementing SQL prepared statements, and parameters bound on the fly - see *Query parameters* (page 145) and below (page 213) - note that this cache is available not only for the *SQLite3* database engine, but also for any external engine - see below (page 240);
- Global JSON result cache at the database level, which is flushed globally on any INSERT / UPDATE - see below (page 318);
- Tuned record cache at the CRUD/RESTful level for specified tables or records on the *server* side - see below (page 360);
- Tuned record cache at the CRUD/RESTful level for specified tables or records on the *client* side - see below (page 360).

Thanks to those specific caching abilities, our framework is able to minimize the number of client-server requests, therefore spare bandwidth and network access, and scales well in a concurrent rich client access architecture. In such perspective, a Client-Server ORM does make sense, and is of huge benefit in comparison to a basic ORM used only for data persistence and automated SQL generation.

5.8. Calculated fields

It is often useful to handle some calculated fields. That is, having some field values computed when you set another field value. For instance, if you set an error code from an enumeration (stored in an INTEGER field), you may want the corresponding text (to be stored on a TEXT field). Or you may want a total amount to be computed automatically from some detailed records.

This should not be done on the Server side. In fact, the framework expects the transmitted JSON transmitted from client to be set directly to the database layer, as stated by this code from the mORMotSQLite3 unit:

```
function TSQLRestServerDB.EngineUpdate(Table: TSQLRecordClass; ID: TID;
  const SentData: RawUTF8): boolean;
begin
  if (self=nil) or (Table=nil) or (ID<=0) then
    result := false else begin
      // this SQL statement use :(inlined params): for all values
      result := ExecuteFmt('UPDATE % SET % WHERE RowID=:(%);',
        [Table.RecordProps.SQLTableName, GetJSONObjectAsSQL(SentData, true, true), ID]);
      if Assigned(OnUpdateEvent) then
        OnUpdateEvent(self, seUpdate, Table, ID);
    end;
end;
```

The direct conversion from the received JSON content into the SQL UPDATE statement values is performed very quickly via the GetJSONObjectAsSQL procedure. It won't use any intermediary TSQLRecord, so there will be no server-side field calculation possible.

Record-level calculated fields should be done on the Client side, using some setters.

There are at least three ways of updating field values before sending to the server:

- Either by using some dedicated setters method for TSQLRecord properties;
- Or by overriding the ComputeFieldsBeforeWrite virtual method of TSQLRecord.
- If the computed fields need a more complex implementation (e.g. if some properties of another record should be modified), a dedicated RESTful service should be implemented - see below (page 373).

5.8.1. Setter for TSQLRecord

For instance, here we define a new table named *INVOICE*, with only two fields. A dynamic array containing the invoice details, then a field with the total amount. The dynamic array property will be stored as BLOB into the database, and no additional Master/Detail table will be necessary.

```
type
  TInvoiceRec = record
    Ident: RawUTF8;
    Amount: currency;
  end;
  TInvoiceRecs = array of TInvoiceRec;
  TSQLInvoice = class(TSQLRecord)
  protected
    fDetails: TInvoiceRecs;
    fTotal: Currency;
  procedure SetDetails(const Value: TInvoiceRecs);
  published
    property Details: TInvoiceRecs read fDetails write SetDetails;
    property Total: Currency read fTotal;
  end;
```

Note that the Total property does not have any *setter* (aka write statement). So it will be read-only,

from the ORM point of view. In fact, the following protected method will compute the Total property content from the Details property values, when they will be modified:

```
procedure TSQLInvoice.SetDetails(const Value: TInvoiceRecs);
var i: integer;
begin
  fDetails := Value;
  fTotal := 0;
  for i := 0 to high(Value) do
    fTotal := fTotal+Value[i].Amount;
  end;
```

When the object content will be sent to the Server, the Total value of the JSON content sent will contain the expected value.

Note that with this implementation, the SetDetails must be called explicitly. That is, you should *not* only modify directly the Details[] array content, but either use a temporary array during edition then assign its value to Invoice.Details, or force the update with a line of code like:

```
Invoice.Details := Invoice.Details; // force Total calculation
```

5.8.2. TSQLRecord.ComputeFieldsBeforeWrite

Even if a TSQLRecord instance should not normally have access to the TSQLRest level, according to OOP principles, the following virtual method have been defined:

```
TSQLRecord = class(TObject)
public
  procedure ComputeFieldsBeforeWrite(aRest: TSQLRest; aOccasion: TSQLEvent); virtual;
  (...)
```

It will be called automatically on the Client side, just before a TSQLRecord content will be sent to the remote server, before adding or update.

In fact, the TSQLRestClientURI.Add / Update / BatchAdd / BatchUpdate methods will call this method before calling TSQLRecord.GetJSONValues and send the JSON content to the server.

On the Server-side, in case of some business logic involving the ORM, the TSQLRestServer.Add / Update methods will also call ComputeFieldsBeforeWrite.

By default, this method will compute the TModTime / sftModTime and TCreateTime / sftCreateTime properties value from the current server time stamp, as such:

```
procedure TSQLRecord.ComputeFieldsBeforeWrite(aRest: TSQLRest; aOccasion: TSQLEvent);
var F: integer;
begin
  if (self<>nil) and (aRest<>nil) then
    with RecordProps do begin
      if HasModTimeFields then
        for F := 0 to high(FieldType) do
          if FieldType[F]=sftModTime then
            SetInt64Prop(Self,Fields[F],aRest.ServerTimestamp);
      if HasCreateTimeField and (aOccasion=seAdd) then
        for F := 0 to high(FieldType) do
          if FieldType[F]=sftCreateTime then
            SetInt64Prop(Self,Fields[F],aRest.ServerTimestamp);
    end;
end;
```

You may override this method for you own purpose, saved the fact that you call this inherited implementation to properly handle TModTime and TCreateTime published properties.

5.9. Audit Trail for change tracking

Since most CRUD operations are centered within the scope of our *mORMot* server, we implemented in the ORM an integrated mean of tracking changes (aka Audit Trail) of any TSQLRecord.

Keeping a track of the history of business objects is one very common need for software modeling, and a must-have for any accurate data modeling, like *Domain-Driven Design* (page 99). By default, as expected by the OOP model, any change to an object will forget any previous state of this object. But thanks to *mORMot*'s exclusive change-tracking feature, you can persist the history of your objects.

5.9.1. Enabling audit-trail

By default, change-tracking feature will be disabled, saving performance and disk use. But you can enable change tracking for any class, by calling the following method, on server side:

```
aServer.TrackChanges([TSQLInvoice]);
```

This single line will let aServer: TSQLRestServer monitor all CRUD operations, and store all changes of the TSQLInvoice table within a TSQLRecordHistory table.

Since all content changes will be stored in this single table by default (note that the TrackChanges() method accepts an *array of classes* as parameters, and can be called several times), it may be handy to define several tables for history storage. Later on, an external database engine may be defined to store history, e.g. on cheap hardware (and big hard drives), whereas your main database may be powered by high-end hardware (and smaller SSDs) - see below (page 240).

To do so, you define your custom class for history storage, then supply it as parameter:

```
type
  TSQLRecordSecondaryHistory = class(TSQLRecordHistory);
  (...)
  aServer.TrackChanges([TSQLInvoice], TSQLRecordSecondaryHistory);
```

Then, all history will be stored in this TSQLRecordSecondaryHistory class (in its own table named SecondaryHistory), and not the default TSQLRecordHistory class (in its History table).

5.9.2. A true Time Machine for your objects

Once the object changes are tracked, you can later on browse the history of the object, by using the TSQLRecordHistory.CreateHistory(), then HistoryGetLast, HistoryCount, and HistoryGet() methods:

```
var aHist: TSQLRecordHistory;
    aInvoice: TSQLInvoice;
    aEvent: TSQLHistoryEvent; // will be either heAdd, heUpdate or heDelete
    aTimestamp: TModTime;
  (...)
  aInvoice := TSQLInvoice.Create;
  aHist := TSQLRecordHistory.CreateHistory(aClient, TSQLInvoice, 400);
  try
    writeln('Number of items in the record history: ', aHist.HistoryCount);
    for i := 0 to aHist.HistoryCount-1 do begin
      aHist.HistoryGet(i, aEvent, aTimestamp, aInvoice);
      writeln;
      writeln('Event: ', GetEnumName(TypeInfo(TSQLHistoryEvent), ord(aEvent))^);
      writeln('Timestamp: ', TTimeLogBits(aTimestamp).ToText);
      writeln('Identifier: ', aInvoice.Number);
      writeln('Value: ', aInvoice.GetJSONValues(true, true, soSelect));
    end;
  finally
    aHist.Free;
    aInvoice.Free;
```

end;

Note that you have several overloaded versions of `TSQLRecordHistory.HistoryGet()` to retrieve the record values.

As a result, our ORM is also transformed into a true *time machine*, for the objects which need it.

This feature will be available on both client and server sides, via the `TSQLRecordHistory` table.

5.9.3. Automatic history packing

This `TSQLRecordHistory` class will in fact create a `History` table in the main database, defined as such:

ID : TID
Event : TSQLHistoryEvent
History : TSQLRawBlob
ModifiedRecord : PtrInt
SentDataJSON : RawUTF8
Timestamp : TModTime

History Record Layout

In short, any modification via the ORM will be stored in the `TSQLRecordHistory` table, as a JSON object of the changed fields, in `TSQLRecordHistory.SentDataJSON`.

By design, direct SQL changes are not handled. If you run some SQL statements like `DELETE FROM ...` or `UPDATE ... SET ...` within your application or from any external program, then the History table won't be updated.

In fact, the ORM does not set any DB trigger to track low-level changes: it will slow down the process, and void the *persistence agnosticism* paradigm we want to follow, e.g. allowing to use a NoSQL database like MongoDB.

When the history grows, the JSON content may become huge, and fill the disk space with a lot of duplicated content. In order to save disk space, when a record reaches a define number of JSON data rows, all this JSON content is gathered and compressed into a BLOB, in `TSQLRecordHistory.History`. You can force this packing process by calling `TSQLRestServer.TrackChangesFlush()` manually in your code. Calling this method will also have a welcome side effect: it will read the actual content of the record from the database, then add a fake `heUpdate` event in the history if the field values do not match the one computed from tracked changes, to ensure that the audit trail will be correct. As a consequence, history will become always synchronized with the actual data persisted in the database, even if external SQL did by-pass the CRUD methods of the ORM, via unsafe `DELETE FROM ...` or `UPDATE ... SET ...` statements.

You can tune how packing is defined for a given `TSQLRecord` table, by using some optional parameters to the registering method:

```
procedure TrackChanges(const aTable: array of TSQLRecordClass;
  aTableHistory: TSQLRecordHistoryClass=nil; aMaxHistoryRowBeforeBlob: integer=1000;
  aMaxHistoryRowPerRecord: integer=10; aMaxUncompressedBlobSize: integer=64*1024); virtual;
```

Take a look at the documentation of this method (or the comments in its declaration code) for further information.

Default options will let `TSQLRestServer.TrackChangesFlush()` be called after 1000 individual `TSQLRecordHistory.SentDataJSON` rows are stored, then will compress them into a BLOB once 10 JSON rows are available for a given record, ensuring that the uncompressed BLOB size for a single record won't use more than 64 KB of memory (but probably much less in the database, since it is

stored with very high compression rate).

5.10. Master/slave replication

As stated during *TSQLRecord fields definition* (page 131), the ORM is able to maintain a revision number for any TSQLRecord table, so that it the table may be easily synchronized remotely by another TSQLRestServer instance.

If you define a TRecordVersion published property, the ORM core will fill this field just before any write with a monotonically increasing revision number, and will take care of any deletion, so that those modifications may be replayed later on any other database.

This synchronization will work as a strict master/slave replication scheme, as a one-way on demand refresh of a replicated table. Each write operation on the master database on a given table may be easily reflected on one or several slave databases, with almost no speed nor storage size penalty.

In addition to this *on demand* synchronization, a real-time notification mechanism, using *WebSockets* communication - see below (page 445) - may be defined.

5.10.1. Enable synchronization

In order to enable this replication mechanism, you should define a TRecordVersion published property in the TSQLRecord class type definition:

```
TSQLRecordPeopleVersioned = class(TSQLRecordPeople)
protected
  fFirstName: RawUTF8;
  fLastName: RawUTF8;
  fVersion: TRecordVersion;
published
  property FirstName: RawUTF8 read fFirstName write fFirstName;
  property LastName: RawUTF8 read fLastName write fLastName;
  property Version: TRecordVersion read fVersion write fVersion;
end;
```

Only a single TRecordVersion field is allowed per TSQLRecord class - it will not mean anything to manage more than one field of this type.

Note that this field will be somewhat "hidden" to most ORM process: a regular TSQLRest.Retrieve won't fill this Version property, since it is an internal implementation detail. If you want to lookup its value, you will have to explicitly state its field name at retrieval. Any TRecordVersion is indeed considered as a "non simple field", just like BLOB fields, so will need explicit retrieval of its value.

In practice, any TSQLRest.Add and TSQLRest.Update on this TSQLRecordPeopleVersioned class will increase this Version revision number field, and a TSQLRest.Delete will populate an external TSQLRecordTableDelete table with the ID of the deleted record, associated with a TRecordVersion revision.

As consequences:

- The monotonic TRecordVersion number is shared at TSQLRestServer level, among all tables containing a TRecordVersion published field;
- The TSQLRecordTableDelete table should be part of the TSQLModel, in conjunction with TSQLRecordPeopleVersioned;
- If the TSQLRecordTableDelete table is not part of the TSQLModel, the TSQLRestServer will add it - but you should better make it explicitly appearing in the data model;
- A single TSQLRecordTableDelete table will maintain the list of all deleted data rows, of all tables containing a TRecordVersion published field;

- The TSQLRecordPeopleVersioned table appearance order in the TSQLModel will matter, since TSQLRecordTableDelete.ID will use this table index order in the database model to identify the table type of the deleted row - in a similar way to TRecordReference and TRecordReferenceToBeDeleted (page 139).

All the synchronization preparation will be taken care by the ORM kernel on its own, during any write operation. There is nothing particular to maintain or setup, in addition to this TRecordVersion field definition, and the global TSQLRecordTableDelete table.

5.10.2. From master to slave

To replicate this TSQLRecordPeopleVersioned table from another TSQLRestServer instance, just call the following method:

```
aServer.RecordVersionSynchronizeSlave(TSQLRecordPeopleVersioned,aClient);
```

This single line will request a remote server via a Client: TSQLRestClientURI connection (which may be over HTTP) for any pending modifications since its last call, then will fill the local aServer: TSQLRestServer database so that the local TSQLRecordPeopleVersioned table will contain the very same content as the remote master TSQLRestServer.

You can safely call TSQLRestServer.RecordVersionSynchronizeSlave from several clients, to replicate the master data in several databases.

Using a TTimer may increase responsiveness of a client application, and allow refresh of displayed data, with limited resources (e.g. with a 500 ms period, on a given screen).

Only the modified data will be transmitted over the wire, as two REST/JSON queries (one for the insertions/updates, another for the deletions), and all the local write process will use optimized BATCH writing - see below (page 351). This means that the synchronization process will try to use as minimal bandwidth and resources as possible, on both sides.

In practice, you may define the *Master* side as such:

```
MasterServer := TSQLRestServerDB.Create(MasterModel,'master.db3');  
HttpMasterServer := TSQLHttpServer.Create('8888',[MasterServer],'+',useBidirSocket);
```

On the *Slave* side, the HTTP client will access the *Master* database as usual:

```
MasterClient := TSQLHttpClientWebsockets.Create('127.0.0.1',HTTP_DEFAULTPORT,MasterModel);
```

Of course, the model should match for both MasterServer and MasterClient instances. This is why we used the same MasterModel variable name (probably defined in a shared unit).

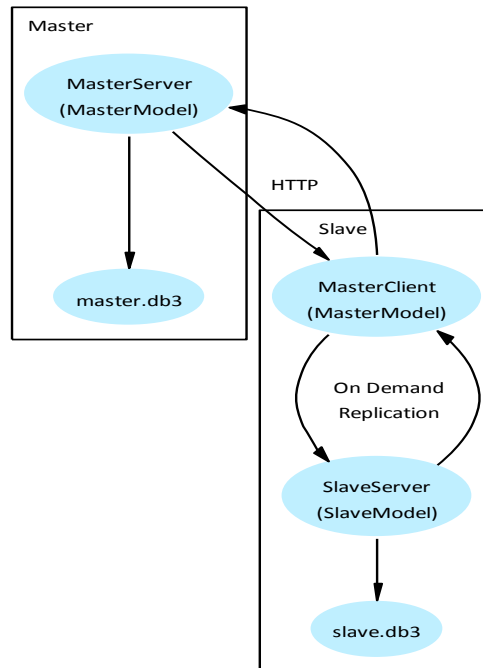

Assuming that the *slave* database has been defined as such:

```
SlaveServer := TSQLRestServerDB.Create(SlaveModel,'slave.db3');
```

Then you can run replication from the *slave* side with a single line, for a given table:

```
SlaveServer.RecordVersionSynchronizeSlave(TSQLRecordPeopleVersioned,MasterClient);
```

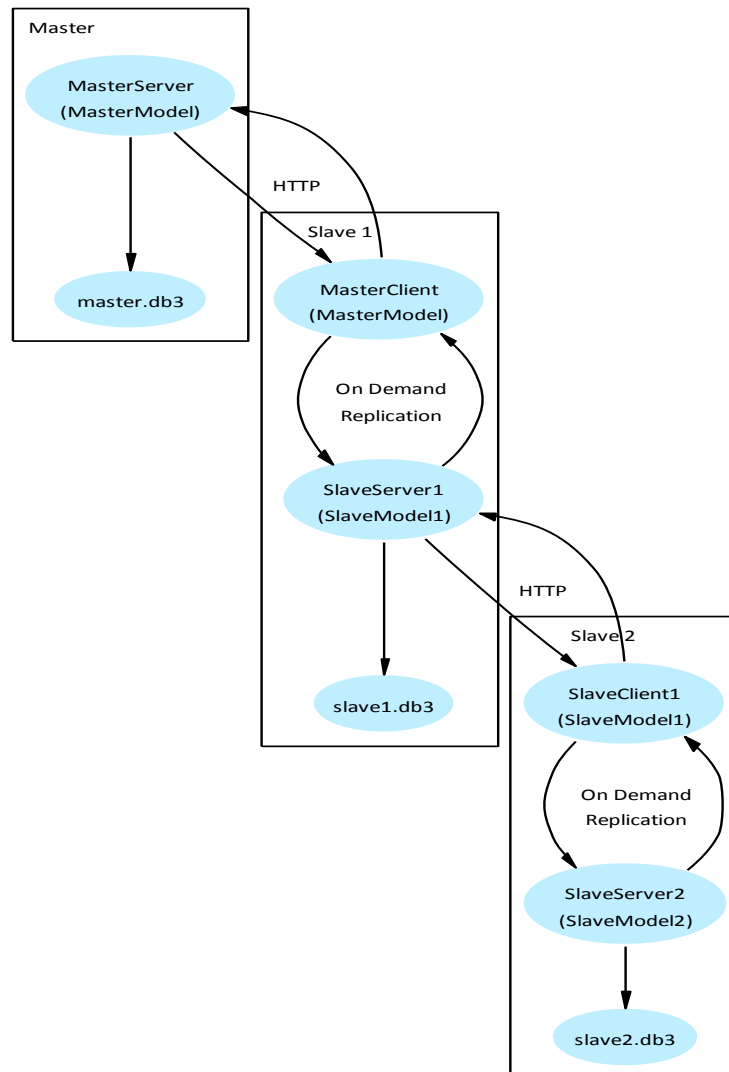

This command will process the replication as such:

ORM Replication Classes via REST

Of course, the slaves should be considered as read-only, otherwise the version numbers may conflict, and the whole synchronization may become a failure.

But you can safely replicate servers in cascade, if needed: the version numbers will be propagated from masters to slaves, and the data will always be in a consistent way.

ORM Cascaded Replication Classes via REST

This cascading Master/Slave replication design may be used in conjunction with the CQRS pattern (*Command Query Responsibility Segregation*). In fact, the *Slave 2* database may be a local read-only database instance, used only for reporting purposes, e.g. by marketing or management people, whereas the *Slave 1* may be the active read-only database, on which all local business process will read their data. As such, the *Slave 2* instance may be replicated much less often than than *Slave 1* database - which may be even be replicated in real time, as we will now see.

5.10.3. Real-time synchronization

Sometimes, the on-demand synchronization is not enough.

For instance, you may need to:

- Synchronize a short list of always evolving items which should be reflected as soon as possible;
- Involve some kind of ACID-like behavior (e.g. handle money!) in your replicated data;
- Replicate not from a GUI application, but from a service, so use of a TTimer is not an option;
- Combine REST requests (for ORM or services) and master/slave ORM replication on the same wire, e.g. in a multi-threaded application;

- Use an *Event Oriented Persistence*, and expect to be notified from any change of state - see below (page 623).

In this case, the framework is able to use *WebSockets* and asynchronous callbacks to let the master/slave replication - see below (page 445) - take place without the need to ask explicitly for pending data. You will need to use `TSQLEstServer.RecordVersionSynchronizeMasterStart`, `TSQLEstServer.RecordVersionSynchronizeSlaveStart` and `TSQLEstServer.RecordVersionSynchronizeSlaveStop` methods over the proper kind of bidirectional connection.

The first requirement is to allow *WebSockets* on your *Master* HTTP server, so initialize the `TSQLEstServer` class as a `useBidirSocket` kind of server - see below (page 326):

```
MasterServer := TSQLEstServerDB.Create(MasterModel, 'master.db3');  
HttpMasterServer := TSQLEstServer.Create('8888', [MasterServer], '+', useBidirSocket);  
HttpMasterServer.WebSocketsEnable(Server, 'PrivateAESEncryptionKey');
```

On the *Slave* side, the HTTP client should also be upgraded to support *WebSockets*:

```
MasterClient := TSQLEstClientWebsockets.Create('127.0.0.1', HTTP_DEFAULTPORT, MasterModel);  
MasterClient.WebSocketsUpgrade('PrivateAESEncryptionKey');
```

Of course, the model should match for both `MasterServer` and `MasterClient` instances. As the *WebSockets* protocol definition - here above the same 'PrivateAESEncryptionKey' private key.

Then you enable the real-time replication service on the *Master* side:

```
MasterServer.RecordVersionSynchronizeMasterStart;
```

In practice, it will publish a `IServiceRecordVersion` interface-based service on the server side - see below (page 420).

Assuming that the *slave* database has been defined as such:

```
SlaveServer := TSQLEstServerDB.Create(SlaveModel, 'slave.db3');
```

(in this case, the `SlaveModel` may not be the same as the `MasterModel`, but `TSQLEstRecordPeopleVersioned` should be part of both models)

Then you can initiate real-time replication from the *slave* side with a single line, for a given table:

```
SlaveServer.RecordVersionSynchronizeSlaveStart(TSQLEstRecordPeopleVersioned, MasterClient);
```

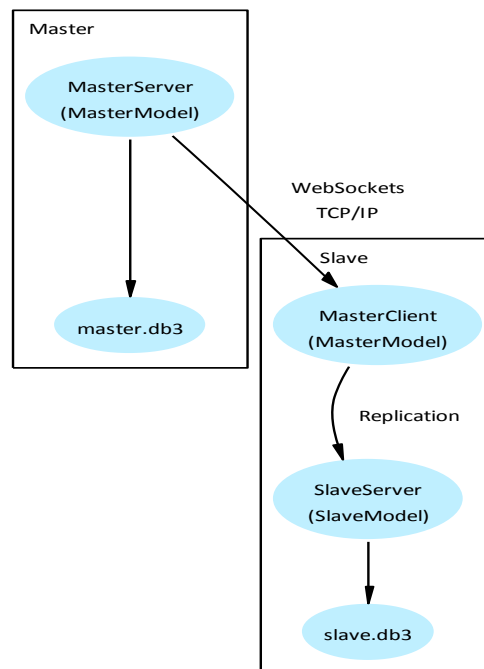

The above command will subscribe to the remote *MasterSlave* replication service (i.e. `IServiceRecordVersion` interface), to receive any change concerning the `TSQLEstRecordPeopleVersioned` ORM table, using the `MasterClient` connection via *WebSockets*, and persist all updates into the local `SlaveServer` database.

To stop the real-time notification for this ORM table, you could execute:

```
SlaveServer.RecordVersionSynchronizeSlaveStop(TSQLEstRecordPeopleVersioned);
```

Even if you do not call `RecordVersionSynchronizeSlaveStop()`, the replication will be stopped when the main `SlaveServer` instance will be released, and the `MasterServer` be *unsubscribe* this connection for its internal notification list.

This typical replication may be represented as such:

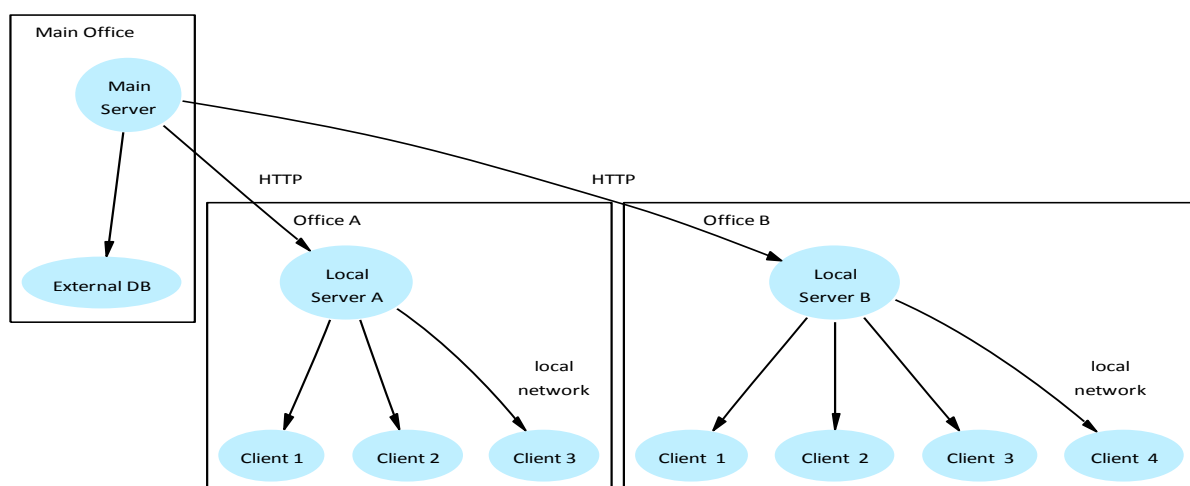

ORM Real-Time Replication Classes

The real-time notification details have been tuned, to consume as minimum bandwidth and resources as possible. For instance, if several modifications are to be notified on a slave connection in a short amount of time, the master is able to gather those modifications as a single *WebSockets* frame, which will be applied as a whole to the slave database, in a single BATCH transaction - see below (page 351).

5.10.4. Replication use cases

We may consider a very common corporate infrastructure:

Corporate Servers Replication

This kind of installation, with a main central office, and a network of local offices, will benefit from this master/slave replication. Simple *redirection* may be used - see below (page 234) - but it will expect the work to continue, even in case of *Internet* network failure. REST redirection will expect a 100%

connection up-link, which may be critical in some cases.

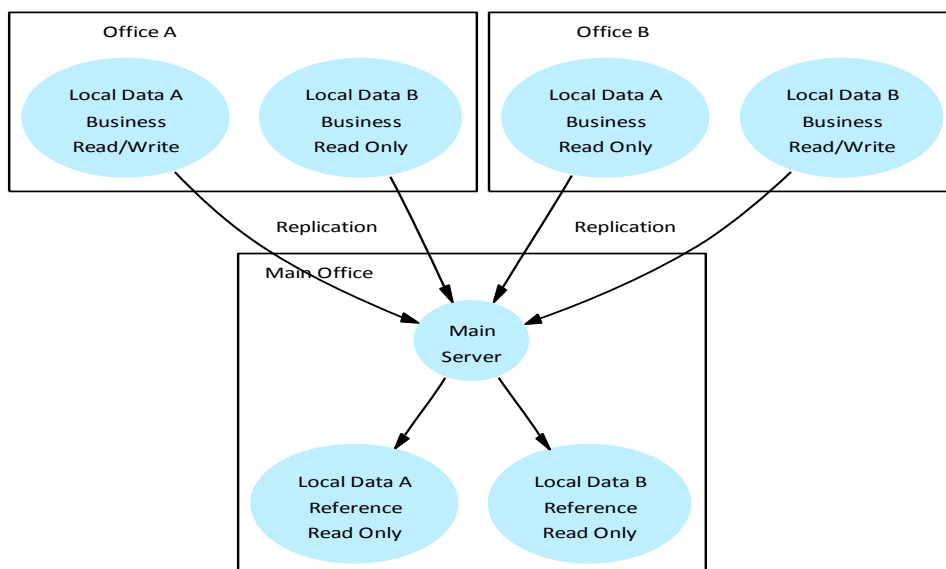

You could therefore implement replication in several ways:

- Either the main office is the master, and any write will be push to the *Main Server*, whereas local offices will have a replicated copy of the information - drawback is that in case of network failure, the local office will be limited to read only data access;

Corporate Servers Master/Slave Replication With All Data On Main Server

- Or each local office may host its own data in a dedicated table, synchronized as a master database; the main office will replicate (as a slave) the private data of each local server; in addition, all this data gathered by the *Main Server* may be further replicated to the other local offices, and be still accessible in read mode - in case of network failure, all the data is available on local servers, and the local private table is still writable.

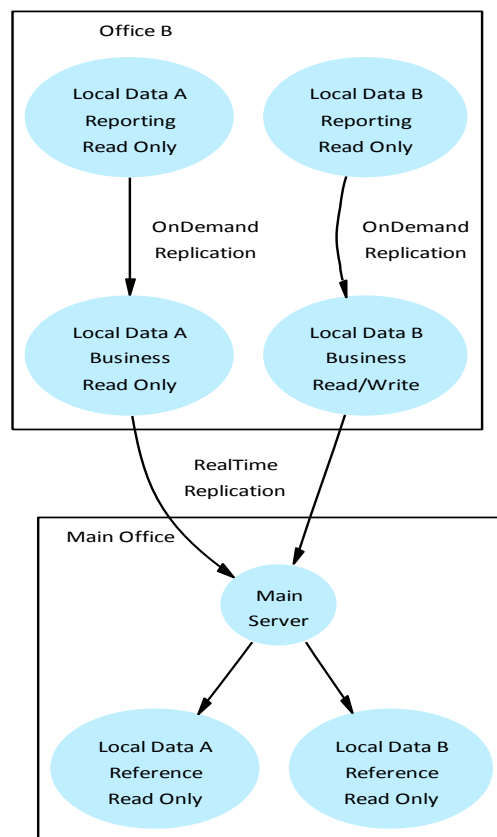

Corporate Servers Master/Slave Replication With Private Local Data

Of course, the second solution seems preferable, even if a bit more difficult to implement. The ability of all local offices to work offline on their own private data, but still having all the other data accessible as read-only, will be a huge ROI.

As a benefit of using replication, the central main server will be less stressed, since most of the process will take place in local servers, and the main office server will only be used for shared data backup and read-only gathering of the other local databases. Only a small network bandwidth will be necessary (much less than a pure web solution), and CPU/storage resources will be minimal.

If needed, the *Real-time synchronization* (page 183) will allow to have the main office data replicated in "near real-time" in the local offices databases, whereas the write operations will still safely take place on the main Office. Another cascading replication may take place within any node, with a on-demand refresh, e.g. a 1 hour period, to implement the CQRS pattern (*Command Query Responsibility Segregation*).

Corporate Servers Master/Slave Replication With CQRS

Following the CQRS pattern, some demanding Queries may take place in those read-only "Reporting" replicated databases, without impacting the main local databases, in which all actual "Business" will take place.

6. Daily ORM

Adopt a mORMot

When you compare ORM and standard SQL, some aspects must be highlighted.

First, you do not have to worry about field orders and names, and can use field completion in the IDE. It is much more convenient to type `Baby.` then select the `Name` property, and access to its value.

The ORM code is much more readable than the SQL. You do not have to switch your mind from one syntax to another, in your code. Because SQL is a true language (see *SQL Is A High-Level Scripting Language* at <http://www.fossil-scm.org/index.html/doc/tip/www/theory1.wiki..>). You can even forget about the SQL itself for most projects; only some performance-related or complex queries should be written in SQL, but you will avoid it most of the time. Think object pascal. And happy coding. Your software architecture will thank you for it.

Another good impact is the naming consistency. For example, what about if you want to rename your table? Just change the class definition, and your IDE will do all refactoring for you, without any risk of missing a hidden SQL statement anywhere. Do you want to rename or delete a field? Change the class definition, and the *Delphi* compiler will let you know all places where this property was used in your code. Do you want to add a field to an existing database? Just add the property definition, and the framework will create the missing field in the database schema for you.

Another risk-related improvement is about the strong type checking, included into the *Delphi* language during compile time, and only during execution time for the SQL. You will avoid most runtime exceptions for your database access: your clients will thank you for that. In one word, forget about field typing mismatch or wrong type assignment in your database tables. Strong typing is great in such cases for code SQA, and if you worked with some scripting languages (like *JavaScript*, *Python* or *Ruby*), you should have wished to have this feature in your project!

It is worth noting that our framework allows writing triggers and stored procedures (or like stored procedures) in *Delphi* code, and can create key indexing and perform foreign key checking in class definition.

Another interesting feature is the enhanced Grid component supplied with this framework, and the AJAX-ready orientation, by using natively JSON flows for Client-Server data streaming. The REST protocol can be used in most application, since the framework provides you with an easy to use "Refresh" and caching mechanism. You can even work off line, with a local database replication of the remote data.

For Client-Server - see below (page 296) - you do not have to open a connection to the database, just create an instance of a `TSQLRestClient` object (with the communication layer you want to use: direct access, Windows Messages, named pipe or HTTP), and use it as any normal *Delphi* object. All the SQL coding or communication and error handling will be done by the framework. The same code can be used in the Client or Server side: the parent `TSQLRest` object is available on both sides, and its properties and methods are strong enough to access the data.

6.1. ORM is not Database

It is worth emphasizing that you should not think about the ORM like a mapping of an existing DB schema. This is an usual mistake in ORM design.

The database is just one way of your objects persistence:

- Don't think about tables with simple types (text/number...), but objects with high level types;
- Don't think about Master/Detail, but logical units;
- Don't think "SQL", think about classes;
- Don't wonder "How will I store it?", but "Which data do I need?".

For instance, don't be tempted to always create a pivot table (via a `TSQLRecordMany` property), but consider using a *dynamic array*, `TPersistent`, `TStrings` or `TCollection` published properties instead.

Or consider that you can use a `TRecordReference` property pointing to any registered class of the `TSQLModel`, instead of creating one `TSQLRecord` property per potential table.

The *mORMot* framework is even able to persist the object without any SQL database, e.g. via `TSQLRestStorageInMemory`. In fact, its ORM core is optimized but not tied to SQL.

6.1.1. Objects, not tables

With an ORM, you should usually define fewer tables than in a "regular" relational database, because you can use the high-level type of the `TSQLRecord` properties to handle some per-row data.

The first point, which may be shocking for a database architect, is that you should better not create Master/Detail tables, but just one "master" object with the details stored within, as JSON, via *dynamic array*, `TPersistent`, `TStrings` or `TCollection` properties.

Another point is that a table is not to be created for every aspect of your software configuration. Let's confess that some DB architects design one configuration table per module or per data table. In an ORM, you could design a configuration class, then use the unique corresponding table to store all configuration encoded as some JSON data, or some DFM-like data. And do not hesitate to separate the configuration from the data, for all not data-related configuration - see e.g. how the `mORMotOptions` unit works. With our framework, you can serialize directly any `TSQLRecord` or

TPersistent instance into JSON, without the need of adding this TSQLRecord to the TSQLModel list. Since revision 1.13 of the framework, you can even define TPersistent published properties in your TSQLRecord class, and it will be automatically serialized as TEXT in the database.

6.1.2. Methods, not SQL

At first, you should be tempted to write code as such (this code sample was posted on our forum, and is not bad code, just not using the ORM orientation of the framework):

```
DrivesModel := CreateDrivesModel();
GlobalClient := TSQLRestClientDB.Create(DrivesModel, CreateDrivesModel(), 'drives.sqlite',
TSQLRestServerDB);
TSQLRestClientDB(GlobalClient).Server.DB.Execute(
  'CREATE TABLE IF NOT EXISTS drives ' +
  '(id INTEGER PRIMARY KEY, drive TEXT NOT NULL UNIQUE COLLATE NOCASE);');
for X := 'A' to 'Z' do
begin
  TSQLRestClientDB(GlobalClient).Server.DB.Execute(
    'INSERT OR IGNORE INTO drives (drive) VALUES (' + StringToUTF8(X) + ' :)');
end;
```

Please, don't do that!

The correct ORM-oriented implementation should be the following:

```
DrivesModel := TSQLModel.Create([TDrives], 'root');
GlobalClient := TMyClient.Create(DrivesModel, nil, 'drives.sqlite', TSQLRestServerDB);
GlobalClient.CreateMissingTables(0);
if GlobalClient.TableRowCount(TDrives)=0 then
begin
  D := TDrives.Create;
  try
    for X := 'A' to 'Z' do
    begin
      D.Drive := X;
      GlobalClient.Add(D,true);
    end;
  finally
    D.Free;
  end;
end;
```

In the above lines, no SQL was written. It is up to the ORM to:

- Create all missing tables, via the CreateMissingTables method - and not compute by hand a "CREATE TABLE IF NOT EXISTS..." SQL statement;
- Check if there is some rows of data, via the TableRowCount method - instead of a "SELECT COUNT(*) FROM DRIVES";
- Append some data using an high-level TDrives *Delphi* instance and the Add method - and not any "INSERT OR IGNORE INTO DRIVES..."

Then, in order to retrieve some data, you'll be tempted to code something like that (extracted from the same forum article):

```
procedure TMyClient.FillDrives(aList: TStrings);
var
  table: TSQLTableJSON;
  X, FieldIndex: Integer;
begin
  table := TSQLRestClientDB(GlobalClient).ExecuteList([TSQLDrives], 'SELECT * FROM drives');
  if (table <> nil) then
  try
    FieldIndex := table.FieldIndex('drive');
    if (FieldIndex >= 0) then
```

```

    for X := 1 to table.RowCount do
      Items.Add(UTF8ToString(table.GetU(X, FieldIndex)));
    finally
      table.Free;
    end;
  end;
end;

```

Thanks to the TSQLTableJSON class, code is somewhat easy to follow. Using a temporary FieldIndex variable make also it fast inside the loop execution.

But it could also be coded as such, using the CreateAndFillPrepare then FillOne method in a loop:

```

procedure TMyClient.FillDrives(aList: TStrings);
begin
  aList.BeginUpdate;
  try
    aList.Clear;
    with TSQLDrives.CreateAndFillPrepare(GlobalClient, '') do
      try
        while FillOne do
          aList.Add(UTF8ToString(Drive));
        finally
          Free;
        end;
      finally
        aList.EndUpdate;
      end;
    end;
  end;
end;

```

We even added the BeginUpdate / EndUpdate VCL methods, to have even cleaner and faster code (if you work with a TListBox e.g.).

Note that in the above code, an hidden TSQLTableJSON class is created in order to retrieve the data from the server. The abstraction introduced by the ORM methods makes the code not slowest, but less error-prone (e.g. Drive is now a RawUTF8 property), and easier to understand.

But ORM is not perfect in all cases.

For instance, if the Drive field is the only column content to retrieve, it could make sense to ask only for this very column. One drawback of the CreateAndFillPrepare method is that, by default, it retrieves all columns content from the server, even if you need only one. This is a common potential issue of an ORM: since the library doesn't know which data is needed, it will retrieve all object data, which is some cases is not worth it.

You can specify the optional aCustomFieldsCSV parameter as such, in order to retrieve only the Drive property content, and potentially save some bandwidth:

```

with TSQLDrives.CreateAndFillPrepare(GlobalClient, '', 'Drive') do

```

Note that for this particular case, you have an even more high-level method, handling directly a TStrings property as the recipient:

```

procedure TMyClient.FillDrives(aList: TStrings);
begin
  GlobalClients.OneFieldValues(TSQLDrives, 'drive', '', aList);
end;

```

The whole query is made in one line, with no SELECT statement to write.

For a particular ID range, you may have written, with a specific WHERE clause using a prepared statement:

```

GlobalClients.OneFieldValues(TSQLDrives, 'drive',
  'ID>=? AND ID<=?', [], [aFirstID, aLastID], aList);

```

It is certainly worth reading all the (verbose) interface part of the `mORMot.pas` unit, e.g. the `TSQLRest` class, to make your own idea about all the high-level methods available. In the following pages, you'll find all needed documentation about this particular unit. Since our framework is used in real applications, most useful methods should already have been made available. If you need additional high-level features, feel free to ask for them, if possible with source code sample, in our forum, freely available at <https://synopse.info..>

6.1.3. Think multi-tier

And do not forget the framework is able to have several level of objects, thanks to our Client-Server architecture - see below (page 296). Such usage is not only possible, but strongly encouraged.

You should have business-logic level objects at the Client side. Then both business-logic and DB objects at the Server side.

If you have a very specific database schema, business-logic objects can be of very high level, encapsulating some SQL views for reading, and accessed via some RESTful service commands for writing - see below (page 373).

Another possibility to access your high-level type, is to use either custom *SQLite3* SQL functions or stored procedures - see below (page 364) - both coded in *Delphi*.

6.2. One ORM to rule them all

Just before entering deeper into the *mORMot* material in the following pages (Database layer, Client-Server, Services), you may find out that this implementation may sounds restricted.

Some common (and founded) criticisms are the following (quoting from our forum):

- "One of the things I don't like so much about your approach to the ORM is the mis-use of existing *Delphi* constructs like "index n" attribute for the maximum length of a string-property. Other ORMs solve this i.e. with official `Class-attributes`";
- "You have to inherit from `TSQLRecord`, and can't persist any plain class";
- "There is no way to easily map an existing complex database".

Those concerns are pretty understandable. Our *mORMot* framework is not meant to fit any purpose, but it is worth understanding why it has been implemented as such, and why it may be quite unique within the family of ORMs - which almost all are following the *Hibernate* way of doing.

6.2.1. Rude class definition

Attributes do appear in *Delphi* 2010, and it is worth saying that FPC has an alternative syntax. Older versions of *Delphi* (still very deployed) do not have attributes available in the language, so it was not possible to be compatible with *Delphi* 6 up to latest versions (as we wished for our units).

It is perfectly right to speak about 'mis-use of index' - but this was the easiest and only way we found out to have such information, just using RTTI. Since this parameter was ignored and not used for most classes, it was re-used (also for dynamic array properties, to have faster lookup).

There is another "mis-use" for the "stored AS_UNIQUE" property, which is used to identify unique mandatory columns.

Using attributes is one of the most common ways of describing tables in most ORMs.

On the other hand, some coders have a concern about such class definitions. They are mixing DB and logic: you are somewhat polluting the business-level class definition with DB-related stuff.

That is why other kind of ORMs provide a way of mapping classes to tables using external files (some ORMs provide both ways of definition). And why those days, even code gurus identified the attributes overuse as a potential weakness of code maintainability.

Attributes do have a huge downside, when you are dealing with a Client-Server ORM, like ours: on the Client side, those attributes are pointless (client does not need to know anything about the database), and you need to link to all the DB plumbing code to your application. For *mORMot*, it was some kind of strong argument.

For the very same reasons, the column definitions (uniqueness, indexes, required) are managed in *mORMot* at two levels:

- At *ORM level* for *DB related stuff* (like indexes, which is a DB feature, not a business feature);
- At *Model level* for *Business related stuff* (like uniqueness, validators and filters).

When you take a look at the supplied validators and filters - see *Filtering and Validating* (page 172) - you'll find out that this is much powerful than the attributes available in "classic" ORMs: how could you validate an entry to be an email, or to match a pattern, or to ensure that it will be stored in uppercase within the DB?

Other question worth asking is about the security. If you access the data remotely, a global access to the DB is certainly not enough. Our framework handle per-table CRUD level access for its ORM, above the DB layer (and has also complete security attributes for services) - see below (page 545). It works however the underneath DB grants are defined (even an DB with no user rights - like in-memory or *SQLite3* is able to do it).

The *mORMot* point of view (which is not the only one), is to let the DB persist the data, as safe and efficient as possible, but rely on higher levels layers to implement the business logic. The framework favors *convention over configuration*, which is known to save a lot of time (if you use WCF on a daily basis, as I do, you and your support team know about the *.config* syndrome). It will make it pretty database-agnostic (you can even not use a SQL database at all), and will make the framework code easier to debug and maintain, since we don't have to deal with all the DB engine particularities. In short, this is the REST point of view, and main cause of success: CRUD is enough in any KISS-friendly design.

6.2.2. Persist TSQLRecord, not any class

About the fact that you need to inherit from *TSQLRecord*, and can't persist any PODO (*Plain Old Delphi Object*), our purpose was in fact very similar to the "Layer Supertype" pattern of Domain-Driven-Design, as explained by Martin Fowler:

It is not uncommon for all the objects in a layer to have methods you don't want to have duplicated throughout the system. You can move all of this behavior into a common Layer Supertype.

In fact, for *TSQLRecord* / *TSQLRest* / ORM remote access, you have already all Client-Server CRUD operations available. Those classes are abstract common Supertypes, ready to be used in your projects. It has been optimized a lot (e.g. with a cache and other nice features), so I do not think reinventing a CRUD / database service is worth the prize. You have secure access to the ORM classes, with user/group attributes. Almost everything is created by code, just from the *TSQLRecord* class definition, via RTTI. So it may be faster (and safer) to rely on it, than defining all your class hierarchy by hand.

To be fair, most DDD frameworks for Java or C# expect e.g. *Entities* classes to inherit from a given Entity class, or add *class attributes* to the POJO/POCO to define the persistence details. So we are not the single one in this case!

But the concern of not being able to persist any class (it needs to inherit from `TSQLRecord`) does perfectly make sense. Especially in the context of DDD modeling, where the DDD objects will benefit from being uncoupled from the framework, which may pollute the domain logic. All those expectations tend to break the *Persistence Ignorance* principle, as requested by DDD patterns.

This is why we added to the framework the ability to persist any plain class, using Repository services, but still using the ORM under the hood, for the actual persistence on any SQL or NoSQL database engine. The `TSQLRecord` can be generated from any Delphi persistent class, then an automated mapping is maintained by *mORMot* between both class instances. Data access is then defined as clean *CQRS Repository Services*.

For instance, a `TUser` class may be persisted via such a service:

```
type
  IDomUserCommand = interface(IDomUserQuery)
    ['{D345854F-7337-4006-B324-5D635FBED312}']
    function Add(const aAggregate: TUser): TCQRSResult;
    function Update(const aUpdatedAggregate: TUser): TCQRSResult;
    function Delete: TCQRSResult;
    function Commit: TCQRSResult;
  end;
```

Here, the write operations are defined in a `IDomUserCommand` service, which is separated (but inherits) from `IDomUserQuery`, which is used for read operations. See below (page 611) for more details about this feature.

6.2.3. Several ORMs at once

To be clear, *mORMot* offers several kind of table definitions:

- Via `TSQLRecord` / `TSQLRecordVirtual` "native ORM" classes: data storage is using either fast in-memory lists via `TSQLRestStorageInMemory`, or *SQLite3* tables (in memory, on file, or virtual). In this case, we do not use index for strings (column length is not used by any of those engines).
- Via `TSQLRecord` "external ORM-managed" classes: after registration via a call to the `VirtualTableExternalRegister()` / `VirtualTableExternalMap()` functions, external DB tables are created and managed by the ORM, via SQL - see below (page 240). These classes will allow creation of tables in any supported database engine - currently *SQLite3*, *Oracle*, *Jet/MSAccess*, *MS SQL*, *Firebird*, *DB2*, *PostgreSQL*, *MySQL*, *Informix* and *NexusDB* - via whatever *OleDB*, *ODBC* / *ZDBC* provider, or any `DB.pas` unit). For the "external ORM-managed" `TSQLRecord` type definitions, the ORM expects to find an index attribute for any text column length (i.e. `RawUTF8` or string published properties). This is the only needed parameter to be defined for such a basic implementation, in regard to `TSQLRecord` kind of classes. Then can specify addition field/column mapping, if needed.
- Via `TSQLRecord` "external ODM-managed" classes: after registration via a call to the `StaticMongoDBRegister()` or `StaticMongoDBRegisterAll()` functions, external *MongoDB* collections are created and managed via *NoSQL and Object-Document Mapping (ODM)* (page 96). In this case, no index attribute for setting text column length is necessary.
- Via `TSQLRecordMappedAutoID` / `TSQLRecordMappedForcedID` "external mapped" classes: DB tables are not created by the ORM, but already existing in the DB, with sometimes a very complex layout. This feature is not yet implemented, but on the road-map. For this kind of classes we won't probably use attributes, nor even external files, but we will rely on definition from code, either with a fluent definition, or with dedicated classes (or interface).
- Via any kind of Delphi class, mapped to their internal `TSQLRecord` class, using *CQRS Repository Services* as presented below (page 611).

Why have several database back-end at the same time?

Most of the existing software architecture rely on one dedicated database per domain, since it is more convenient to administrate one single server.

But there are some cases when it does make sense to have several databases at once.

In practice, when your data starts to grow, you may need to *archive* older data in a dedicated remote database, e.g. using cheap storage (bunch of Hard Drives in RAID). Since this data will be seldom retrieved, it is not an issue to have slower access time. And you will be able to keep your most recent data accessible in a local high-speed engine (running on SSD).

Another pattern is to use dedicated consolidation DBs for any analysis. In fact, SQL *normalization* is good for most common relation work, but sometimes *denormalization* is necessary, e.g. for statistic or business analyse purposes. In this case, dedicated consolidation databases, containing the data already prepared and indexed in a ready-to-use denormalized layout.

Last but not least, some Event Sourcing architectures even *expect* several DB back-end at once:

- It will store the status on one database (e.g. high-performance in-memory) for most common requests to be immediate;
- And store the modification events in another ACID database (e.g. *SQLite3*, *Oracle*, *Jet/MSAccess*, *MS SQL*, *Firebird*, *DB2*, *PostgreSQL*, *MySQL*, *Informix* or *NexusDB*), even a high-speed NoSQL engine like *MongoDB*.

It is possible to directly access ORM objects remotely (e.g. the consolidation DB), mostly in a read-only way, for dedicated reporting, e.g. from consolidated data - this is one potential CQRS implementation pattern with *mORMot*. Thanks to the framework security, remote access will be safe: your clients won't be able to change the consolidation DB content!

As can be easily guessed, such design models are far away from a basic ORM built only for class persistence. And *mORMot*'s ORM/ODM offers you all those possibilities.

6.2.4. The best ORM is the one you need

Therefore, we may sum up some potential use of ORM, depending of your intent:

- If you want to persist some data objects (not tied to complex business logic), the framework's ORM will be a light and fast candidate, targetting *SQLite3*, *Oracle*, *Jet/MSAccess*, *MS SQL*, *Firebird*, *DB2*, *PostgreSQL*, *MySQL*, *Informix*, *NexusDB* databases, or even with no SQL engine, using *TSQLEstStorageInMemory* class which is able to persist its content in small files - see below (page 231);
- If your understanding of ORM is just to persist some *existing* objects with associated business code, *mORMot* could help you, thanks to its *Repository Services* automatically generated over *TSQLEstRecord*, as presented below (page 611);
- If you want a very fast low-level Client-Server layer, *mORMot* is a first class candidate: we identified that some users are using the built-in JSON serialization and HTTP server features to create their application, using a RESTful/SOA architecture - see below (page 374) and below (page 420);
- If your expectation is to map an existing complex RDBMS, *mORMot* will allow to publish existing SQL statements as services, using e.g. interface-based services - see below (page 420) - over optimized *SynDB.pas* data access - see below (page 242) - as explained in *Legacy code and existing projects* (page 77);
- If you need (perhaps not now, but probably in the future) to create some kind of scalable *Domain-Driven* design architecture, you'll have all needed features at hand with *mORMot*;

Therefore, *mORMot* is not just an ORM, nor just a "classic" ORM.

7. Database layer

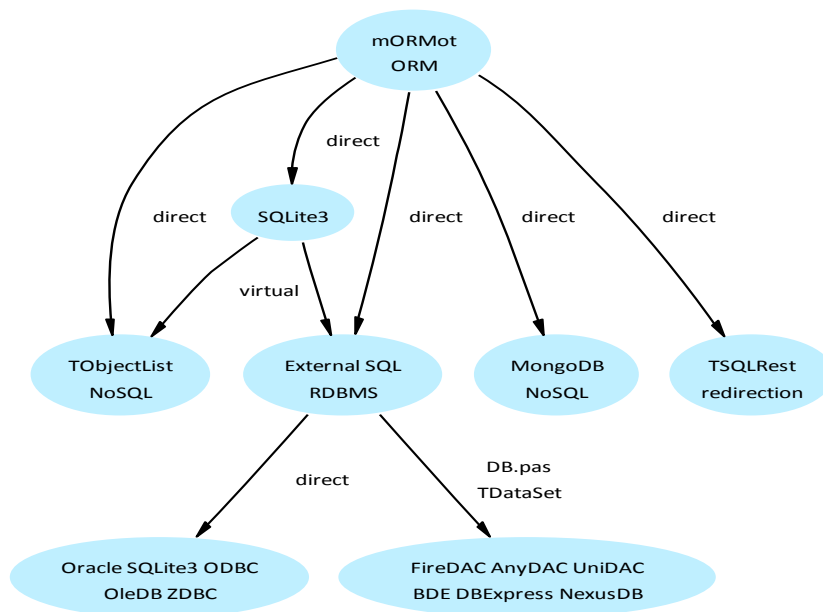

Adopt a mORMot

7.1. SQLite3-powered, not SQLite3-limited

The core database of this framework uses the *SQLite3* library, which is a Free, Secure, Zero-Configuration, Server-less, Single Stable Cross-Platform Database File database engine.

As stated below, you can use any other database access layer, if you wish:

- A fast in-memory engine is included, which outperforms any SQL-based solution in terms of speed - but to the price of a non ACID behavior on disk (but ACID in RAM);
- An integrated *SQLite3* engine, which is the best candidate for an embedded solution, even on server side;
- Any remote RDBMS database, via one or more *OleDB*, *ODBC*, *Zeos* or *Oracle* connections to store your precious ORM objects. Or you can use any *DB.pas* unit, e.g. to access *NexusDB* or any database engines supported by *DBExpress*, *FireDAC*, *AnyDAC*, *UniDAC* (or the deprecated *BDE*). In all cases, the ORM supports currently *SQLite3*, *Oracle*, *Jet/MSAccess*, *MS SQL*, *Firebird*, *DB2*, *PostgreSQL*, *MySQL*, *Informix* and *NexusDB* SQL dialects;
- Any other *TSQRest* instance (either another *TSQRestServer*, or a remote *TSQRestClientHTTP*) - see below (page 234);
- Direct access to a *MongoDB* database, which implements a true *NoSQL* and *Object-Document Mapping (ODM)* (page 96) design.

mORMot Persistence Layer Architecture

SQLite3 will be used as the main SQL engine, able to JOIN all those tables, thanks to its *Virtual Table* unique feature. You can in fact *mix* internal and external engines, in the same database model, and access all data in one unique SQL statement.

7.1.1. SQLite3 as core

This framework uses a compiled version of the official *SQLite3* library source code, and includes it natively into *Delphi* code. This framework therefore adds some very useful capabilities to the Standard *SQLite3* database engine, but keeping all its advantages, as listed in the previous paragraph of this document:

- Can be either statically linked to the executable, or load external `sqlite3.dll`;
- Faster database access, through unified memory model, and usage of the FastMM4 memory manager (which is almost 10 times faster than the default Windows memory manager for memory allocation);
- Optional direct encryption of the data on the disk (up to AES256 level, that is Top-Secret security);
- Use via *mORMot*'s ORM let database layout be declared once in the *Delphi* source code (as published properties of classes), avoiding most SQL writing, hence common field or table names mismatch;
- Locking of the database at the record level (*SQLite3* only handles file-level locking);
- Of course, the main enhancement added to the *SQLite3* engine is that it can be deployed in a stand-alone or Client-Server architecture, whereas the default *SQLite3* library works only in stand-alone mode.

From the technical point of view, here are the current compilation options used for building the *SQLite3* engine:

- Uses ISO 8601:2004 format to properly handle date/time values in TEXT field, or in faster and smaller Int64 custom types: `TTimeLog` / `TModTime` / `TCreateTime` or `TUnixTime` / `TUnixMSTime`;
- *SQLite3* library unit was compiled including RTREE extension for doing very fast range queries;
- It can include FTS3/FTS4 full text search engine (MATCH operator), with integrated SQL optimized ranking function;

- The framework makes use only of newest API (sqlite3_prepare_v2) and follows latest *SQLite3* official documentation;
- Additional *collations* (i.e. sorting functions) were added to handle efficiently not only UTF-8 text, but also e.g. ISO 8601 time encoding, fast *Win1252* diacritic-agnostic comparison and native slower but accurate Windows UTF-16 functions;
- Additional SQL functions like *Soundex* for English/French/Spanish phonemes, MOD or CONCAT, and some dedicated functions able to directly search for data within BLOB fields containing an *Delphi* high-level type (like a serialized dynamic array);
- Additional REGEXP operator/function using the Open Source PCRE library to perform regular expression queries in SQL statements;
- Custom SQL functions can be defined in *Delphi* code;
- Automatic SQL statement parameter preparation, for execution speed up;
- TSQLDatabase can cache the last results for SELECT statements, or use a tuned client-side or server-side per-record caching, in order to speed up most read queries, for lighter web server or client User Interface e.g.;
- User authentication handling (*SQLite3* is user-free designed);
- *SQLite3* source code was compiled without thread mutex: the caller has to be thread-safe aware; this is faster on most configurations, since mutex has to be acquired once): low level sqlite3_*() functions are not thread-safe, as TSQLRequest and TSQLBlobStream which just wrap them; but TSQLDataBase is thread-safe, as TSQLTableDB/TSQLRestServerDB/TSQLRestClientDB which call TSQLDataBase;
- Compiled with SQLITE_OMIT_SHARED_CACHE define, since with the new Client-Server approach of this framework, no concurrent access could happen, and an internal efficient caching algorithm is added, avoiding most call of the *SQLite3* engine in multi-user environment (any AJAX usage should benefit of it);
- The embedded *SQLite3* database engine can be easily updated from the official *SQLite3* source code available at <https://sqlite.org..> - use the amalgamation C file with a few minor changes (documented in the SynSQLite3Static.pas unit) - the resulting C source code delivered as .obj/.o is also available in the official *Synapse* source code repository.

The overhead of including *SQLite3* in your server application will be worth it: just around 1 MB to the executable, but with so many nice features, even if only external databases are used.

7.1.2. Extended by *SQLite3* virtual tables

Since the framework is truly object oriented, another database engine could be used instead of the framework. You could easily write your own TSQLRestServer descendant (as an example, we included a fast in-memory database engine as TSQLRestServerFullMemory) and link to a another engine (like *FireBird*, or a private one). You can even use our framework without any link to the *SQLite3* engine itself, via our provided very fast in memory dataset (which can be made persistent by writing and reading JSON files on disk). The *SQLite3* engine is implemented in a separate unit, named SynSQLite3.pas, and the main unit of the framework is mORMot.pas. A bridge between the two units is made with mORMotSQLite3.pas, which will found our ORM framework using *SQLite3* as its core.

The framework ORM is able to access any database class (internal or external), via the powerful *SQLite3* Virtual Table mechanisms - see below (page 226). For instance, any external database (via OleDB / ODBC / ZDBC providers or direct *Oracle* connection) can be accessed via our SynDB.pas-based dedicated units, as stated below (page 240).

As a result, the framework has several potential database back-ends, in addition to the default *SQLite3* file-based engine. Each engine may have its own purpose, according to the application expectations.

Currently *SQLite3*, *Oracle*, *Jet/MSAccess*, *MS SQL*, *Firebird*, *DB2*, *PostgreSQL*, *MySQL*, *Informix* and *NexusDB* SQL dialects are handled by our ORM.

7.1.3. Data access benchmark

Purpose here is not to say that one library or database is better or faster than another, but publish a snapshot of *mORMot* persistence layer abilities, depending on each access library.

In this timing, we do not benchmark only the "pure" SQL/DB layer access (SynDB.pas units), but the whole Client-Server ORM of our framework.

Process below includes all aspects of our ORM:

- Access via high level CRUD methods (*Add/Update/Delete/Retrieve*, either per-object or in BATCH mode);
- Read and write access of TSQLRecord instances, via optimized RTTI;
- JSON marshalling of all values (ready to be transmitted over a network);
- REST routing, with security, logging and statistic;
- Virtual cross-database layer using its *SQLite3* kernel;
- SQL on-the-fly generation and translation (in *virtual* mode);
- Access to the database engines via several libraries or providers.

In those tests, we just bypassed the communication layer, since TSQLRestClient and TSQLRestServer are run in-process, in the same thread - as a TSQLRestServerDB instance. So you have here some raw performance testimony of our framework's ORM and RESTful core, and may expect good scaling abilities when running on high-end hardware, over a network.

On a recent notebook computer (*Core i7* and SSD drive), depending on the back-end database interfaced, *mORMot* excels in speed, as will show the following benchmark:

- You can persist up to 570,000 objects per second, or retrieve 870,000 objects per second (for our pure *Delphi* in-memory engine);
- When data is retrieved from server or client *ORM Cache* (page 174), you can read more than 900,000 objects per second, whatever the database back-end is;
- With a high-performance database like Oracle, and our direct access classes, you can write 70,000 (via array binding) and read 160,000 objects per second, over a 100 MB network;
- When using alternate database access libraries (e.g. Zeos, or DB.pas based classes), speed is lower (even if comparable for DB2, MS SQL, PostgreSQL, MySQL) but still enough for most work, due to some optimizations in the *mORMot* code (e.g. caching of prepared statements, SQL multi-values insertion, direct export to/from JSON, *SQLite3* virtual mode design, avoid most temporary memory allocation...).

Difficult to find a faster ORM, I suspect.

7.1.3.1. Software and hardware configuration

The following tables try to sum up all available possibilities, and give some benchmark (average objects/second for writing or reading).

In these tables:

- 'SQLite3 (file full/off/exc)' indicates use of the internal *SQLite3* engine, with or without Synchronous := smOff and/or DB.LockingMode := lmExclusive - see below (page 222);
- 'SQLite3 (mem)' stands for the internal *SQLite3* engine running in memory;
- 'SQLite3 (ext ...)' is about access to a *SQLite3* engine as external database - see below (page 240),

either as file or memory;

- 'TObjectList' indicates a *TSQLRestStorageInMemory* instance - see below (page 231) - either static (with no SQL support) or virtual (i.e. SQL featured via *SQLite3* virtual table mechanism) which may persist the data on disk as JSON or compressed binary;
- 'WinHTTP SQLite3' and 'Sockets SQLite3' stands for a *SQLite3* engine published over HTTP using our *SynDBRemote.pas* unit using the WinHTTP API or plain sockets on the client side - see below (page 264), then accessed as an external database by our ORM;
- 'NexusDB' is the free embedded edition, available from official site;
- 'Jet' stands for a *Jet/MSAccess* database engine, accessed via *OleDB*.
- 'Oracle' shows the results of our direct OCI access layer (*SynDBOracle.pas*);
- 'Zeos *' indicates that the database was accessed directly via the ZDBC layer;
- 'FireDAC *' stands for *FireDAC* library;
- 'UniDAC *' stands for *UniDAC* library;
- 'BDE *' when using a *BDE* connection;
- 'ODBC *' for a direct access to ODBC;
- 'MongoDB ack/no ack' for direct *MongoDB* access (*SynMongoDB.pas*) with or without write acknowledge.

This list of database providers is to be extended in the future. Any feedback is welcome!

Numbers are expressed in rows/second (or objects/second). This benchmark was compiled with *Delphi XE4*, since newer compilers tends to give better results, mainly thanks to function in-lining (which was not existing e.g. in *Delphi 6-7*).

Note that these tests are not about the relative speed of each database engine, but reflect the current status of the integration of several DB libraries within the *mORMot* database access.

Benchmark was run on a *Core i7* notebook, running *Windows 7*, with a standard SSD, including anti-virus and background applications:

- Linked to a shared *Oracle 11.2.0.1* database over 100 Mb Ethernet;
- *MS SQL Express 2008 R2* running locally in 64-bit mode;
- *IBM DB2 Express-C* edition 10.5 running locally in 64-bit mode;
- *PostgreSQL 9.2.7* running locally in 64-bit mode;
- *MySQL 5.6.16* running locally in 64-bit mode;
- *Firebird* embedded in revision 2.5.2;
- *NexusDB 3.11* in Free Embedded Version;
- *MongoDB 2.6* in 64-bit mode.

So it was a development environment, very similar to low-cost production site, not dedicated to give best performance. During the process, CPU was noticeable used only for *SQLite3* in-memory and *TObjectList* - most of the time, the bottleneck is not the CPU, but the storage or network. As a result, rates and timing may vary depending on network and server load, but you get results similar to what could be expected on customer side, with an average hardware configuration. When using high-head servers and storage, running on a tuned *Linux* configuration, you can expect even better numbers.

Tests were compiled with the *Delphi XE4* 32-bit mode target platform. Most of the tests do pass when compiled as a 64-bit executable, with the exception of some providers (like Jet), not available on this platform. Speed results are almost the same, only slightly slower; so we won't show them here.

You can compile the "15 - External DB performance" supplied sample code, and run the very same benchmark on your own configuration. Feedback is welcome!

From our tests, the UniDAC version we were using had huge stability issues when used with DB2: the

tests did not pass, and the DB2 server just hang processing the queries, whereas there was no problem with other libraries. It may have been fixed since, but you won't find any "UniDAC DB2" results in the benchmark below in the meanwhile.

7.1.3.2. Insertion speed

Here we insert 5,000 rows of data, with diverse scenarios:

- 'Direct' stands for a individual `Client.Add()` insertion;
- 'Batch' mode will be described below (page 351);
- 'Trans' indicates that all insertion is nested within a transaction - which makes a great difference, e.g. with a *SQLite3* database.

Here are some insertion speed values, in objects/second:

	Direct	Batch	Trans	Batch Trans
SQLite3 (file full)	462	28123	84823	181455
SQLite3 (file off)	2102	83093	88006	202667
SQLite3 (file off exc)	28847	193453	89451	207615
SQLite3 (mem)	89456	236540	104249	239165
TObjectList (static)	314465	543892	326370	542652
TObjectList (virtual)	325393	545672	298846	545018
SQLite3 (ext full)	424	14523	102049	164636
SQLite3 (ext off)	2245	47961	109706	189250
SQLite3 (ext off exc)	41589	180759	108481	192071
SQLite3 (ext mem)	101440	211389	113530	209713
WinHTTP SQLite3	2165	36464	2079	38478
Sockets SQLite3	8118	75251	8553	80550
MongoDB (ack)	10081	84585	9800	85232
MongoDB (no ack)	33223	273672	34665	274393
ODBC SQLite3	492	11746	35367	82425

ODBC PostgreSQL	4068	26262	5130	30435
FireDAC PostgreSQL	4181	26635	10111	36483
UniDAC PostgreSQL	2705	18563	4442	28337
ODBC MySQL	3160	38309	10856	47630
ZEOS MySQL	3426	34037	12217	40186
FireDAC MySQL	3078	43053	10955	45781
UniDAC MySQL	3119	27772	11246	33288

Due to its ACID implementation, *SQLite3* process on file waits for the hard-disk to have finished flushing its data, therefore it is the reason why it is slower than other engines at individual row insertion (less than 10 objects per second with a mechanical hard drive instead of a SSD) outside the scope of a transaction.

So if you want to reach the best writing performance in your application with the default engine, you should better use transactions and regroup all writing into services or a BATCH process. Another possibility could be to execute `DB.Synchronous := smOff` and/or `DB.LockingMode := lmExclusive` at *SQLite3* engine level before process: in case of power loss at wrong time it may corrupt the database file, but it will increase the rate by a factor of 50 (with hard drive), as stated by the "off" and "off exc" rows of the table - see below (page 222). Note that by default, the *FireDAC* library set both options, so results above are to be compared with "*SQLite3 off exc*" rows. In *SQLite3* direct mode,

BATCH process benefits of multi-INSERT statements (just like external databases): it explain why `BatchAdd()` is faster than plain `Add()`, even in the slowest and safest "file full" mode.

For our direct *Oracle* access `SynDBOracle.pas` unit, and for `SynDBZeos.pas` or `SynDBFireDAC.pas` (known as *Array DML* in *FireDAC/AnyDAC*) libraries, BATCH process benefits of the array binding feature a lot.

For most engines, our ORM kernel is able to generate the appropriate SQL statement for speeding up bulk insertion. For instance:

- *SQLite3*, *MySQL*, *PostgreSQL*, *MSSQL 2008*, *DB2*, *MySQL* or *NexusDB* handle INSERT statements with multiple INSERT INTO .. VALUES (...), (...), (...)..;
- *Oracle* handles INSERT INTO .. INTO .. SELECT 1 FROM DUAL (weird syntax, isn't it?);
- *Firebird* implements EXECUTE BLOCK.

As a result, some engines show a nice speed boost when `BatchAdd()` is used. Even *SQLite3* is faster when used as external engine, in respect to direct execution! This feature is at ORM/SQL level, so it benefits to any external database library. Of course, if a given library has a better implementation pattern (e.g. our direct *Oracle*, *Zeos* or *FireDAC* with native array binding), it is used instead.

MongoDB bulk insertion has been implemented, which shows an amazing speed increase in Batch mode. Depending on the *MongoDB* write concern mode, insertion speed can be very high: by default, every write process will be acknowledge by the server, but you can by-pass this request if you set the `wcUnacknowledged` mode - note that in this case, any error (e.g. an unique field duplicated value) will never be notified, so it should not be used in production, unless you need this feature to quickly populate a database, or consolidate some data as fast as possible.

7.1.3.3. Reading speed

Now the same data is retrieved via the ORM layer:

- 'By one' states that one object is read per call (ORM generates a SELECT * FROM table WHERE ID=? for `Client.Retrieve()` method);
- 'All *' is when all 5000 objects are read in a single call (i.e. running SELECT * FROM table from a `FillPrepare()` method call), either forced to use the virtual table layer, or with direct static call.

Here are some reading speed values, in objects/second:

	By one	All Virtual	All Direct
SQLite3 (file full)	127284	558721	550842
SQLite3 (file off)	126896	549450	526149
SQLite3 (file off exc)	128077	557537	535905
SQLite3 (mem)	127106	557537	563316
TObjectList (static)	300012	912408	913742
TObjectList (virtual)	303287	402706	866551
SQLite3 (ext full)	135380	267436	553158
SQLite3 (ext off)	133696	262977	543065

The *SQLite3* layer gives amazing reading results, which makes it a perfect fit for most typical ORM use. When running with `DB.LockingMode := lmExclusive` defined (i.e. "off exc" rows), reading speed is very high, and benefits from exclusive access to the database file - see below (page 222). External database access is only required when data is expected to be shared with other processes, or for better scaling: e.g. for physical n-Tier installation with dedicated database server(s).

In the above table, it appears that all libraries based on `DB.pas` are slower than the others for reading speed. In fact, `TDataSet` sounds to be a real bottleneck, due to its internal data marshalling. Even *FireDAC*, which is known to be very optimized for speed, is limited by the `TDataSet` structure. Our direct classes, or even *ZEOS/ZDBC* performs better, since they are able to output JSON content with no additional marshalling, via a dedicated `ColumnsToJSON()` method.

For both writing and reading, `TObjectList` / `TSQLRestStorageInMemory` engine gives impressive results, but has the weakness of being in-memory, so it is not ACID by design, and the data has to fit in memory. Note that indexes are available for IDs and stored `AS_UNIQUE` properties.

As a consequence, search of non-unique values may be slow: the engine has to loop through all rows of data. But for unique values (defined as stored `AS_UNIQUE`), both insertion and search speed is awesome, due to its optimized $O(1)$ hash algorithm - see the following benchmark, especially the "By name" row for "*TObjectList*" columns, which correspond to a search of an unique `RawUTF8` property value via this hashing method.

	SQLite3 (file full)	SQLite3 (file off)	SQLite3 (mem)	TObjectList (static)	TObjectList (virt.)	SQLite3 (ext file full)	SQLite3 (ext file off)	SQLite3 (ext mem)	Oracle	Jet

All Direct	167123	144250	168577	254284	256383	170794	165601	168856	88342	75999

Above table results were run on a Core 2 duo laptop, so numbers are lower than with the previous tables.

During the tests, internal caching - see below (page 318) and *ORM Cache* (page 174) - was disabled, so you may expect speed enhancements for real applications, when data is more read than written: for instance, when an object is retrieved from the cache, you achieve more than 1,00,000 read requests per second, whatever database is used.

7.1.3.4. Analysis and use case proposal

When declared as virtual table (via a `VirtualTableRegister` call), you have the full power of SQL (including JOINS) at hand, with incredibly fast CRUD operations: 100,000 requests per second for objects read and write, including serialization and Client-Server communication!

Some providers are first-class citizens to *mORMot*, like *SQLite3*, *Oracle*, *MS SQL*, *PostgreSQL*, *MySQL* or *IBM DB2*. You can connect to them without the bottleneck of the *DB.pas* unit, nor any restriction of your *Delphi* license (a *Starter edition* is enough).

First of all, *SQLite3* is still to be considered, even for a production server. Thanks to *mORMot*'s architecture and design, this "embedded" database could be used as main database engine for a client-server application with heavy concurrent access - if you have doubts about its scaling abilities, see below (page 336). Here, "embedded" is not restricted to "mobile", but sounds like a self-contained, zero-configuration proven engine.

The remote access via HTTP gives pretty good results, and in this local benchmark, plain socket client (i.e. `TSQLDBSocketConnectionProperties` class) gives better results than the WinHTTP API (using `TSQLDBWinHTTPConnectionProperties` on the client side). But in real use, e.g. over the Internet, the WinHTTP API has been reported as more stable, so may be preferred on production. With a *SQLite3* backend, this offers pretty good performance, and the benefit of using standard HTTP for its transport.

Most recognized *closed source* databases are available:

- Direct access to *Oracle* gives impressive results in BATCH mode (aka array binding). It may be an obligation if your end-customer stores already its data in such a server, for instance, and want to leverage the licensing cost of its own IT solution. *Oracle Express* edition is free, but somewhat heavy and limited in terms of data/hardware size (see its licensing terms);
- *MS SQL Server*, directly accessed via *OleDB* (or *ODBC*) gives pretty good timing. A *MS SQL Server 2008 R2 Express* instance is pretty well integrated with the *Windows* environment, for a very affordable price (i.e. for free) - the *LocalDB* (MSI installer) edition is enough to start with, but also with data/hardware size limitation, just like *Oracle Express*;
- *IBM DB2* is another good candidate, and the *Express-C* ("C" standing for Community) offers a no-charge opportunity to run an industry standard engine, with no restriction on the data size, and somewhat high hardware limitations (16 GB of RAM and 2 CPU cores for the latest 10.5 release) or enterprise-level features;
- We did not include *Informix* numbers here, since support for this database was provided by an user patch - thanks Esteban Martin for sharing! - and we do not have any such server available here;
- *NexusDB* may be considered, if you have existing *Delphi* code and data - but it is less known and recognized as the its commercial competitors.

Open Source databases are worth considering, especially in conjunction with an Open Source framework like *mORMot*:

- *MySQL* is the well-known engine used by a lot of web sites, mainly with *LAMP* (*Linux Apache MySQL PHP*) configurations. *Windows* is not the best platform to run it, but it could be a fairly good candidate, especially in its *MariaDB* fork, which sounds more attractive those days than the official main version, owned by *Oracle*;
- *PostgreSQL* is an Enterprise class database, with amazing features among its Open Source alternatives, and really competes with commercial solutions. Even under *Windows*, we think it is easy to install and administrate, and uses less resource than the other commercial engines.
- *Firebird* gave pretty consistent timing, when accessed via *Zeos/ZDBC*. We show here the embedded version, but the server edition is worth considering, since a lot of *Delphi* programmers are skilled with this free alternative to *Interbase*;

- *MongoDB* appears as a serious competitor to SQL databases, with the potential benefit of horizontal scaling and installation/administration ease - performance is very high, and its document-based storage fits perfectly with *mORMot*'s advanced ORM features like *Shared nothing architecture (or sharding)* (page 155).

To access those databases, OleDb, ODBC or ZDBC providers may also be used, with direct access. *mORMot* is a very open-minded rodent: you can use any DB.pas provider, e.g. *FireDAC*, *UniDAC*, *DBExpress*, *NexusDB* or even the *BDE*, but with the additional layer introduced by using a *TDataSet* instance, at reading.

Therefore, the typical use may be the following:

Database	Use case
internal SQLite3 file	Created by default. General safe data handling, with amazing speed in "off exc" mode
internal SQLite3 in-memory	Created with ' :memory: ' file name. Fast data handling with no persistence (e.g. for testing or temporary storage)
TObjectList static	Created with StaticDataCreate. Best possible performance for small amount of data, without ACID nor SQL
TObjectList virtual	Created with VirtualTableRegister. Best possible performance for SQL over small amount of data (or even unlimited amount under Win64), if ACID is not required nor complex SQL
external SQLite3 file	Created with VirtualTableExternalRegister External back-end, e.g. for disk spanning
external SQLite3 in-memory	Created with VirtualTableExternalRegister and ' :memory: ' Fast external back-end (e.g. for testing)
external Oracle / MS SQL / DB2 / PostgreSQL / MySQL / Informix / Firebird	Created with VirtualTableExternalRegister Fast, secure and industry standard back-ends; data can be shared outside <i>mORMot</i>
external NexusDB	Created with VirtualTableExternalRegister The free embedded version let the whole engine be included within your executable, and use any existing code, but <i>SQLite3</i> sounds like a better option
external Jet/MSAccess	Created with VirtualTableExternalRegister Could be used as a data exchange format (e.g. with Office applications)
external Zeos	Created with VirtualTableExternalRegister Allow access to several external engines, with direct Zeos/ZDBC access which will by-pass the DB.pas unit and its <i>TDataSet</i> bottleneck - and we will also prefer an active Open Source project!

external FireDAC/UniDAC	Created with <code>VirtualTableExternalRegister</code> Allow access to several external engines, including the <code>DB.pas</code> unit and its <code>TDataSet</code> bottleneck
----------------------------	---

external <i>MongoDB</i>	Created with <code>StaticMongoDBRegister()</code> High-speed document-based storage, with horizontal scaling and advanced query abilities of nested sub-documents
-------------------------	--

Whatever database back-end is used, don't forget that *mORMot* design will allow you to switch from one library to another, just by changing a `TSQLDBConnectionProperties` class type. And note that you can *mix* external engines, on purpose: you are not tied to one single engine, but the database access can be tuned for each ORM table, according to your project needs.

7.2. SQLite3 implementation

Beginning with the revision 1.15 of the framework, the *SQLite3* engine itself has been separated from our `mORMotSQLite3.pas` unit, and defined as a stand-alone unit named `SynSQLite3.pas`. See *SDD # DI-2.2.1*.

It can be used therefore:

- Either stand-alone with direct access of all its features, even using its lowest-level C API, via `SynSQLite3.pas` - but you won't be able to switch to another database engine easily;
- Or stand-alone with high-level SQL access, using our `SynDB.pas` generic access classes, via `SynDBSQLite3.pas` - so you will be able to change to any other database engine (e.g. MS SQL, PostgreSQL, MySQL or Oracle) when needed;
- Or Client-Server based access with all our ORM features - see `mORMotSQLite3.pas`.

We'll define here some highlights specific to our own implementation of the *SQLite3* engine, and let you consult the official documentation of this great Open Source project at <http://sqlite.org> for general information about its common features.

7.2.1. Statically linked or using external dll

Since revision 1.18 of the framework, our `SynSQLite3.pas` unit is able to access the *SQLite3* engine in two ways:

- Either *statically linked* within the project executable;
- Or from an external `sqlite3.dll` library file.

The *SQLite3* APIs and constants are defined in `SynSQLite3.pas`, and accessible via a `TSQLite3Library` class definition. It defines a global `sqlite3` variable as such:

```
var
  sqlite3: TSQLite3Library;
```

To use the *SQLite3* engine, an instance of `TSQLite3Library` class shall be assigned to this global variable. Then all *mORMot*'s calls will be made through it, calling e.g. `sqlite3.open()` instead of `sqlite3_open()`.

There are two implementation classes:

TSQLite3Library classes hierarchy

Class	Unit	Purpose
<code>TSQLite3LibraryStatic</code>	<code>SynSQLite3Static.pas</code>	Statically linked engine (<code>sqlite3.obj/sqlite3.o</code> within the <code>.exe</code>)
<code>TSQLite3LibraryDynamic</code>	<code>SynSQLite3.pas</code>	Instantiate an external <code>sqlite3.dll</code> instance

Referring to `SynSQLite3Static.pas` in the `uses` clause of your project is enough to link the `.obj/.o` engine into your executable.

Warning - breaking change: before version 1.18 of the framework, link of static `.obj` was forced - so you must now add a reference to `SynSQLite3Static` in your project `uses` clause to work as expected.

In order to use an external `sqlite3.dll` library, you have to set the global `sqlite3` variable as such:

```
FreeAndNil(sqlite3); // release any previous instance (e.g. static)
sqlite3 := TSQLite3LibraryDynamic.Create;
```

Of course, `FreeAndNil(sqlite3)` is not mandatory, and should be necessary only to avoid any memory leak if another `SQLite3` engine instance was allocated (may be the case if `SynSQLite3Static` is referred somewhere in your project's units).

Here are some benchmarks, compiled with *Delphi XE3*, run in a 32-bit project, using either the static bcc-compiled engine, or an external `sqlite3.dll`, compiled via MinGW or Visual C++.

7.2.1.1. Static bcc-compiled .obj

First of all, our version included with `SynSQLite3Static.pas` unit, is to be benchmarked.

Under *Windows*, the *Visual C++* compiler gives very good results. It is a bit faster than the other two, despite a somewhat less efficient virtual table process.

As a conclusion, our `SynSQLite3Static.pas` statically linked implementation sounds like the best overall approach for *Windows 32-bit*: best speed for virtual tables (which is the core of our ORM), and no *dll hell*. No library to deploy and copy, everything is embedded in the project executable, ready to run as expected. External `sqlite3.dll` will be used for cross-platform support, and when targeting

64-bit Windows applications.

7.2.2. Prepared statement

In order to speed up the time spent in the *SQLite3* engine (it may be useful for high-end servers), the framework is able to natively handle prepared SQL statements.

Starting with version 1.12 of the framework, we added an internal SQL statement cache in the database access, available for all SQL request. Previously, only the one-record SQL `SELECT * FROM ... WHERE RowID=...` was prepared (used e.g. for the `TSQLRest.Retrieve` method).

That is, if a previous SQL statement is run with some given parameters, a prepared version, available in cache, is used, and new parameters are bounded to it before the execution by *SQLite3*.

In some cases, it can speed the *SQLite3* process a lot. From our profiling, prepared statements make common requests (i.e. `select / insert / update` on one row) at least two times faster, on an in-memory database (':memory:' specified as file name).

In order to use this statement caching, any SQL statements must have the parameters to be surrounded with ':(' and '):''. The SQL format was indeed enhanced by adding an optional way of marking parameters inside the SQL request, to enforce statement preparing and caching.

Therefore, there are now two ways of writing the same SQL request:

Write the SQL statement as usual:

```
SELECT * FROM TABLE WHERE ID=10;
```

in this case, the SQL will be parsed by the *SQLite3* engine, a statement will be compiled, then run.

Use the new optional markers to identify the changing parameter:

```
SELECT * FROM TABLE WHERE ID=: (10) ;;
```

in this case, any matching already prepared statement will be re-used for direct run.

In the later case, an internal pool of prepared `TSQLRequest` statements is maintained. The generic SQL code used for the matching will be this one:

```
SELECT * FROM TABLE WHERE ID=?;
```

and the integer value 10 will be bounded to the prepared statement before execution.

Example of possible inlined values are (note double " quotes are allowed for the text parameters, whereas SQL statement should only use single ' quotes):

```
:(1234): :(12.34): :(12E-34): :("text"): :('It's great'):
```

All internal SQL statement generated by the ORM are now using this new parameter syntax.

For instance, here is how an object deletion is implemented for the *SQLite3* engine:

```
function TSQLRestServerDB.EngineDelete(Table: TSQLRecordClass; ID: TID): boolean;  
begin  
  if Assigned(OnUpdateEvent) then  
    OnUpdateEvent(self, seDelete, Table, ID); // notify BEFORE deletion  
  result := ExecuteFmt('DELETE FROM % WHERE RowID=:(%):;', [Table.SQLTableName, ID]);  
end;
```

Using `:(%):` will let the `DELETE FROM table_name WHERE RowID=?` statement be prepared and reused between calls.

In your code, you should better use, for instance:

```
aName := OneFieldValue(TSQLMyRecord, 'Name', 'ID=:(%):',[aID]);
```

or even easier

```
aName := OneFieldValue(TSQLMyRecord, 'Name', 'ID=?',[aID]);
```

instead of

```
aName := OneFieldValue(TSQLMyRecord, 'Name', 'ID=%',[aID]);
```

or instead of a plain

```
aName := OneFieldValue(TSQLMyRecord, 'Name', 'ID='+Int32ToUtf8(aID));
```

In fact, from your client code, you may not use directly the `:(...):` expression in your request, but will rather use the overloaded `TSQLRecord.Create`, `TSQLRecord.FillPrepare`, `TSQLRecord.CreateAndFillPrepare`, `TSQLRest.OneFieldValue`, `TSQLRest.MultiFieldValues`, `TSQLRestClient.ExecuteFmt` and `TSQLRestClient.ListFmt` methods, available since revision 1.15 of the framework, which will accept both `'%'` and `'?'` characters in the SQL WHERE format text, in-lining `'?'` parameters with proper `:(...):` encoding and quoting the `RawUTF8` / strings parameters on purpose.

I found out that this SQL format enhancement is much easier to use (and faster) in the *Delphi* code than using parameters by name or by index, like in this classic VCL code:

```
SQL.Text := 'SELECT Name FROM Table WHERE ID=:Index';  
SQL.ParamByName('Index').AsInteger := aID;
```

At a lowest-level, in-lining the bounds values inside the statement enabled better serialization in a Client-Server architecture, and made caching easier on the Server side: the whole SQL query contains all parameters within one unique `RawUTF8` value, and can be therefore directly compared to the cached entries. As such, our framework is able to handle prepared statements without keeping bound parameters separated from the main SQL text.

It is also worth noting that external databases (see next paragraph) will also benefit from this statement preparation. Inlined values will be bound separately to the external SQL statement, to achieve the best speed possible.

7.2.3. R-Tree inclusion

Since the 2010-06-25 source code repository update, the RTREE extension is now compiled by default within all supplied `.obj` files.

An R-Tree is a special index that is designed for doing range queries. R-Trees are most commonly used in geospatial systems where each entry is a rectangle with minimum and maximum X and Y coordinates. Given a query rectangle, an R-Tree is able to quickly find all entries that are contained within the query rectangle or which overlap the query rectangle. This idea is easily extended to three dimensions for use in CAD systems. R-Trees also find use in time-domain range look-ups. For example, suppose a database records the starting and ending times for a large number of events. A R-Tree is able to quickly find all events, for example, that were active at any time during a given time interval, or all events that started during a particular time interval, or all events that both started and ended within a given time interval. And so forth. See <http://www.sqlite.org/rtree.html>.

A dedicated ORM class, named `TSQLRecordRTree`, is available to create such tables. It inherits from `TSQLRecordVirtual`, like the other virtual tables types (e.g. `TSQLRecordFTS5`).

Any record which inherits from this `TSQLRecordRTree` class must have only `sftFloat` (i.e. *Delphi* double) published properties grouped by pairs, each as minimum- and maximum-value, up to 5 dimensions (i.e. 11 columns, including the ID property). Its `ID: TID` property must be set before adding a `TSQLRecordRTree` to the database, e.g. to link an R-Tree representation to a regular

TSQLRecord table containing the main data.

Queries against the ID or the coordinate ranges are almost immediate: so you can e.g. extract some coordinates box from the main regular TSQLRecord table, then use a TSQLRecordRTree-joined query to make the process faster; this is exactly what the TSQLRestClient. RTreeMatch method offers: for instance, running with aMapData. BlobField filled with [-81, -79.6, 35, 36.2] the following lines:

```
aClient.RTreeMatch(TSQLRecordMapData, 'BlobField', TSQLRecordMapBox,  
aMapData.BlobField, ResultID);
```

will execute the following SQL statement:

```
SELECT MapData.ID From MapData, MapBox WHERE MapData.ID=MapBox.ID  
AND minX>=(-81.0): AND maxX<=(-79.6): AND minY>=(35.0): AND :(maxY<=36.2):  
AND MapBox_in(MapData.BlobField, ('\\uFFF0base64encoded-81,-79.6,35,36.2'));
```

The MapBox_in SQL function is registered in TSQLRestServerDB. Create constructor for all TSQLRecordRTree classes of the current database model. Both BlobToCoord and ContainedIn class methods are used to handle the box storage in the BLOB. By default, it will process a raw array of double, with a default box match (that is ContainedIn method will match the simple minX>=...maxY<=... where clause).

7.2.4. FTS3/FTS4/FTS5

FTS3/FTS4/FTS5 are *SQLite3* virtual table modules that allow users to perform full-text searches on a set of documents. The most common (and effective) way to describe full-text searches is "what Google, Yahoo and Altavista do with documents placed on the World Wide Web". Users input a term, or series of terms, perhaps connected by a binary operator or grouped together into a phrase, and the full-text query system finds the set of documents that best matches those terms considering the operators and groupings the user has specified.

See <http://www.sqlite.org/fts3.html>.. as reference material about FTS3/FTS4 usage in *SQLite3*, and <https://www.sqlite.org/fts5.html>.. about FTS5. In short, FTS5 is a new version of FTS4 that includes various fixes and solutions for problems that could not be fixed in FTS4 without sacrificing backwards compatibility.

Since recent versions of the framework, the *sqlite3.obj/.o* static file available with the distribution includes the FTS3/FTS4/FTS5 engines (also on other platforms with FPC).

7.2.4.1. Dedicated FTS3/FTS4/FTS5 record type

In order to allow easy use of the FTS feature, some types have been defined:

- TSQLRecordFTS3 to create a FTS3 table with default "simple" stemming;
- TSQLRecordFTS3Porter to create a FTS3 table using the *Porter Stemming* algorithm (see below);
- TSQLRecordFTS3Unicode61 to create a FTS3 table using the *Unicode61 Stemming* algorithm (see below);
- TSQLRecordFTS4 to create a FTS4 table with default "simple" stemming;
- TSQLRecordFTS4Porter to create a FTS4 table using the *Porter Stemming* algorithm;
- TSQLRecordFTS4Unicode61 to create a FTS4 table using the *Unicode61 Stemming*;
- TSQLRecordFTS5 to create a FTS5 table with default "simple" stemming;
- TSQLRecordFTS5Porter to create a FTS5 table using the *Porter Stemming* algorithm;
- TSQLRecordFTS5Unicode61 to create a FTS5 table using the *Unicode61 Stemming*;

The following graph will detail this class hierarchy:

FTS ORM classes

In practice, you should use `TSQLRecordFTS5` when working with latin content, `TSQLRecordFTS5Unicode61` for better non-latin support, and `TSQLRecordFTS5Porter` if your content is some plain English text.

7.2.4.2. Stemming

The "stemming" algorithm - see <http://sqlite.org/fts3.html#tokenizer..> - is the way the english text is parsed for creating the word index from raw text.

The *simple* (default) tokenizer extracts tokens from a document or basic FTS full-text query according to the following rules:

- A term is a contiguous sequence of eligible characters, where eligible characters are all alphanumeric characters, the "_" character, and all characters with UTF code-points greater than or equal to 128. All other characters are discarded when splitting a document into terms. Their only contribution is to separate adjacent terms.
- All uppercase characters within the ASCII range (UTF code-points less than 128), are transformed to their lowercase equivalents as part of the tokenization process. Thus, full-text queries are case-insensitive when using the simple tokenizer.

For example, when a document containing the text *"Right now, they're very frustrated."*, the terms extracted from the document and added to the full-text index are, in order, "right now they re very frustrated". Such a document will match a full-text query such as "MATCH 'Frustrated'", as the simple tokenizer transforms the term in the query to lowercase before searching the full-text index.

The *Porter Stemming algorithm* tokenizer uses the same rules to separate the input document into terms, but as well as folding all terms to lower case it uses the *Porter Stemming* algorithm to reduce related English language words to a common root. For example, using the same input document as in the paragraph above, the porter tokenizer extracts the following tokens: "right now thei veri frustrat". Even though some of these terms are not even English words, in some cases using them to build the full-text index is more useful than the more intelligible output produced by the simple

tokenizer. Using the porter tokenizer, the document not only matches full-text queries such as "MATCH 'Frustrated'", but also queries such as "MATCH 'Frustration'", as the term "Frustration" is reduced by the Porter stemmer algorithm to "frustrat" - just as "Frustrated" is. So, when using the porter tokenizer, FTS is able to find not just exact matches for queried terms, but matches against similar English language terms. For more information on the Porter Stemmer algorithm, please refer to the <http://tartarus.org/~martin/PorterStemmer..> page.

The *Unicode61 Stemming algorithm* tokenizer works very much like "simple" except that it does simple unicode case folding according to rules in Unicode Version 6.1 and it recognizes unicode space and punctuation characters and uses those to separate tokens. By default, "Unicode61" also removes all diacritics from Latin script characters.

7.2.4.3. FTS searches

A good approach is to store your data in a regular TSQLRecord table, then store your text content in a separated FTS table, associated to this TSQLRecordFTS5 table via its ID / DocID property. Note that for TSQLRecordFTS* types, the ID property was renamed as DocID, which is the internal name for the FTS virtual table definition of its unique integer key ID property.

For example (extracted from the regression test code), you can define this new class:

```
TSQFTSTest = class(TSQLRecordFTS5)
private
  fSubject: RawUTF8;
  fBody: RawUTF8;
published
  property Subject: RawUTF8 read fSubject write fSubject;
  property Body: RawUTF8 read fBody write fBody;
end;
```

Note that FTS tables must only content UTF-8 text field, that is RawUTF8 (under *Delphi* 2009 and up, you could also use the Unicode string type, which is mapped as a UTF-8 text field for the *SQLite3* engine).

Then you can add some *Body/Subject* content to this FTS table, just like any regular TSQLRecord content, via the ORM feature of the framework:

```
FTS := TSQFTSTest.Create;
try
  Check(aClient.TransactionBegin(TSQFTSTest)); // MUCH faster with this
  for i := StartID to StartID+COUNT-1 do
  begin
    FTS.DocID := IntArray[i];
    FTS.Subject := aClient.OneFieldValue(TSQLRecordPeople, 'FirstName', FTS.DocID);
    FTS.Body := FTS.Subject + ' body' + IntToStr(FTS.DocID);
    aClient.Add(FTS, true);
  end;
  aClient.Commit; // Commit must be BEFORE OptimizeFTS3, memory leak otherwise
  Check(FTS.OptimizeFTS3Index(Client.fServer));
```

The steps above are just typical. The only difference with a "standard" ORM approach is that the DocID property must be set *before* adding the TSQLRecordFTS5 instance: there is no ID automatically created by *SQLite*, but an ID must be specified in order to link the FTS record to the original TSQLRecordPeople row, from its ID.

To support full-text queries, FTS maintains an inverted index that maps from each unique term or word that appears in the dataset to the locations in which it appears within the table contents. The dedicated OptimizeFTS3Index method is called to merge all existing index b-trees into a single large b-tree containing the entire index - this method will work with FTS3, FTS4 and FTS5 classes, whatever

its name states. This can be an expensive operation, but may speed up future queries: you should not call this method after every modification of the FTS tables, but after some text has been added.

Then the FTS search query will use the custom FTSMATCH method:

```
Check(aClient.FTSMATCH(TSQLFTSTest, 'Subject MATCH 'salvador1'', IntResult));
```

The matching IDs are stored in the IntResult integer *dynamic array*. Note that you can use a regular SQL query instead. Use of the FTSMATCH method is not mandatory: in fact, it is just a wrapper around the OneFieldValues method, just using the "neutral" RowID column name for the results:

```
function TSQLRest.FTSMATCH(Table: TSQLRecordFTS3Class;  
  const WhereClause: RawUTF8; var DocID: TIntegerDynArray): boolean;  
begin // FTS3 tables do not have any ID, but RowID or DocID  
  result := OneFieldValues(Table, 'RowID', WhereClause, DocID);  
end;
```

An overloaded FTSMATCH method has been defined, and will handle detailed matching information, able to use a ranking algorithm. With this method, the results will be sorted by relevance:

```
Check(aClient.FTSMATCH(TSQLFTSTest, 'body1*', IntResult, [1,0.5]));
```

This method expects some additional constant parameters for weighting each FTS table column (there must be the same number of PerFieldWeight parameters as there are columns in the TSQLRecordFTS5 table). In the above sample code, the Subject field will have a weight of 1.0, and the Body will be weighted as 0.5, i.e. any match in the 'body' column content will be ranked twice less than any match in the 'subject', which is probably of higher density.

The above query will call the following SQL statement:

```
SELECT RowID FROM FTSTest WHERE FTSTest MATCH 'body1*'  
ORDER BY rank(matchinfo(FTSTest),1.0,0.5) DESC
```

The rank internal SQL function has been implemented in *Delphi*, following the guidelines of the official *SQLite3* documentation - as available from their Internet web site at http://www.sqlite.org/fts3.html#appendix_a - to implement the most efficient way of implementing ranking. It will return the RowID of documents that match the full-text query sorted from most to least relevant. When calculating relevance, query term instances in the 'subject' column are given twice the weighting of those in the 'body' column.

7.2.4.4. FTS4 index tables without content

Just as *SQLite3* allows, the framework permits FTS4 to forego storing the text being indexed, letting the indexed documents be stored in a database table created and managed by the user (an "external content" FTS4 table).

Because the indexed documents themselves are usually much larger than the full-text index, this option can be used to achieve significant storage space savings. Contentless FTS4 tables still support SELECT statements. However, it is an error to attempt to retrieve the value of any table column other than the docid column. The auxiliary function matchinfo() may be used - so TSQLRest.FTSMATCH method will work as expected, but snippet() and offsets() will cause an exception at execution.

For instance, in sample "30 - MVC Server", we define those two tables:

```
TSQLArticle = class(TSQLContent)  
private  
  fContent: RawUTF8;  
  fTitle: RawUTF8;  
  fAbstract: RawUTF8;  
  fPublishedMonth: Integer;  
  fTags: TIntegerDynArray;
```

```
published
property Title: RawUTF8 index 80 read fTitle write fTitle;
property Content: RawUTF8 read fContent write fContent;
property PublishedMonth: Integer read fPublishedMonth write fPublishedMonth;
property Abstract: RawUTF8 index 1024 read fAbstract write fAbstract;
property Tags: TIntegerDynArray index 1 read fTags write fTags;
end;

TSQLArticleSearch = class(TSQLRecordFTS4Porter)
private
fContent: RawUTF8;
fTitle: RawUTF8;
fAbstract: RawUTF8;
published
property Title: RawUTF8 read fTitle write fTitle;
property Abstract: RawUTF8 read fAbstract write fAbstract;
property Content: RawUTF8 read fContent write fContent;
end;
```

And we initialized the database model to let all data be stored only in TSQLArticle, not in TSQLArticleSearch, using an "external content" FTS4 table to index the text from the selected Title, Abstract and Content fields of TSQLArticle:

```
function CreateModel: TSQLModel;
begin
result := TSQLModel.Create([TSQlBlogInfo, TSQLAuthor,
TSQlTag, TSQLArticle, TSQLComment, TSQLArticleSearch], 'blog');
result.Props[TSQLArticleSearch].FTS4WithoutContent(TSQLArticle);
...
```

The TSQLModelRecordProperties.FTS4WithoutContent() will in fact create the needed *SQLite3* triggers, to automatically populate the ArticleSearch Full Text indexes when the main Article row changes.

Since this FTS4 feature is specific to *SQLite3*, and triggers do not work on virtual tables (by now), this method won't do anything if the TSQLArticleSearch or TSQLArticle are on an external database - see below (page 240). Both need to be stored in the main *SQLite3* DB.

In the 30 - MVC Server sample, the search will be performed as such:

```
if scop^.GetAsRawUTF8('match', match) and fHasFTS then begin
if scop^.GetAsDouble('lastrank', rank) then
whereClause := 'and rank<? ';
whereClause := 'join (select docid, rank(matchinfo(ArticleSearch), 1.0, 0.7, 0.5) as rank '+
'from ArticleSearch where ArticleSearch match ? '+ whereClause +
'order by rank desc limit 100) as r on (r.docid=Article.id)';
articles := RestModel.RetrieveDocVariantArray(
TSQLArticle, '', whereClause, [match, rank],
'id, title, tags, author, authorname, createdat, abstract, contenthtml, rank');
```

In the above query expression, the rank() function is used over the detailed FTS4 search statistics returned by matchinfo(), using a 1.0 weight for any match in the Title column, 0.7 for the Abstract column, and 0.5 for Content. The matching articles content is then returned in an articles: TDocVariant array, ready to be rendered on the web page.

7.2.5. Column collations

In any database, there is a need to define how column data is to be compared. It is needed for proper search and ordering of the data. This is the purpose of so-called *collations*.

By default, when *SQLite* compares two strings, it uses a collating sequence or collating function (two words for the same thing) to determine which string is greater or if the two strings are equal. *SQLite* has three built-in collating functions: BINARY, NOCASE, and RTRIM:

- BINARY - Compares string data using memcmp(), regardless of text encoding.
- NOCASE - The same as binary, except the 26 upper case characters of ASCII are folded to their lower case equivalents before the comparison is performed. Note that only ASCII characters are case folded. Plain *SQLite* does not attempt to do full Unicode case folding due to the size of the tables required - but you could use *mORMot*'s SYSTEMNOCASE, or WIN32CASE/WIN32NOCASE custom collations for enhanced case folding support (see below);
- RTRIM - The same as binary, except that trailing space characters are ignored.

In the *mORMot* ORM, we defined some additional kind of collations, via some internal calls to the sqlite3_create_collation() API:

TSQLFieldType	Default collation
sftAnsiText	NOCASE
sftUTF8Text	SYSTEMNOCASE, i.e. using UTF8ILComp(), which will ignore <i>Win-1252</i> Latin accents
sftEnumerate sftSet sftInteger sftID sftTID sftRecord sftBoolean sftFloat sftCurrency ftTimeLog sftModTime sftCreateTime	BINARY is used for those numerical values
sftDateTime ftDateTimeMS	ISO8601, i.e. decoding the text into a date/time value before comparison
sftObject sftVariant	BINARY, since it is stored as plain JSON content
sftBlob sftBlobDynArray sftBlobCustom	BINARY

You can override those default collation schemes by calling TSQLRecordProperties.SetCustomCollationForAll() (which will override all fields collation for a given type) or SetCustomCollation() method (which will override a given field) in an overridden class procedure InternalRegisterCustomProperties() or InternalDefineModel(), so that it will be common to all database models, for both client and server, every time the corresponding TSQLRecord is used.

As an alternative, you may call TSQLModel.SetCustomCollationForAll() method, which will do it for a given model.

The following collations are therefore available when using *SQLite3* within the *mORMot* ORM:

Collation	Description
BINARY	Default memcmp() comparison

NOCASE	Default ASCII 7 bit comparison
RTRIM	Default memcmp() comparison with right trim
SYSTEMNOCASE	mORMot's Win-1252 8 bit comparison
ISO8601	mORMot's date/time comparison
WIN32CASE	mORMot's comparison using case-insensitive Windows API
WIN32NOCASE	mORMot's comparison using not case-insensitive Windows API

Note that WIN32CASE/WIN32NOCASE will be slower than the others, but will handle properly any kind of complex scripting. For instance, if you want to use the Unicode-ready Windows API at database level, you can set for each database model:

```
aModel.SetCustomCollationForAll(sftUTF8Text, 'WIN32CASE');
aModel.SetCustomCollationForAll(sftDateTime, 'NOCASE');
```

An alternative may be to inherit your ORM class from TSQLRecordNoCase or TSQLRecordCaseSensitive, to use the NOCASE or BINARY standard collations.

Note that the ORM won't change the collation once the table is created, since *SQLite3* itself does not support this directly. Its REINDEX command is somewhat useful if you need to change the collation function implementation, but it won't help directly to change the collation itself on a given column...

On non-Windows platform, it will either use the system ICU library (if available), or fallback to the FPC RTL with temporary UnicodeString values - which requires to include ``cwstrings`` in your project uses clause. Note that depending on the library used, the results may not be consistent: so if you move a *SQLite3* database file e.g. from a Windows system to a Linux system with WIN32CASE collation, you should better regenerate all your indexes!

If you use our non-standard/extended collations (i.e. SYSTEMNOCASE/ISO8601/WIN32CASE/WIN32NOCASE), you may have trouble running requests with "plain" *SQLite3* tools. But you can use our SynDBExplorer safely, since it will declare all the above collations.

When using external databases - see below (page 240), if the content is retrieved directly from the database driver and by-passes the virtual table mechanism - see below (page 226), returned data may not match your expectations according to the custom collations: you will need to customize the external tables definition by hand, with the proper SQL statement of each external DB engine.

Note that mORMot 2 offers a new UNICODENOCASE collation, which follows Unicode 10.0 without any Windows or ICU API call, so is consistent on all systems - and is also faster.

7.2.6. REGEXP operator

Our *SQLite3* engine can use *regular expression* within its SQL queries, by enabling the REGEXP operator in addition to standard SQL operators (= == != <> IS IN LIKE GLOB MATCH).

7.2.6.1. Default REGEXP Engine

By default, and since mORMot 1.18.6218 (25 January 2021), our static *SQLite3* engine includes a compact and efficient enough C extension, as available from the official *SQLite3* project source code tree. It is included with the official amalgamation file during our compilation phase.

So you don't need to do anything to be able to use the REGEXP operator in your queries:

```
Server := TSQLRestServerDB.Create(Model, 'test.db3');
try
  with TSQLRecordPeople.CreateAndFillPrepare(Client,
    'FirstName REGEXP ?', ['\bFinley\b']) do
    try
      while FillOne do begin
        Check(LastName='Morse');
        Check(IdempChar(pointer(FirstName), 'SAMUEL FINLEY '));
      end;
    finally
      Free;
    end;
  finally
    Server.Free;
  end;
```

The above code will execute the following SQL statement (with a prepared parameter for the regular expression itself):

```
SELECT * from People WHERE Firstname REGEXP '\bFinley\b';
```

That is, it will find all objects where TSQLRecordPeople.FirstName will contain the 'Finley' word - in a regular expression, \b defines a word boundary search.

In fact, the REGEXP operator is a special syntax for the regexp() user function. No regexp() user function is defined by default and so use of the REGEXP operator will normally result in an error message. Calling CreateRegExFunction() for a given connection will add a SQL function named "regexp()" at run-time, which will be called in order to implement the REGEXP operator.

7.2.6.2. PCRE REGEXP Engine

If you want to use the Open Source PCRE library to perform the searches, instead of this default C extension, you should include the SynSQLite3RegEx.pas unit to your uses clause, and register the RegExp() SQL function to a given SQLite3 database instance, as such:

```
uses SynCommons, mORMot, mORMotSQLite3,
    SynSQLite3RegEx;
...
Server := TSQLRestServerDB.Create(Model, 'test.db3');
try
  CreateRegExFunction(Server.DB.DB);
  with TSQLRecordPeople.CreateAndFillPrepare(Client,
    'FirstName REGEXP ?', ['\bFinley\b']) do
    try
      while FillOne do begin
        Check(LastName='Morse');
      end;
    finally
      ...
    end;
  finally
    ...
  end;
```

It will use the statically linked PCRE library as available since Delphi XE, or will rely on the PCRE.pas wrapper unit as published at <http://www.regular-expressions.info/download/TPerlRegEx.zip..> for older versions of Delphi.

This unit will call directly the UTF-8 API of the PCRE library, and maintain a per-connection cache of compiled regular expressions to ensure the best performance possible.

7.2.7. ACID and speed

As stated above in *Data access benchmark* (page 199), the default SQLite3 write speed is quite slow, when running on a normal hard drive. By default, the engine will pause after issuing a OS-level write command. This guarantees that the data is written to the disk, and features the ACID properties of the

database engine.

ACID is an acronym for "*Atomicity Consistency Isolation Durability*" properties, which guarantee that database transactions are processed reliably: for instance, in case of a power loss or hardware failure, the data will be saved on disk in a consistent way, with no potential loss of data.

In *SQLite3*, ACID is implemented by two means at file level:

- *Synchronous writing*: it means that the engine will wait for any written content to be flushed to disk before processing the next request;
- *File locking*: it means that the database file is locked for exclusive use during writing, allowing several processes to access the same database file concurrently.

Changing these default settings can ensure much better writing performance.

7.2.7.1. Synchronous writing

You can overwrite the default ACID behavior by setting the `TSQLDataBase.Synchronous` property to `smOff` instead of the default `smFull` setting. When `Synchronous` is set to `smOff`, *SQLite* continues without syncing as soon as it has handed data off to the operating system. If the application running *SQLite* crashes, the data will be safe, but the database might become corrupted if the operating system crashes or the computer loses power before that data has been written to the disk surface. On the other hand, some operations are as much as 50 or more times faster with this setting.

When the tests performed during *Data access benchmark* (page 199) use `Synchronous := smOff`, "Write one" speed is enhanced from 8-9 rows per second into about 400 rows per second, on a physical hard drive (SSD or NAS drives may not suffer from this delay).

So depending on your application requirements, you may switch `Synchronous` setting to off.

To change the main *SQLite3* engine synchronous parameter, you may code for instance:

```
Client := TSQLRestClientDB.Create(Model,nil,MainDBFileName,TSQLRestServerDB,false,'');  
Client.Server.DB.Synchronous := smOff;
```

Note that this setting is common to a whole `TSQLDatabase` instance, so will affect all tables handled by the `TSQLRestServerDB` instance.

But if you defined some *SQLite3* external tables - see below (page 240), you can define the setting for a particular external connection, for instance:

```
Props := TSQLDBSQLite3ConnectionProperties.Create(DBFileName,'','');  
VirtualTableExternalRegister(Model,TSQLRecordSample,Props,'SampleRecord');  
Client := TSQLRestClientDB.Create(Model,nil,MainDBFileName,TSQLRestServerDB,false,'');  
TSQLDBSQLite3Connection(Props.MainConnection).Synchronous := smOff;
```

Never forget that you may have several *SQLite3* engines within a single *mORMot* server!

7.2.7.2. File locking

You can overwrite the first default ACID behavior by setting the `TSQLDataBase.LockingMode` property to `lmExclusive` instead of the default `lmNormal` setting. When `LockingMode` is set to `lmExclusive`, *SQLite* will lock the database file for exclusive use during the whole session. It will prevent other processes (e.g. database viewer tools) to access the file at the same time, but small write transactions will be much faster, by a factor usually greater than 40. Bigger transactions involving several hundredths/thousands of INSERT won't be accelerated - but individual insertions will have a major speed up - see *Data access benchmark* (page 199).

To change the main *SQLite3* engine locking mode parameter, you may code for instance:

```
Client := TSQLRestClientDB.Create(Model, nil, MainDBFileName, TSQLRestServerDB, false, '');  
Client.Server.DB.LockingMode := lmExclusive;
```

Note that this setting is common to a whole TSQLDatabase instance, so will affect all tables handled by the TSQLRestServerDB instance.

But if you defined some *SQLite3* external tables - see below (page 240), you can define the setting for a particular external connection, for instance:

```
Props := TSQLDBSQLite3ConnectionProperties.Create(DBFileName, '', '');  
VirtualTableExternalRegister(Model, TSQLRecordSample, Props, 'SampleRecord');  
Client := TSQLRestClientDB.Create(Model, nil, MainDBFileName, TSQLRestServerDB, false, '');  
TSQLDBSQLite3Connection(Props.MainConnection).LockingMode := lmExclusive;
```

In fact, exclusive file locking improves the reading speed by a factor of 4 (in case of individual row retrieval). As such, defining `LockingMode := lmExclusive` without `Synchronous := smOff` could be of great benefit for a server which purpose is mainly to serve ORM content to clients.

7.2.7.3. Performance tuning

By default, the slow but truly ACID setting will be used with *mORMot*, just as with *SQLite3*. We do not change this policy, since it will ensure best safety, in the expense of slow writing outside a transaction.

The best performance will be achieved by combining the two previous options, as such:

```
Client := TSQLRestClientDB.Create(Model, nil, MainDBFileName, TSQLRestServerDB, false, '');  
Client.Server.DB.LockingMode := lmExclusive;  
Client.Server.DB.Synchronous := smOff;
```

Or, for external tables:

```
Props := TSQLDBSQLite3ConnectionProperties.Create(DBFileName, '', '');  
VirtualTableExternalRegister(Model, TSQLRecordSample, Props, 'SampleRecord');  
Client := TSQLRestClientDB.Create(Model, nil, MainDBFileName, TSQLRestServerDB, false, '');  
TSQLDBSQLite3Connection(Props.MainConnection).Synchronous := smOff;  
TSQLDBSQLite3Connection(Props.MainConnection).LockingMode := lmExclusive;
```

If you can afford loosing some data in very rare border case, or if you are sure your hardware configuration is safe (e.g. if the server is connected to a power inverter and has RAID disks) and that you have backups at hand, setting `Synchronous := smOff` will help your application scale for writing. Setting `LockingMode := lmExclusive` will benefit of both writing and reading speed. Consider using an external and dedicated database (like *Firebird*, *Oracle*, *PostgreSQL*, *MySQL*, *DB2*, *Informix* or *MS SQL*) if your security expectations are very high, and if the default safe but slow setting is not enough for you.

7.2.8. Database backup

In all cases, do not forget to perform backups of your *SQLite3* database as often as possible (at least several times a day). Adding a backup feature on the server side is as simple as running:

```
Server.DB.BackupBackground('backup.db3', 1024, 10, nil);
```

The above line will perform a background live backup of the main *SQLite3* database, by steps of 1024 pages (i.e. it will process 1 MB per step, since default page size is 1024 bytes), performing a little sleep of 10 milliseconds between each 1 MB copy step, allowing main CRUD / ORM operations to continue uninterrupted during the backup.

You can even specify an `OnProgress: TSQLDatabaseBackupEvent` callback event, to monitor the backup process.

Note that `TSQLRestServerDB.Backup` or `TSQLRestServerDB.BackupGZ` methods are not recommended any more on a running *mORMot* database, due to some potential issues with virtual

tables, especially on the *Win64* platform. You should definitively use `TSQLDatabase.BackupBackground()` instead.

The same backup process can be used e.g. to save an in-memory *SQLite3* database into a *SQLite3* file, as such:

```
if aInMemoryDB.BackupBackground('backup.db3',-1,0,nil) then  
  aInMemoryDB.BackupBackgroundWaitUntilFinished;
```

Above code will save the `aInMemoryDB` database into the 'backup.db3' file.

7.3. Virtual Tables magic

The *SQLite3* engine has the unique ability to create Virtual Tables from code. From the perspective of an SQL statement, the virtual table object looks like any other table or view. But behind the scenes, queries from and updates to a virtual table invoke callback methods on the virtual table object instead of reading and writing to the database file.

The virtual table mechanism allows an application to publish interfaces that are accessible from SQL statements as if they were tables. SQL statements can in general do anything to a virtual table that they can do to a real table, with the following exceptions:

- One cannot create a trigger on a virtual table.
- One cannot create additional indices on a virtual table. (Virtual tables can have indices but that must be built into the virtual table implementation. Indices cannot be added separately using `CREATE INDEX` statements.)
- One cannot run `ALTER TABLE ... ADD COLUMN` commands against a virtual table.
- Particular virtual table implementations might impose additional constraints. For example, some virtual implementations might provide read-only tables. Or some virtual table implementations might allow `INSERT` or `DELETE` but not `UPDATE`. Or some virtual table implementations might limit the kinds of `UPDATES` that can be made.

Example of virtual tables, already included in the *SQLite3* engine, are FTS or RTREE tables.

Our framework introduces new types of custom virtual table. You'll find classes like `TSQLVirtualTableJSON` or `TSQLVirtualTableBinary` which handle in-memory data structures. Or it might represent a view of data on disk that is not in the *SQLite3* format (e.g. `TSQLVirtualTableLog`). It can be used to access any external database, just as if they were native *SQLite3* tables - see below (page 240). Or the application might compute the content of the virtual table on demand.

Thanks to the generic implementation of Virtual Table in *SQLite3*, you can use such tables in your SQL statement, and even safely execute a `SELECT` statement with `JOIN` or custom functions, mixing normal *SQLite3* tables and any other Virtual Table. From the ORM point of view, virtual tables are just tables, i.e. they inherit from `TSQLRecordVirtual1`, which inherits from the common base `TSQLRecord` class.

7.3.1. Virtual Table module classes

A dedicated mechanism has been added to the framework, beginning with revision 1.13, in order to easily add such virtual tables with pure *Delphi* code.

In order to implement a new Virtual Table type, you'll have to define a so called *Module* to handle the fields and data access and an associated *Cursor* for the `SELECT` statements. This is implemented by the two `TSQLVirtualTable` and `TSQLVirtualTableCursor` classes as defined in the `mORMot.pas` unit.

For instance, here are the default Virtual Table classes deriving from those classes:

Virtual Tables classes hierarchy

TSQLVirtualTableJSON, TSQLVirtualTableBinary and TSQLVirtualTableCursorJSON classes will implement a Virtual Table using a TSQLRestStorageInMemory instance to handle fast in-memory static databases. Disk storage will be encoded either as UTF-8 JSON (for the TSQLVirtualTableJSON class, i.e. the 'JSON' module), or in a proprietary SynLZ compressed format (for the TSQLVirtualTableBinary class, i.e. the 'Binary' module). File extension on disk will be simply .json for the 'JSON' module, and .data for the 'Binary' module. Just to mention the size on disk difference, the 502 KB People.json content (as created by included regression tests) is stored into a 92 KB People.data file, in our proprietary optimized format.

Note that the virtual table module name is retrieved from the class name. For instance, the TSQLVirtualTableJSON class will have its module named as 'JSON' in the SQL code.

To handle external databases, two dedicated classes, named TSQLVirtualTableExternal and TSQLVirtualTableCursorExternal will be defined in a similar manner - see *External Databases classes hierarchy* below (page 274).

As you probably have already stated, all those Virtual Table mechanism is implemented in mORMot.pas. Therefore, it is independent from the *SQLite3* engine, even if, to my knowledge, there is no other SQL database engine around able to implement this pretty nice feature.

7.3.2. Defining a Virtual Table module

Here is how the TSQLVirtualTableLog class type is defined, which will implement a Virtual Table module named "Log". Note that the *SQLite3* virtual table module name will be computed from the class name, trimming its first characters, e.g. TSQLVirtualTableLog will trim trailing TSQLVirtualTable and define a 'Log' virtual module.

Adding a new module is just made by overriding some *Delphi* methods:

```
TSQLVirtualTableLog = class(TSQLVirtualTable)
protected
  fLogFile: TSynLogFile;
public
  class procedure GetTableModuleProperties(
    var aProperties: TVirtualTableModuleProperties); override;
  constructor Create(aModule: TSQLVirtualTableModule; const aTableName: RawUTF8;
    FieldCount: integer; Fields: PPUTF8CharArray); override;
  destructor Destroy; override;
end;
```

This module will allow direct Read-Only access to a .log file content, which file name will be specified by the corresponding SQL table name.

The following method will define the properties of this Virtual Table Module:

```
class procedure TSQLVirtualTableLog.GetTableModuleProperties(
  var aProperties: TVirtualTableModuleProperties);
begin
  aProperties.Features := [vtWhereIDPrepared];
  aProperties.CursorClass := TSQLVirtualTableCursorLog;
  aProperties.RecordClass := TSQLRecordLogFile;
end;
```

The supplied feature set defines a read-only module (since vtWrite is not selected), and vtWhereIDPrepared indicates that any RowID=? SQL statement will be handled as such in the cursor class (we will use the log row as ID number, start counting at 1, so we can speed up RowID=? WHERE clause easily). The associated cursor class is returned. And a TSQLRecord class is specified, to define

the handled fields - its published properties definition will be used by the inherited Structure method to specify to the *SQLite3* engine which kind of fields are expected in the SQL statements:

```
TSQLRecordLogFile = class(TSQLRecordVirtualTableAutoID)
protected
  fContent: RawUTF8;
  fDateTime: TDateTime;
  fLevel: TSynLogInfo;
published
  /// the Log event time stamp
  property DateTime: TDateTime read fDateTime;
  /// the Log event Level
  property Level: TSynLogInfo read fLevel;
  /// the textual message associated to the log event
  property Content: RawUTF8 read fContent;
end;
```

You could have overridden the Structure method in order to provide the CREATE TABLE SQL statement expected. But using *Delphi* class RTTI allows the construction of this SQL statement with the appropriate column type and collation, common to what the rest of the ORM will expect.

Of course, this RecordClass property is not mandatory. For instance, the TSQLVirtualTableJSON.GetTableModuleProperties method won't return any associated TSQLRecordClass, since it will depend on the table it is implementing, i.e. the running TSQLRestStorageInMemory instance. Instead, the Structure method is overridden, and will return the corresponding field layout of each associated table.

Here is how the Prepare method is implemented, and will handle the vtWhereIDPrepared feature:

```
function TSQLVirtualTable.Prepare(var Prepared: TSQLVirtualTablePrepared): boolean;
begin
  result := Self<>nil;
  if result then
    if (vtWhereIDPrepared in fModule.Features) and
       Prepared.IsWhereIDEquals(true) then
      with Prepared.Where[0] do begin // check ID=?
        Value.VType := varAny; // mark TSQLVirtualTableCursorJSON expects it
        OmitCheck := true;
        Prepared.EstimatedCost := 1;
      end else
        Prepared.EstimatedCost := 1E10; // generic high cost
    end;
```

Then here is how each 'log' virtual table module instance is created:

```
constructor TSQLVirtualTableLog.Create(aModule: TSQLVirtualTableModule;
  const aTableName: RawUTF8; FieldCount: integer; Fields: PUTF8CharArray);
var aFileName: TFileName;
begin
  inherited;
  if (FieldCount=1) then
    aFileName := UTF8ToString(Fields[0]) else
    aFileName := aModule.FileName(aTableName);
  fLogFile := TSynLogFile.Create(aFileName);
end;
```

It only associates a TSynLogFile instance according to the supplied file name (our SQL CREATE VIRTUAL TABLE statement only expects one parameter, which is the .log file name on disk - if this file name is not specified, it will use the SQL table name instead).

The TSQLVirtualTableLog.Destroy destructor will free this fLogFile instance:

```
destructor TSQLVirtualTableLog.Destroy;
begin
  FreeAndNil(fLogFile);
```

```
inherited;  
end;
```

Then the corresponding cursor is defined as such:

```
TSQLVirtualTableCursorLog = class(TSQLVirtualTableCursorIndex)  
public  
function Search(const Prepared: TSQLVirtualTablePrepared): boolean; override;  
function Column(aColumn: integer; var aResult: TVarData): boolean; override;  
end;
```

Since this class inherits from TSQLVirtualTableCursorIndex, it will have the generic fCurrent / fMax protected fields, and will have the HasData, Next and Search methods using those properties to handle navigation throughout the cursor.

The overridden Search method consists only in:

```
function TSQLVirtualTableCursorLog.Search(  
const Prepared: TSQLVirtualTablePrepared): boolean;  
begin  
result := inherited Search(Prepared); // mark EOF by default  
if result then begin  
fMax := TSQLVirtualTableLog(Table).fLogFile.Count-1;  
if Prepared.IsWhereIDEquals(false) then begin  
fCurrent := Prepared.Where[0].Value.VInt64-1; // ID=? -> index := ID-1  
if cardinal(fCurrent)<=cardinal(fMax) then  
fMax := fCurrent else // found one  
fMax := fCurrent-1; // out of range ID  
end;  
end;  
end;
```

The only purpose of this method is to handle RowID=? statement SELECT WHERE clause, returning fCurrent=fMax=ID-1 for any valid ID, or fMax<fCurrent, i.e. no result if the ID is out of range. In fact, the Search method of the cursor class must handle all cases which has been notified as handled during the call to the Prepare method. In our case, since we have set the vtWhereIDPrepared feature and the Prepare method identified it in the request and set the OmitCheck flag, our Search method MUST handle the RowID=? case.

If the WHERE clause is not RowID=? (i.e. if Prepared.IsWhereIDEquals returns false), it will return fCurrent=0 and fMax=fLogFile.Count-1, i.e. it will let the *SQLite3* engine loop through all rows searching for the data.

Each column value is retrieved by this method:

```
function TSQLVirtualTableCursorLog.Column(aColumn: integer;  
var aResult: TVarData): boolean;  
var LogFile: TSynLogFile;  
begin  
result := false;  
if (self=nil) or (fCurrent>fMax) then  
exit;  
LogFile := TSQLVirtualTableLog(Table).fLogFile;  
if LogFile=nil then  
exit;  
case aColumn of  
-1: SetColumn(aResult,fCurrent+1); // ID = index + 1  
0: SetColumn(aResult,LogFile.EventDateTime(fCurrent));  
1: SetColumn(aResult,ord(LogFile.EventLevel[fCurrent]));  
2: SetColumn(aResult,LogFile.LinePointers[fCurrent],LogFile.LineSize(fCurrent));  
else exit;  
end;  
result := true;  
end;
```

As stated by the documentation of the TSQLVirtualTableCursor class, -1 is the column index for the

RowID, and then will follow the columns as defined in the text returned by the Structure method (in our case, the DateTime, Level, Content fields of TSQLRecordLogFile).

The SetColumn overloaded methods can be used to set the appropriate result to the aResult variable. For UTF-8 text, it will use a temporary in-memory space, to ensure that the text memory will be still available at least until the next Column method call.

7.3.3. Using a Virtual Table module

From the low-level *SQLite3* point of view, here is how this "Log" virtual table module can be used, directly from the *SQLite3* engine.

First we will register this module to a DB connection (this method is to be used only in case of such low-level access - in our ORM you should never call this method, but TSQLModel.VirtualTableRegister instead, cf. next paragraph):

```
RegisterVirtualTableModule(TSQLVirtualTableLog,Demo);
```

Then we can execute the following SQL statement to create the virtual table for the Demo database connection:

```
Demo.Execute('CREATE VIRTUAL TABLE test USING log(temptest.log);');
```

This will create the virtual table. Since all fields are already known by the TSQLVirtualTableLog class, it is not necessary to specify the fields at this level. We only specify the log file name, which will be retrieved by TSQLVirtualTableLog. Create constructor.

```
Demo.Execute('select count(*) from test',Res);
Check(Res=1);
s := Demo.ExecuteJSON('select * from test');
s2 := Demo.ExecuteJSON('select * from test where rowid=1');
s3 := Demo.ExecuteJSON('select * from test where level=3');
```

You can note that there is no difference with a normal *SQLite3* table, from the SQL point of view. In fact, the full power of the SQL language as implemented by *SQLite3* - see <http://sqlite.org/lang.html> - can be used with any kind of data, if you define the appropriate methods of a corresponding Virtual Table module.

7.3.4. Virtual Table, ORM and TSQLRecord

The framework ORM is able to use Virtual Table modules, just by defining some TSQLRecord, inheriting from some TSQLRecordVirtual dedicated classes:

Custom Virtual Tables records classes hierarchy

TSQLRecordVirtualTableAutoID children can be defined for Virtual Table implemented in *Delphi*, with a new ID generated automatically at INSERT.

TSQLRecordVirtualTableForcedID children can be defined for Virtual Table implemented in *Delphi*, with an ID value forced at INSERT (in a similar manner than for TSQLRecordRTree or TSQLRecordFTS3/FTS4/FTS5).

TSQLRecordLogFile was defined to map the column name as retrieved by the TSQLVirtualTableLog ('log') module, and should not to be used for any other purpose.

The Virtual Table module associated from such classes is retrieved from an association made to the server TSQLModel. In a Client-Server application, the association is not needed (nor to be used, since it may increase code size) on the Client side. But on the server side, the TSQLModel.VirtualTableRegister method must be called to associate a TSQLVirtualTableClass (i.e. a Virtual Table module implementation) to a TSQLRecordVirtualClass (i.e. its ORM representation).

For instance, the following code will register two TSQLRecord classes, the first using the 'JSON' virtual table module, the second using the 'Binary' module:

```
Model.VirtualTableRegister(TSQLRecordDali1, TSQLVirtualTableJSON);  
Model.VirtualTableRegister(TSQLRecordDali2, TSQLVirtualTableBinary);
```

This registration should be done on the Server side only, *before* calling TSQLRestServer.Create (or TSQLRestClientDB.Create, for a stand-alone application). Otherwise, an exception is raised at virtual table creation.

7.3.5. In-Memory "static" process

We have seen that the TSQLVirtualTableJSON, TSQLVirtualTableBinary and TSQLVirtualTableCursorJSON classes implement a Virtual Table module using a TSQLRestStorageInMemory instance to handle fast static in-memory database.

Why use such a database type, when you can create a *SQLite3* in-memory table, using the :memory: file name? That is the question...

- *SQLite3* in-memory tables are not persistent, whereas our JSON or Binary virtual table modules can be written on disk on purpose, if the `aServer.StaticVirtualTable[aClass].CommitShouldNotUpdateFile` property is set to true - in this case, file writing should be made by calling explicitly the `aServer.StaticVirtualTable[aClass].UpdateToFile` method;
- *SQLite3* in-memory tables will need two database connections, or call to the ATTACH DATABASE SQL statement - both of them are not handled natively by our Client-Server framework;
- *SQLite3* in-memory tables are only accessed via SQL statements, whereas TSQLRestStorageInMemory tables can have faster direct access for most common RESTful commands (GET / POST / PUT / DELETE individual rows) - this could make a difference in server CPU load, especially with the Batch feature of the framework;
- On the server side, it could be very convenient to have a direct list of in-memory TSQLRecord instances to work with in pure *Delphi* code; this is exactly what TSQLRestStorageInMemory allows, and definitively makes sense for an ORM framework;
- On the client or server side, you could create calculated fields easily with TSQLRestStorageInMemory dedicated "getter" methods written in *Delphi*, whereas *SQLite3* in-memory tables will need additional SQL coding;
- *SQLite3* tables are stored in the main database file - in some cases, it could be much convenient to provide some additional table content in some separated database file (for a round robin table, a configuration table written in JSON, some content to be shared among users...): this is made

- possible using our JSON or Binary virtual table modules (but, to be honest, the ATTACH DATABASE statement could provide a similar feature);
- The TSQLRestStorageInMemory class can be used stand-alone, i.e. without the *SQLite3* engine so it could be used to produce small efficient server software - see the "SQLite3\Samples\01 - In Memory ORM" folder.

7.3.5.1. In-Memory tables

A first way of using static tables, independently from the *SQLite3* engine, is to call the TSQLRestServer. StaticDataCreate method.

This method is only to be called server-side, of course. For the Client, there is no difference between a regular and a static table.

The in-memory TSQLRestStorageInMemory instance handling the storage can be accessed later via the StaticDataServer[] property array of TSQLRestServer.

As we just stated, this primitive but efficient database engine can be used without need of the *SQLite3* database engine to be linked to the executable, saving some KB of code if necessary. It will be enough to handle most basic RESTful requests.

7.3.5.2. In-Memory virtual tables

A more advanced and powerful way of using static tables is to define some classes inheriting from TSQLRecordVirtualTableAutoID, and associate them with some TSQLVirtualTable classes. The TSQLRecordVirtualTableAutoID parent class will specify that associated virtual table modules will behave like normal *SQLite3* tables, so will have their RowID property computed at INSERT).

For instance, the supplied regression tests define such two tables with three columns, named FirstName, YearOfBirth and YearOfDeath, after the published properties definition:

```
TSQLRecordDali1 = class(TSQLRecordVirtualTableAutoID)
private
  fYearOfBirth: integer;
  fFirstName: RawUTF8;
  fYearOfDeath: word;
published
  property FirstName: RawUTF8 read fFirstName write fFirstName;
  property YearOfBirth: integer read fYearOfBirth write fYearOfBirth;
  property YearOfDeath: word read fYearOfDeath write fYearOfDeath;
end;
TSQLRecordDali2 = class(TSQLRecordDali1);
```

Both class types are then added to the TSQLModel instance of the application, common to both Client and Server side:

```
ModelC := TSQLModel.Create(
  [TSQLRecordPeople, (...)
  TSQLRecordDali1, TSQLRecordDali2], 'root');
```

Then, on the Server side, the corresponding Virtual Table modules are associated with those both classes:

```
ModelC.VirtualTableRegister(TSQLRecordDali1, TSQLVirtualTableJSON);
ModelC.VirtualTableRegister(TSQLRecordDali2, TSQLVirtualTableBinary);
```

Thanks to the VirtualTableRegister calls, on the server side, the 'JSON' and 'Binary' Virtual Table modules will be launched automatically when the *SQLite3* DB connection will be initialized:

```
Client := TSQLRestClientDB.Create(ModelC, nil, Demo, TSQLRestServerTest);
```

This TSQLRestClientDB has in fact a TSQLRestServerDB instance running, which will be used for all Database access, including Virtual Table process.

Two files will be created on disk, named 'Dali1.json' and 'Dali2.data'. As stated above, the JSON version will be much bigger, but also more easy to handle from outside the application.

From the code point of view, there is no difference in our ORM with handling those virtual tables, compared to regular TSQLRecord tables. For instance, here is some code extracted from the supplied regression tests:

```
if aClient.TransactionBegin(TSQLRecordDali1) then
try
  // add some items to the file
  V2.FillPrepare(aClient, 'LastName= ("Dali"):');
  n := 0;
  while V2.FillOne do begin
    VD.FirstName := V2.FirstName;
    VD.YearOfBirth := V2.YearOfBirth;
    VD.YearOfDeath := V2.YearOfDeath;
    inc(n);
    Check(aClient.Add(VD,true)=n,Msg);
  end;
  // update some items in the file
  for i := 1 to n do begin
    Check(aClient.Retrieve(i,VD),Msg);
    Check(VD.ID=i);
    Check(IdemPChar(pointer(VD.FirstName),'SALVADOR'));
    Check(VD.YearOfBirth=1904);
    Check(VD.YearOfDeath=1989);
    VD.YearOfBirth := VD.YearOfBirth+i;
    VD.YearOfDeath := VD.YearOfDeath+i;
    Check(aClient.Update(VD),Msg);
  end;
  // check SQL requests
  for i := 1 to n do begin
    Check(aClient.Retrieve(i,VD),Msg);
    Check(VD.YearOfBirth=1904+i);
    Check(VD.YearOfDeath=1989+i);
  end;
  Check(aClient.TableRowCount(TSQLRecordDali1)=1001);
  aClient.Commit;
except
  aClient.Rollback;
end;
```

A Commit is needed from the Client side to write anything on disk. From the Server side, in order to create disk content, you'll have to explicitly call such code on purpose:

As we already noticed, data will be written by default on disk with our TSQLRestStorageInMemory-based virtual tables. In fact, the Commit method in the above code will call TSQLRestStorageInMemory.UpdateFile.

Please note that the *SQLite3* engine will handle any Virtual Table just like regular *SQLite3* tables, concerning the atomicity of the data. That is, if no explicit transaction is defined (via TransactionBegin / Commit methods), such a transaction will be performed for every database modification (i.e. all CRUD operations, as INSERT / UPDATE / DELETE). The TSQLRestStorageInMemory.UpdateToFile method is not immediate, because it will write all table data each time on disk. It is therefore mandatory, for performance reasons, to nest multiple modification to a Virtual Table with such a transaction, for better performance. And in all cases, it is the standard way of using the ORM. If for some reason, you later change your mind and e.g. move your table from the TSQLVirtualTableJSON / TSQLVirtualTableBinary engine to the default

SQLite3 engine, your code could remain untouched.

It is possible to force the In-Memory virtual table data to stay in memory, and the COMMIT statement to write nothing on disk, using the following property:

```
Server.StaticVirtualTable[TSQLRecordDali1].CommitShouldNotUpdateFile := true;
```

In order to create disk content, you'll then have to explicitly call the corresponding method on purpose:

```
Server.StaticVirtualTable[TSQLRecordDali1].UpdateToFile;
```

Since `StaticVirtualTable` property is only available on the Server side, you are the one to blame if your client updates the table data and this update never reaches the disk!

7.3.5.3. In-Memory and ACID

For data stored in memory, the `TSQLRestStorageInMemory` table is ACID.

It means that concurrent access will be consistent and work safely, as expected.

On disk, this kind of table is ACID only when its content is written to the file.

I mean, the whole file which will be written in an ACID way. The file will always be consistent.

The exact process of these in-memory tables is that each time you write some new data to a `TSQLRestStorageInMemory` table:

- It will be ACID in memory (i.e. work safely in concurrent mode);
- Individual writes (INSERT/UPDATE/DELETE) won't automatically be written to file;
- COMMIT will by default write the whole table to file (either as JSON or compressed binary);
- COMMIT won't write the data to file if the `CommitShouldNotUpdateFile` property is set to TRUE;
- ROLLBACK process won't do anything, so won't be ACID - but since your code may later use a real RDBMS, it is a good habit to always write the command, like in the sample code above, as except `aClient.Rollback`.

When you write the data to file, the whole file is rewritten: it seems not feasible to write the data to disk at every write - in this case, *SQLite3* in exclusive mode will be faster, since it will write only the new data, not the whole table content.

This may sound like a limitation, but on our eyes, it could be seen more like a feature. For a particular table, we do not need nor want to have a whole RDBMS/SQL engine, just direct and fast access to a `TObjectList`. The feature is to integrate it with our REST engine, and still be able to store your data in a regular database later (*SQLite3* or external), if it appears that `TSQLRestStorageInMemory` storage is too limited for your process.

7.3.6. Redirect to an external TSQLRest

Sometimes, having all database process hosted in a single process may not be enough. You can use the `TSQLRestServer.RemoteDataCreate()` method to instantiate a `TSQLRestStorageRemote` class which will redirect all ORM operation to a specified `TSQLRest` instance, may be remote (via `TSQLRestClientHttp`) or in-process (`TSQLRestServer`). REST redirection may be enough in simple use cases, when full *Master/slave replication* (page 180) could be oversized.

For instance, in `TTestExternalDatabase` regression tests, you will find the following code:

```
aExternalClient :=  
TSQLRestClientDB.Create(fExternalModel, nil, 'testExternal.db3', TSQLRestServerDB);  
historyDB := TSQLRestServerDB.Create(  
  TSQLModel.Create([TSQLRecordMyHistory], 'history'),
```

```
'history.db3',false);
historyDB.Model.Owner := historyDB;
historyDB.DB.Synchronous := smOff;
historyDB.DB.LockingMode := lmExclusive;
historyDB.CreateMissingTables;
'history.db3',false);
aExternalClient.Server.RemoteDataCreate(TSQLRecordMyHistory,historyDB);
aExternalClient.Server.DB.Synchronous := smOff;
aExternalClient.Server.DB.LockingMode := lmExclusive;
aExternalClient.Server.CreateMissingTables;
...
```

It will create two SQLite3 databases, one main "testExternal.db3", and a separated "history.db3" database. Both will use *synch off* and *lock exclusive* access mode - see *ACID and speed* (page 222) just above.

In the "history.db3" file, there will be the MyHistory table, whereas in testExternal.db3", there won't be any MyHistory table. All TSQLRecordMyHistory CRUD process will be transparently redirected to historyDB.

Then any ORM access from the main aExternalClient to the TSQLRecordMyHistory table via will be redirected, via an hidden TSQLRestStorageRemote instance, to historyDB. There won't be any noticeable performance penalty - on the contrary a separated database will be much better.

An alternative may have been to use the ATTACH TABLE statement at *SQLite3* level, but it will have been only locally, and you will not be able to switch to another database engine. Whereas the RemoteDataCreate() method is generic, and will work with external databases - see below (page 240), even *NoSQL* databases - see below (page 288), or remote *mORMot* servers, accessible via a TSQLRestClientHTTP instance. The only prerequisite is that all TSQLRecord classes in the main model do exist in the redirected database model.

Note that the redirected TSQLRest instance can have its own model, its own authentication and authorization scheme, its own caching policy. It may be of great interest when tuning your application.

Be aware that if you use TRecordReference published fields, the model should better be shared among the local and redirected TSQLRest instances, or at least the TSQLRecord classes should have the same order - otherwise the TRecordReference values will point to the wrong table, depending on the side the query is run.

See *General mORMot architecture - Client Server implementation* (page 82) and *Client-Server implementation - Server side* for some explanation about how this redirection feature interacts with other abilities of the framework.

One practical application of this redirection pattern may be with a typical corporate business. There may be a main *mORMot* server, at corporation headquarters, then local *mORMot* servers at each branch office, hosting applications for end users on the local network:

Corporate Servers Redirection

Each branch office may have its own TSQLRecord dedicated table, with all its data. Some other tables will be shared among local offices, like global configuration.

Creating a dedicated table can be done in Delphi code by creating your own class type:

```

type
  TSQLRecordCustomerAbstract = class // never declared in Model
  ... // here the fields used for Customer business
  end;
  TSQLRecordCustomerA = class(TSQLRecordCustomerAbstract); // for office A
  TSQLRecordCustomerB = class(TSQLRecordCustomerAbstract); // for office B

  TSQLRecordCustomerClass = class of TSQLRecordCustomerAbstract;
  
```

Here, TSQLRecordCustomerA may be part only of the Office A server's TSQLModel, and TSQLRecordCustomerB only of the Office B server's TSQLModel. It will increase security, and, in the main headquarters server, both TSQLRecordCustomerA and TSQLRecordCustomerB classes will be part of the TSQLModel, and dedicated interface-based services will be able to publish some high-level data and statistics about all stored tables.

Then you can use a TSQLRecordCustomerClass variable in your client code, which will contain either TSQLRecordCustomerA or TSQLRecordCustomerB, depending on the place it runs on, and the server it is connected to.

On the main server, each office will have its own storage table in the (external) database, named CustomerA or CustomerB.

You will benefit of the caching abilities - see below (page 360) - of each TSQLRest instance. You may have some cache tuned at a local site, whereas the cache in the main database will remain less aggressive, but safer.

Furthermore, even on a single-siter server, a TSQLRecordHistory table, or more generally any aggregation data may benefit to be hosted locally or on cheap storage, whereas the main database will stay on SSD or SAS. Thanks to this redirection feature, you can tune your hosting as expected.

Finally, if your purpose is to redirect all tables of a given TSQLRestServer to another remote TSQLRestServer (for security or hosting purpose), you may consider using TSQLRestServerRemoteDB instead. This class will redirect all tables to one external instance.

Note that both TSQLRestStorageRemote and TSQLRestServerRemoteDB classes do not support yet the *Virtual Tables* mechanism of *SQLite3*. So if you use those features, you may not be able to run

JOINED queries from the redirected instance: in fact, the main SQLite3 engine will complain about a missing MyHistory table in "testExternal.db3". We will eventually define the needed TSQLVirtualTableRemote and TSQLVirtualTableCursorRemote classes to implement this feature.

Sadly, this redirection pattern won't work if the connection is lost. The main office server needs to be always accessible so that the local offices continue to work. You may consider using *Master/slave replication* (page 180) to allow the local offices to work with their own local copy of the master data. Replication sounds in fact preferred than simple redirection, especially in terms of network and resource use, in some cases.

7.3.7. Virtual Tables to access external databases

As will be stated below (page 240), some external databases may be accessed by our ORM.

The Virtual Table feature of *SQLite3* will allow those remote tables to be accessed just like "native" *SQLite3* tables - in fact, you may be able e.g. to write a valid SQL query with a JOIN between *SQLite3* tables, *MS SQL Server*, *MySQL*, *FireBird*, *PostgreSQL*, *MySQL*, *DB2*, *Informix* and *Oracle* databases, even with multiple connections and several remote servers. Think as an ORM-based *Business Intelligence* from any database source. Added to our code-based reporting engine (able to generate pdf), it could be a very powerful way of consolidating any kind of data.

In order to define such *external* tables, you define your regular TSQLRecord classes as usual, then a call to the VirtualTableExternalRegister() or VirtualTableExternalMap() functions will define this class to be managed as a virtual table, from an external database engine. Using a dedicated external database server may allow better response time or additional features (like data sharing with other applications or languages). Server-side may omit a call to VirtualTableExternalRegister() if the need of an internal database is expected: it will allow custom database configuration at runtime, depending on the customer's expectations (or license).

7.3.8. Virtual tables from the client side

For external databases - see below (page 240) - the SQL conversion will be done on the fly in a more advanced way, so you should be able to work with such virtual tables from the client side without any specific model notification. In this case, you can safely define your tables as TSQLValue1 = class(TSQLRecord), with no further code on client side.

When working with *static* (in-memory / TObjectList) storage, if you expect all ORM features to work remotely, you need to notify the Client-side model that a table is implemented as virtual. Otherwise you may encounter some SQL errors when executing requests, like "*no such column: ID*".

For instance, imagine you defined two in-memory JSON virtual tables on Server side:

```
type
  TSQLServer = class(TSQLRestServerDB)
  private
    FHttpServer: TSQLHttpServer;
  public
    constructor Create;
    destructor Destroy; override;
  end;

constructor TSQLServer.Create;
var aModel: TSQLModel;
begin
  aModel := CreateModel;
  aModel.VirtualTableRegister(TSQLValue1, TSQLVirtualTableJSON);
```

```
aModel.VirtualTableRegister(TSQLValue2, TSQLVirtualTableJSON);
aModel.Owner := self; // model will be released with TSQLServer instance
inherited Create(aModel, ChangeFileExt(ParamStr(0), '.db'), True);
Self.CreateMissingTables(0);
FHttpServer:= TSQLHttpServer.Create('8080', Self);
end;

destructor TSQLServer.Destroy;
begin
  FHttpServer.Free;
  inherited;
end;
```

You will need to specify also on the client side that those TSQLValue1 and TSQLValue2 tables are virtual.

You have several possibilities:

- Inherit each table not from TSQLRecord, but from TSQLRecordVirtualTableAutoID, as was stated above as standard procedure for virtual tables - see *In-Memory virtual tables* (page 232);
- If your tables are defined as TSQLRecord, ensure that the Client side set the table property of its own model to rCustomAutoID;
- If your tables are defined as TSQLRecord, ensure that both Client and Server set the table property of its own model to rCustomAutoID.

First option could be done as such:

```
type
  TSQLValue1 = class(TSQLRecordVirtualTableAutoID)
    (...)
  TSQLValue2 = class(TSQLRecordVirtualTableAutoID)
    (...)
```

Or, in case the table is defined as TSQLValue1 = class(TSQLRecord), the client model could be updated as such:

```
type
  TSQLClient = class(TSQLHttpClient)
  public
    constructor Create;
  end;

constructor TSQLClient.Create;
var aModel: TSQLModel;
begin
  aModel:= CreateModel;
  aModel.Props[TSQLValue1].Kind := rCustomAutoID;
  aModel.Props[TSQLValue2].Kind := rCustomAutoID;
  aModel.Owner := self; // model will be released within TSQLServer instance
  inherited Create('127.0.0.1', '8080', aModel);
  SetUser('Admin', 'synapse');
end;
```

Or, in case the table is defined as TSQLValue1 = class(TSQLRecord), perhaps the easiest way of doing it, is to set the property when creating the shared model:

```
function CreateModel: TSQLModel;
begin
  result:= TSQLModel.Create([TSQLAuthGroup, TSQLAuthUser, TSQLValue1, TSQLValue2]);
  result.Props[TSQLValue1].Kind := rCustomAutoID;
  result.Props[TSQLValue2].Kind := rCustomAutoID;
end;
```

The easiest is definitively to let your static in-memory tables inherit from TSQLRecordVirtualTableAutoID. Just use the framework by the book - see *In-Memory virtual tables*

(page 232).

Once again, this restriction does not apply to below (page 240).

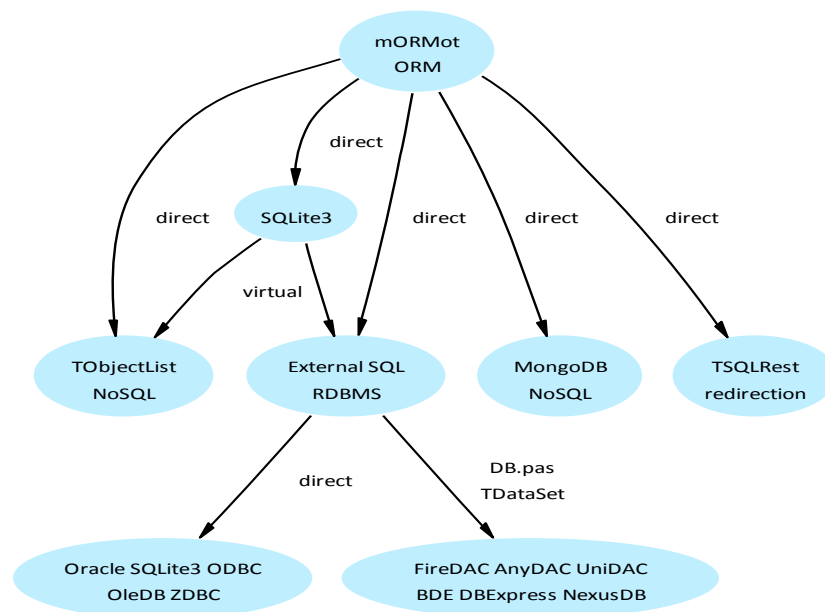

8. External SQL database access

Adopt a mORMot

Our ORM RESTful framework is able to access most available database engines, via a set of generic units and classes. Both SQL and NoSQL engines could be accessed - quite a unique feature in the ORM landscape (in *Delphi*, of course, but also in Java or C# environments).

Remember the diagram introducing *mORMot's Database layer* (page 196):

mORMot Persistence Layer Architecture

The framework still relies on *SQLite3* as its SQL core on the server, but a dedicated mechanism allows access to any remote database, and mixes those tables content with the native ORM tables of the framework. Thanks to the unique *Virtual Tables magic* (page 226) mechanism of *SQLite3*, those external tables may be accessed as native *SQLite3* tables in our SQL statements, even for NoSQL engines.

Mode	Engines
SQL	<i>SQLite3, Oracle, NexusDB, MS SQL, Jet/MSAccess, FireBird, MySQL, PostgreSQL, IBM DB2, IBM Informix</i> See below (page 242)
NoSQL	<i>MongoDB, TObjectList</i> with JSON or binary disk persistence See below (page 279) and <i>In-Memory "static" process</i> (page 231)

You can even mix databases, i.e. the same *mORMot* ORM could persist, at the same time, its data in several databases, some *TSQLRecord* as fast internal *SQLite3* tables or as *TObjectList*, others in a *PostgreSQL* database (tied to an external reporting/SAP engine), and e.g. flat consolidated data in a *MongoDB* instance.

8.1. SynDB direct RDBMS access

External *Relational Database Management System* (RDBMS) can be accessed via our SynDB.pas units. Then, the framework ORM is able to access them via the mORMotDB.pas bridge unit. But you can use the SynDB.pas units directly, without any link to our ORM.

The current list of handled data access libraries is:

Provider	SynDB Unit	RDBMS Engines
<i>SQLite3</i>	SynDBSQLite3.pas	direct <i>SQLite3</i> access (as dll or linked to the exe) See below (page 260)
<i>Oracle</i>	SynDBOracle.pas	direct <i>Oracle</i> access (via OCI) See below (page 257)
<i>OleDB</i>	SynOleDB.pas	<i>MS SQL, Jet/MSAccess</i> or others See below (page 254)
<i>ODBC</i>	SynDBODBC.pas	<i>MS SQL, FireBird, MySQL, PostgreSQL, IBM DB2, Informix</i> or others See below (page 254)
<i>ZeosLib</i>	SynDBZeos.pas	<i>MS SQL, SQLite3, FireBird, MySQL, PostgreSQL</i> See below (page 255)
DB.pas/ TDataset	SynDBDataset.pas	NexusDB and databases supported by DBExpress, FireDAC, AnyDac, UniDAC, BDE... See below (page 260)
HTTP	SynDBRemote.pas	remote access to any SynDB database, over HTTP

This list is not closed, and may be completed in the near future. Any help is welcome here: it is not difficult to implement a new unit, following the patterns already existing. You may start from an existing driver (e.g. *Zeos* or *Alcinoe* libraries). Open Source contribution are always welcome!

Thanks to the design of our SynDB.pas classes, it was very easy (and convenient) to implement *SQLite3* direct access. It is even used for our regression tests, in order to implement stand-alone unitary testing.

An *Oracle* dedicated direct access was added, because all available *OleDB* providers for *Oracle* (i.e. both Microsoft's and Oracle's) do have problems with handling BLOB, and we wanted our Clients to have a light-weight and as fast as possible access to this great database.

In fact, *OleDB* is a good candidate for database access with good performance, Unicode native, with a lot of available providers. Thanks to *OleDB*, we are already able to access to almost any existing database. The code overhead in the server executable will also be much less than with adding any other third-party *Delphi* library. And we will let Microsoft or the *OleDB* provider perform all the testing and debugging for each driver.

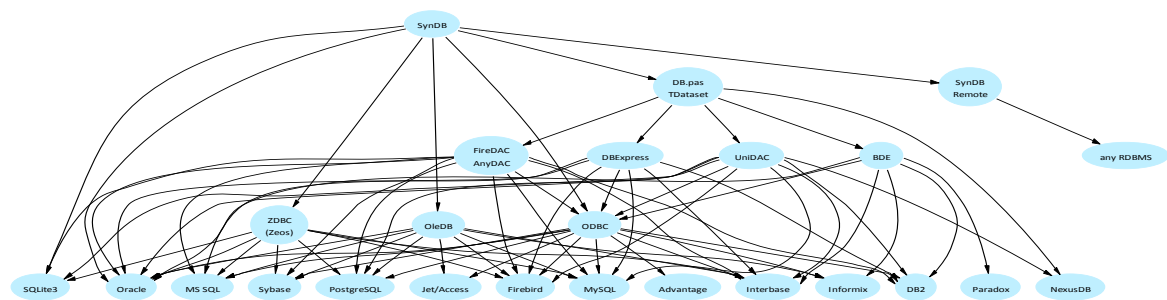

Since revision 1.17, direct access to the *ODBC* layer has been included to the framework database units. It has a wider range of free providers (including e.g. *MySQL* or *FireBird*), and is the official replacement for *OleDB* (next version of *MS SQL Server* will provide only ODBC providers, as far as *Microsoft* warned its customers).

Since revision 1.18, any *ZeosLib* / *ZDBC* driver can be used, with fast direct access to the underlying RDBMS client library. Since the *ZDBC* library does not rely on *DB.pas*, and by-passes the slow *TDataSet* component, its performance is very high. The *ZDBC* maintainers did a lot of optimizations, especially to work with *mORMot*, and this library is a first-class citizen to work with our framework.

Since the same 1.18 revision, *DB.pas* can be used with our *SynDB.pas* classes. Of course, using *TDataSet* as intermediate layer will be slower than the *SynDB.pas* direct access pattern. But it will allow you to re-use any existing (third-party) database connection driver, which could make sense in case of evolution of an existing application, or to use an unsupported database engine.

Last but not least, the *SynDBRemote.pas* unit allows you to create database applications that perform SQL operations on a remote *SynDB* HTTP server, instead of a database server. You can create connections just like any other *SynDB* database, but the transmission will take place over HTTP, with no need to install a database client with your application - see below (page 264).

The following connections are therefore possible:

SynDB Architecture

This diagram is a bit difficult to follow at the latest level - but you got the general layered design, I guess. It will be split into smaller focused diagrams later.

8.1.1. Direct access to any RDBMS engine

The *SynDB.pas* units have the following features:

- Direct fast access via *OleDB*, *ODBC*, *ZDBC*, *Oracle* (OCI) or *SQLite3* (statically linked or via external dll);
- Thin wrapper around any *DB.pas* / *TDataSet* based components (e.g. *NexusDB*, *DBExpress*, *FireDAC*, *AnyDAC*, *UniDAC*, *BDE*...);
- Generic abstract OOP layout, with a restricted set of data types, but able to work with any SQL-based database engine;
- Tested with *MS SQL Server 2008/2012*, *Firebird 2.5.1*, *PostgreSQL 9.2/9.3*, *MySQL 5.6*, *IBM DB2 10.5*, *Oracle 11g*, and the latest *SQLite3* engine;
- Could access any local or remote Database, from any edition of *Delphi* (even *Delphi 7 personal*, the *Turbo Explorer* or *Starter edition*), just for free (in fact, it does not use the *DB.pas* standard unit and all its dependencies);
- Unicode, even with pre-Unicode version of *Delphi* (like *Delphi 7* or 2007), since it uses internally UTF-8 encoding;
- Handle NULL or BLOB content for parameters and results, including stored procedures;
- Avoid most memory copy or unnecessary allocation: we tried to access the data directly from the retrieved data buffer, just as given from *OleDB* / *ODBC* or the low-level database client (e.g. OCI for *Oracle*, or the *SQLite3* engine);
- Designed to achieve the best possible performance on 32-bit or 64-bit Windows: most time is spent

in the database provider (OleDB, ODBC, OCI, *SQLite3*) - the code layer added to the database client is very thin and optimized;

- Could be safely used in a multi-threaded application/server (with dedicated thread-safe methods, usable even if the database client is not officially multi-thread);
- Allow parameter bindings of prepared requests, with fast access to any parameter or column name (thanks to TDynArrayHashed);
- Column values accessible with most *Delphi* types, including Variant or generic string / WideString;
- Available ISQLDBRows interface - to avoid typing try...finally Query.Free end; and allow one-line SQL statement;
- Late-binding column access, via a custom variant type when accessing the result sets;
- two kind of optimized TDataSet result sets: one read-write based on TClientDataSet, and a much faster read-only TSynSQLStatementDataSet
- Direct UTF-8 JSON content creation, with no temporary data copy nor allocation (this feature will be the most used in our JSON-based ORM server);
- High-level catalog / database layout abstract methods, able to retrieve the table and column properties (including indexes), for database reverse-engineering; provide also SQL statements to create a table or an index in a database-abstract manner; those features will be used directly by our ORM;
- Designed to be used with our ORM, but could be used stand-alone (a full *Delphi 7* client executable is just about 200 KB), or even in any existing *Delphi* application, thanks to a TQuery-like wrapper;
- TQuery *emulation class*, for direct re-use with existing code, in replacement to DB.pas based code (including the deprecated BDE technology), with huge speed improvement for result sets (since we bypass the slow TDataSet component);
- Fast and safe remote access over HTTP to any SynDB engine, without the need to deploy the RDBMS client library with the application;
- Free SynDBExplorer tool provided, which is a small but efficient way of running queries in a simple User Interface, on all supported engines, and publish as server or consume as client SynDB remote access over HTTP - see below (page 264); it is also a good sample program of a stand-alone usage of those libraries.

8.1.2. Data types

Of course, our ORM does not need a whole feature set (do not expect to use this database classes with your VCL DB RAD components), but handles directly the basic SQL column types, as needed by our ORM (derived from SQLite's internal column types): NULL, Int64, Double, Currency, DateTime, RawUTF8 and BLOB.

They are defined as such in SynDB.pas:

```
TSQLDBFieldType =  
(ftUnknown, ftNull, ftInt64, ftDouble, ftCurrency, ftDate, ftUTF8, ftBlob);
```

TSQLDBFieldType	Content
ftNull	Maps the SQL NULL value
ftInt64	Any <i>integer</i> value, with 64-bit resolution
ftDouble	Any <i>floating-point</i> value, with 64-bit (double) resolution
ftCurrency	Fixed <i>financial</i> type, with up to 4 fixed decimal digits (currency)

ftDate	Date and time, mapping the Delphi TDateTime type
ftUTF8	Unicode text, encoded as UTF-8, with or without size limit
ftBlob	Binary content, stored as a RawByteString

Those types will map low-level database-level access types, not high-level *Delphi* types as `TSQLFieldType` defined in `mORMot.pas`, or the generic huge `TFieldType` as defined in the standard `VCL DB.pas` unit. In fact, it is more tied to the standard *SQLite3* generic types, i.e. NULL, INTEGER, REAL, TEXT, BLOB (with the addition of a `ftCurrency` and `ftDate` type, for better support of most DB engines) see <http://www.sqlite.org/datatype3.html>.

You can note that the only string type handled here uses UTF-8 encoding (implemented using our `RawUTF8` type), for cross-*Delphi* true Unicode process. Code can access to the textual data via `variant`, `string` or `widestring` variables and parameters, but our units will use UTF-8 encoding internally - see *Unicode and UTF-8* (page 105). It will therefore interface directly with our ORM, which uses the same encoding. Of course, if the column was not defined as Unicode text in the database, any needed conversion to/from the corresponding charset will take place at the data provider level; but in your user code, you will have always access to the Unicode content.

BLOB columns or parameters are accessed as `RawByteString` variables, which may be mapped to a standard `TStream` via our `TRawByteStringStream`.

8.1.3. Database types

In addition to raw data access, the `SynDB.pas` unit handles some SQL-level generation, which will be used by our *Object-Relational Mapping* (page 130) kernel.

The following RDBMS database engines are defined as such in `SynDB.pas`:

```
TSQLDBDefinition = (dUnknown, dDefault, dOracle, dMSSQL, dJet,
  dMySQL, dSQLite, dFirebird, dNexusDB, dPostgreSQL, dDB2, dInformix);
```

TSQLDBDefinition	RDBMS tested
dDefault	Any database, following the SQL-92 standard
dOracle	Oracle 11g
dMSSQL	MS SQL Server 2008/2012
dJet	Jet/MSAccess (under <i>Win32</i> only)
dMySQL	MySQL 5.6
dSQLite	SQLite3 3.7.11 and up (we supply the latest version for static linking)
dFirebird	Firebird 2.5.1
dNexusDB	NexusDB 3.11
dPostgreSQL	PostgreSQL 9.2/9.3
dDB2	IBM DB2 10.5
dInformix	IBM Informix 11.70

The above versions have been tested, but newer or older revisions may also work. Your feedback is welcome: we cannot achieve to test all possible combinations of databases and clients on our own!

The SynDB.pas unit is able to generate the SQL statements of those engines, for a CREATE TABLE / CREATE INDEX command, retrieve metadata (e.g. the tables and fields information), compute the right limit/offset syntax for a SELECT, compute multi-INSERT statements - see below (page 358), check the SQL keywords, define specific schema/owner naming conventions, process date and time values, handle errors and exceptions, or even create a database.

8.1.4. SynDB Units

Here are the units implementing the external database-agnostic features:

File	Description
SynDB.pas	abstract database direct access classes
SynOleDB.pas	OleDB direct access classes
SynDBODBC.pas	ODBC direct access classes
SynDBZeos.pas	ZDBC direct access classes
SynDBOracle.pas	Oracle DB direct access classes (via OCI)
SynDBSQLite3.pas	SQLite3 direct access classes
SynDBDataset.pas SynDBFireDAC.pas SynDBUniDAC.pas SynDBNexusDB.pas SynDBBDE.pas	TDataset (DB.pas) access classes
SynDBRemote.pas	remote access over HTTP
SynDBVCL	read/only TSynSQLStatementDataSet result sets
SynDBMidasVCL	read/write TClientDataSet result sets

It is worth noting that those units only depend on SynCommons.pas, therefore are independent of the ORM part of our framework (even the remote access). They may be used separately, accessing all those external databases with regular SQL code. Since all their classes inherit from abstract classes defined in SynDB.pas, switching from one database engine to another (even a remote HTTP access) is just a matter of changing one class type.

8.1.5. SynDB Classes

The data is accessed via three families of classes:

- *Connection properties*, which store the database high-level properties (like database implementation classes, server and database name, user name and password);
- *Connections*, which implements an actual connection to a remote database, according to the specified *Connection properties* - of course, there can be multiple *connections* for the same *connection properties* instance;
- *Statements*, which are individual SQL queries or requests, which may be multiple for one existing *connection*.

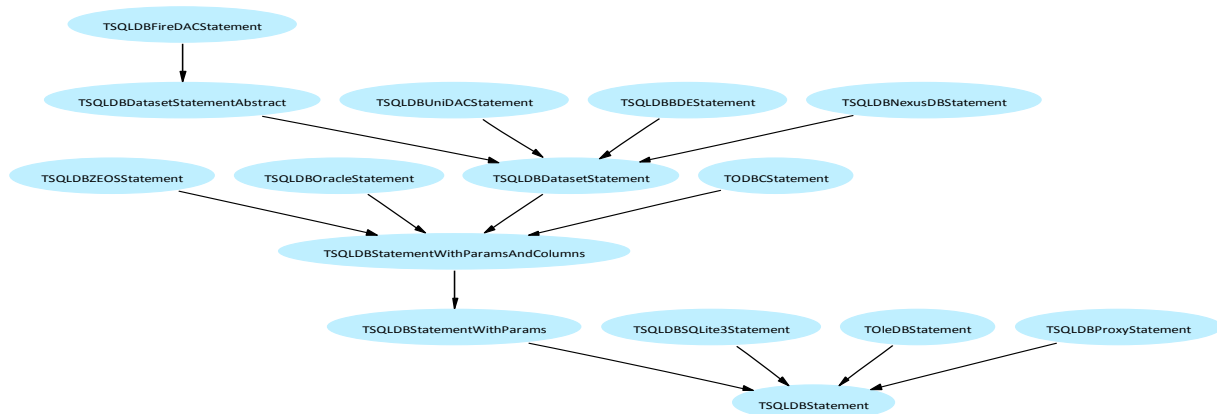

Here is the general class hierarchy, for all available remote *connection properties*:

Those classes are the root classes of the SynDB.pas units, by which most of your database process will be implemented. For instance, the *mORMot* framework ORM only needs a given *TSQldbConnectionProperties* instance to access any external database.

```
graph TD; TODBCConnection --> TSQLDBConnectionThreadSafe; TOleDBConnection --> TSQLDBConnectionThreadSafe; TSQLDBBDEConnection --> TSQLDBConnectionThreadSafe; TSQLDBOracleConnection --> TSQLDBConnectionThreadSafe; TSQLDBFireDACConnection --> TSQLDBConnectionThreadSafe; TSQLDBUniDACConnection --> TSQLDBConnectionThreadSafe; TSQLDBZEOSConnection --> TSQLDBConnectionThreadSafe; TSQLDBNexusDBConnection --> TSQLDBConnectionThreadSafe; TSQLDBSQLite3Connection --> TSQLDBConnection; TSQLDBProxyConnection --> TSQLDBConnection; TSQLDBConnectionThreadSafe --> TSQLDBConnection;
```

Each connection may create a corresponding *statement* instance:

In the above hierarchy, `TSQLDBDatasetStatementAbstract` is used to allow the use of custom classes for parameter process, e.g. `TADParams` for FireDAC (which features *Array DML*).

Some dedicated Exception classes are also defined:

Check the Test01eDB.dpr sample program, located in SQLite3 folder, using our Syn01eDB unit to connect to a local *MS SQL Server 2008 R2 Express edition*, which will write a file with the JSON representation of the Person. Address table of the sample database *AdventureWorks2008R2*.

8.1.6. ISQLDBRows interface

The easiest is to stay at the `TSQLDBConnectionProperties` level, using the `Execute()` methods of this instance, and access any returned data via an `ISQLDBRows` interface. It will automatically use a thread-safe connection to the database, in an abstracted way.

Typical use of SynDB.pas classes could be:

- Initialize a shared `TSQldbConnectionProperties` instance;
- Execute statements directly from this instance's `Execute*()` methods.

Defining a database connection is as easy as:

```
var Props: TSQLDBConnectionProperties;
...
Props := ToleDBMSSQLConnectionProperties.Create('.\SQLEXPRESS','AdventureWorks2008R2','', '');
try
    UseProps(Props);
finally
    Props.Free;
end;
```

Depending on the `TSQLEDBConnectionProperties` sub-class, input parameters do vary. Please refer to the documentation of each `Create()` constructor to set all parameters as expected.

Then any sub-code is able to execute any SQL request, with optional bound parameters, as such:

```
procedure UseProps(Props: TSQLDBConnectionProperties);
var I: ISQLDBRows;
begin
  I := Props.Execute('select * from Sales.Customer where AccountNumber like ?', ['AW000001%']);
  while I.Step do
    assert(Copy(I['AccountNumber'], 1, 8) = 'AW000001');
end;
```

In this procedure, no TSQLDBStatement is defined, and there is no need to add a try ... finally Query.Free; end; block.

In fact, the MyConnProps.Execute method returns a TSQLDBStatement instance as a ISQLDBRows, which methods can be used to loop for each result row, and retrieve individual column values. In the code above, I['FirstName'] will in fact call the I.Column[] default property, which will return the column value as a variant. You have other dedicated methods, like ColumnUTF8 or ColumnInt, able to retrieve directly the expected data.

Note that all bound parameters will appear within the SQL statement, when logged using our TSynLog classes - see below (page 642).

8.1.7. Using properly the ISQLDBRows interface

You may have noticed in the previous code sample, that we used a UseProps() sub-procedure. This was made on purpose.

We may have written our little test as such:

```
var Props: TSQLDBConnectionProperties;
  I: ISQLDBRows;
...
Props := TOLDBMSSQLConnectionProperties.Create('.\SQLEXPRESS', 'AdventureWorks2008R2', '', '');
try
  I := Props.Execute('select * from Sales.Customer where AccountNumber like ?', ['AW000001%']);
  while I.Step do
    assert(Copy(I['AccountNumber'], 1, 8) = 'AW000001');
  finally
    Props.Free;
end;
end;
```

In fact, you should **not** use this pattern. This code will lead to an unexpected *access violation* at runtime.

Behind the scene, as will be detailed below (page 386), the compiler is generating some hidden code to finalize the I: ISQLDBRows local variable, as such:

```
...
finally
  Props.Free;
end;
I := nil; // this is generated by the compiler, just before the final "end;"
end;
```

So ISQLDBRows is released *after* the Props instance, and an access violation occurs.

The correct way to write is either to use a sub-function (which will release the local ISQLDBRows when the function leaves), or explicitly release the interface variable:

```
  while I.Step do
    assert(Copy(I['AccountNumber'], 1, 8) = 'AW000001');
  finally
```

```
'select * from Sales.Customer where AccountNumber like ?',
['AW000001%'],@Customer) do begin
  Customer := ColumnIndex('AccountNumber');
  while Step do
    assert(Copy(ColumnString(Customer),1,8)='AW000001');
  end;
end;
```

But to be honest, after profiling, most of the time is spend in the Step method, especially in FRowSet.GetData. In practice, I was not able to notice any speed increase worth mentioning, with the code above.

Our name lookup via a hashing function (i.e. TDynArrayHashed) just does its purpose very well.

On the contrary the *Ole-Automation* based late-binding was found out to be slower, after profiling. In fact, the Row.AccountNumber expression calls an hidden DispInvoke function, which is slow when called multiple times. Our SynCommons.pas unit is able to hack the VCL, and by patching the VCL code in-memory, will call an optimized version of this function. Resulting speed is very close to direct Column['AccountNumber'] call. See *SDD # DI-2.2.3*.

8.1.9. TDataSet and SynDB

Since our SynDB.pas unit does not rely on the Delphi's DB.pas unit, its result sets do not inherit from the TDataSet.

As a benefit, those result sets will be much faster, when accessed from your object code.

But as a drawback, you won't be able to use them in your regular VCL applications.

In order to easily use the SynDB.pas unit with VCL components, you can create TDataSet results sets from any SynDB query.

You have access to two kind of optimized TDataSet result sets:

TDataSet class	Operation	Unit	Remark
TClientDataSet	read write	SynDBMidasVCL.pas	Slow due to memory copy
TSynSQLStatementDataSet	read only	SynDBVCL.pas	Fast due to direct mapping

You can therefore assign the result of a SynDB request to any TDataSource, as such for our fast TSynSQLStatementDataSet read/only storage:

```
ds1.DataSet.Free; // release previous TDataSet
ds1.DataSet := ToDataSet(ds1,aProps.Execute('select * from people',[]));
```

or for a TClientDataSet kind of in-memory storage:

```
ds1.DataSet.Free; // release previous TDataSet
ds1.DataSet := ToClientDataSet(ds1,aProps.Execute('select * from people',[]));
```

See sample "17 - TClientDataset use" to find out more about using such TDataSet, including some speed information. You need to have run the TestSQL3.dpr set of regression tests before, to have the expected *SQLite3* data file.

8.1.10. TQuery emulation class

The SynDB.pas unit offers a TQuery-like class. This class emulates regular TQuery classes, without inheriting from DB.pas nor its slow TDataSet.

It mimics basic TQuery VCL methods, with the following benefits:

- Does not inherit from TDataSet, but has its own light implementation over SynDB.pas ISQLDBStatement result sets, so is usually much faster;
- Will be also faster for field and parameters access by name - or even index;
- Is Unicode-ready, even with older pre-Unicode version of Delphi, able to return the data as WideString, independently from the current system charset;
- You can still create a TDataSet from SynDB's TQuery, via the ToDataSet() function defined in SynDBVCL.pas.

Of course, since it is not a TDataSet component, you can not use it directly as a regular replacement for your RAD code.

But if your application is data-centric and tried to encapsulate its business logic with some classes - i.e. if it tried to properly implement OOP, not RAD - you can still replace directly your existing code with the TQuery emulator:

```
Q := TQuery.Create(aSQLDBConnection);
try
  Q.SQL.Clear; // optional
  Q.SQL.Add('select * from DOMAIN.TABLE');
  Q.SQL.Add(' WHERE ID_DETAIL=:detail;');
  Q.ParamByName('DETAIL').AsString := '123420020100000430015';
  Q.Open;
  Q.First; // optional
  while not Q.Eof do begin
    assert(Q.FieldByName('id_detail').AsString='123420020100000430015');
    Q.Next;
  end;
  Q.Close; // optional
finally
  Q.Free;
end;
```

You should better use TSQLDBStatement instead of this wrapper, but having such code-compatible TQuery replacement could make easier some existing code upgrade, especially for *Legacy code and existing projects* (page 77).

For instance, it will help to avoid deploying the deprecated BDE, generate (much) smaller executable, access any database without paying a big fee, avoid rewriting a lot of existing code lines of a big legacy application, or let your old application communicate with the database over plain HTTP, without the need to install any RDBMS client - see below (page 264).

8.1.11. Storing connection properties as JSON

You can use a TSynConnectionDefinition storage to persist the connection properties as a JSON content, in memory or file.

Typical stored content could be:

```
{
  "Kind": "TSQLDBSQLite3ConnectionProperties",
  "ServerName": "database.db3",
  "DatabaseName": "",
  "UserID": "",
  "Password": "Ptv1PA=="
}
```

The "Kind" parameter will be used to store the actual TSQLDBConnectionProperties class name. So switching from one database to another could be easily done at runtime, by modifying a setting stored e.g. in a JSON text file, without the need to recompile the application. Note that the SynDB* units implementing the class should be compiled within the executable, e.g. SynDBSQLite3.pas for TSQLDBSQLite3ConnectionProperties, or SynDBZeos.pas for TSQLDBZeosConnectionProperties.

To create a new `TSQLDBConnectionProperties` instance from a local JSON file, you could simply write:

```
var Props: TSQLDBConnectionProperties;  
...  
Props := TSQLDBConnectionProperties.CreateFromFile('localDBsettings.json');
```

The password will be encrypted and encoded as *Base64* in the file, for safety. You could use `TSynConnectionDefinition`'s `Password` and `PasswordPlain` properties to compute the value to be written on disk.

Since `TSynConnectionDefinition` is a `TSynPersistent` class, you can nest it into a `TSynAutoCreateFields` instance containing all settings of your application.

Then `mORMot.pas`' `ObjectToJSON/ObjectToJSONFile` and `JSONToObject/JSONFileToObject` functions could be used for persistence as a file or in a database, of those global settings.

See also `TSQLRest.CreateFrom()` for a similar feature at ORM/REST level, and function `TSQLRestCreateFrom(aDefinition: TSynConnectionDefinition)` as defined in `mORMotDB.pas` which is able to create a regular local ORM if `aDefinition.Kind` is a `TSQLRest` class name, but also an ORM with external DB storage - see below (page 269) - if `aDefinition.Kind` is a `TSQLDBConnectionProperties` class name.

8.2. SynDB clients

From the SynDB.pas logical point of view, here is how databases can be accessed:

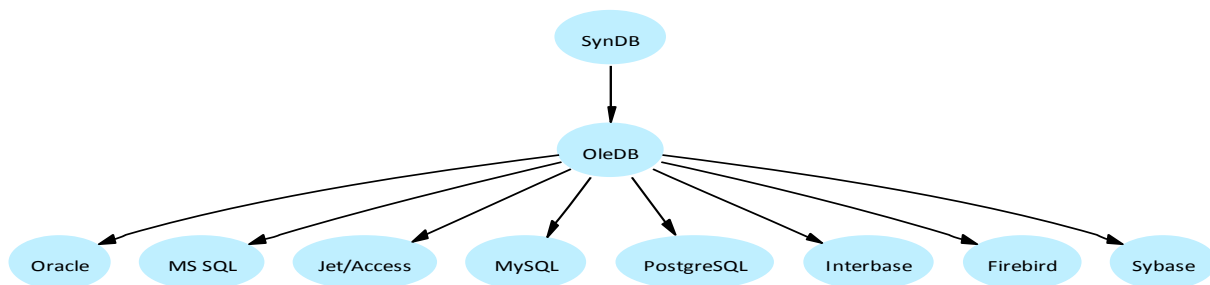

SynDB First Level Providers

Of course, the physical implementation is more complicated, as was stated in *SynDB Architecture* (page 243).

We will now detail how these available database connections are interfaced as SynDB.pas classes.

8.2.1. OleDB or ODBC to rule them all

OleDB (Object Linking and Embedding, Database, sometimes written as OLE DB or OLE-DB) is an API designed by Microsoft for accessing data from a variety of sources in a uniform manner.

SynDB and OleDB

Of course, you have got the *Microsoft SQL Native Client* to access the MS SQL Server 2005/2008/2012, but *Oracle* provides a native OleDB provider (even if we found out that this Oracle provider, including the Microsoft's version, have problems with BLOBs). Do not forget about the *Advantage Sybase OleDB* driver and such...

If you plan to connect to a MS SQL Server, we highly recommend using the `TOLEDBMSSQL2012ConnectionProperties` class, corresponding to `SQLNCLI11`, part of the *Microsoft® SQL Server® 2012 Native Client*, it is able to connect to any revision of MS SQL Server (event MS SQL Server 2008), and was found to be the more stable. You can get it from <http://www.microsoft.com/en-us/download/details.aspx?id=29065..> by downloading the `sqlncli.msi` corresponding to your Operating System. Most of the time, you should download the X64 Package of `sqlncli.msi`, which will also install the 32-bit version of *SQL Server Native Client*, so will work for a 32-bit Delphi executable - the X86 Package is for a 32-bit Windows system only.

ODBC (Open DataBase Connectivity) is a standard C programming language middle-ware API for accessing database management systems (DBMS). *ODBC* was originally developed by Microsoft during the early 1990s, then was deprecated in favor to *OleDB*. More recently, Microsoft is officially deprecating *OleDB*, and urge all developers to switch to the open and cross-platform *ODBC* API for native connection. Back & worse strategy from Micro\$oft... one more time!

<http://blogs.msdn.com/b/sqlnativeclient/archive/2011/08/29/microsoft-is-aligning-with-odbc-for-native-relational-data-access.aspx..>

SynDB and ODBC

By using our own *OleDB* and *ODBC* implementations, we will for instance be able to convert directly the *OleDB* or *ODBC* binary rows to JSON, with no temporary conversion into the *Delphi* high-level types (like temporary string or variant allocations). The resulting performance is much higher than using standard *TDataSet* or other components, since we will bypass most of the layers introduced by *BDE/dbExpress/FireDAC/AnyDAC* component sets.

Most *OleDB* / *ODBC* providers are free (even maintained by the database owner), others will need a paid license.

It is worth saying that, when used in a *mORMot* Client-Server architecture, object persistence using an *OleDB* or *ODBC* remote access expects only the database instance to be reachable on the Server side. Clients could communicate via standard HTTP, so won't need any specific port forwarding or other IT configuration to work as expected.

8.2.2. ZEOS via direct ZDBC

8.2.2.1. The mORMot's best friend

ZeosLib, aka *Zeos*, is a Open Source library which provides native access to many database systems, developed for *Delphi*, *Kylix* and *Lazarus / FreePascal*.

It is fully object-oriented and with a totally modular design. It connects to the databases by wrapping their native client libraries, and makes them accessible via its abstract layer, named *ZDBC*. Originally, *ZDBC* was a port of *JDBC 2.0* (Java Database Connectivity API) to Object Pascal. Since that time the API was slightly extended but the main ideas remain unchanged, so official *JDBC 2.0* specification is the main entry point to the *ZDBC* API.

The latest 7.x branch was deeply re-factored, and new methods and performance optimization were introduced. In fact, we worked hand by hand with Michael (the main contributor of *ZeosLib*) to ensure that the maximum performance is achieved. The result is an impressive synergy of *mORMot* and *ZeosLib*, for both reading or writing data.

Since revision 1.18 of the framework, we included direct integration of *ZeosLib* into *mORMot* persistence layer, with direct access to the *ZDBC* layer. That is, our *SynDBZeos* unit does not reference *DB.pas*, but access directly to the *ZDBC* interfaces.

SynDB and Zeos / ZDBC

Such direct access, by-passing the VCL DB.pas layer and its TDataSet bottleneck, is very close to our SynDB.pas design. As such, *ZeosLib* is a first class citizen library for *mORMot*. The SynDBZeos unit is intended to be a privileged access point to external SQL databases.

8.2.2.2. Recommended version

We recommend that you download the 7.2 branch of *Zeos/ZDBC*, which is the current *trunk*, at the time of this writing.

A deep code refactoring has been made by the *Zeos/ZDBC* authors (thanks a lot Michael, aka *EgonHugeist!*), even taking care of *mORMot* expectations, to provide the best performance and integration, e.g. for UTF-8 content processing.

In comparison with the previous 7.1 release, speed increase can be of more than 10 times, depending on the database back-end and use case!

When writing data (i.e. *Add/Update/Delete* operations), *Array binding* support has been added to the *Zeos/ZDBC* 7.2 branch, and our SynDBZeos unit will use it if available, detecting if *IZDatabaseInfo.SupportsArrayBindings* property is true - which will be the case for *Oracle* and *FireBird* providers by now. Our ORM benefits from it, when processing in BATCH mode, even letting ZDBC creates the optimized SQL - see below (page 358).

Performance at reading is very high, much higher than any other DB.pas based library, in case of single record retrieval. For instance, *TSQLDBZEOSStatement.ColumnsToJSON()* will avoid most temporary memory allocation, and is able to create the JSON directly from the low-level ZDBC binary buffers.

If you need to stick to a version prior to 7.2, and want to work as expected with a *SQLite3* back-end (but you shouldn't have any reason to do so, since *Zeos* will be slower compared to *SynDBSQLite3*), you need to apply some patches for *Zeos* < 7.2, in methods *TZSQLiteCAPIPreparedStatement.ExecuteQueryPrepared()* and *TZSQLiteResultSet.FreeHandle*, as stated as comment at the beginning of *SynDBZeos.pas*.

8.2.2.3. Connection samples

If you want e.g. to connect to MySQL via *Zeos/ZDBC*, follow those steps:

- Download "*Windows (x86, 32-bit), ZIP Archive*" from <http://dev.mysql.com/downloads/connector/c..> - then extract the archive: only *libmysql.dll* is needed and should be placed either in the executable folder, either in the system PATH;
- Connect as usual e.g. via

```
fConnection := TSQLDBZEOSConnectionProperties.Create(  
  'zdbc:mysql://192.168.2.60:3306/world?username=root;password=dev', '', '', '');
```

- Or using the `URI()` method:

```
fConnection := TSQldbZEOSConnectionProperties.Create(  
  TSQldbZEOSConnectionProperties.URI(dMySQL, '192.168.2.60:3306'), 'root', 'dev');
```

For *PostgreSQL*, the *Zeos* driver needs only `libpq.dll` and `libintl.dll` e.g. from <http://www.enterprisedb.com/products-services-training/pgbindownload..>

```
PropsPostgreSQL := TSQldbZEOSConnectionProperties.Create(  
  TSQldbZEOSConnectionProperties.URI(dPostgreSQL, 'localhost:5432'),  
  'dbname', 'username', 'password');
```

You may therefore use the `TSQldbZEOSConnectionProperties.URI()` method to compute the expected ZDBC connection string:

```
PropsOracle := TSQldbZEOSConnectionProperties.Create(  
  TSQldbZEOSConnectionProperties.URI(dOracle, '', 'oci64\oci.dll'),  
  'tnsname', 'user', 'pass');  
PropsFirebirdEmbedded := TSQldbZEOSConnectionProperties.Create(  
  TSQldbZEOSConnectionProperties.URI(dFirebird, '', 'Firebird\fbembed.dll'),  
  'databasefilename', '', '');  
PropsFirebirdRemote := TSQldbZEOSConnectionProperties.Create(  
  TSQldbZEOSConnectionProperties.URI(dFirebird, '192.168.1.10:3055',  
  'c:\Firebird_2_5\bin\fbclient.dll', false),  
  '3camadas', 'sysdba', 'masterkey');
```

See `TSQldbZEOSConnectionProperties` documentation for further information about the expected syntax, and available abilities of this great open source library.

8.2.3. Oracle via OCI

For our framework, and in completion to *SynDBZeos* or our *SynOLEDB* / *SynDBODBC* units, the *SynDBOracle* unit has been implemented. It allows *direct access* to any remote Oracle server, using the *Oracle Call Interface*.

Oracle Call Interface (OCI) is the most comprehensive, high performance, native unmanaged interface to the Oracle Database that exposes the full power of the Oracle Database. A direct interface to the `oci.dll` library was written, using our DB abstraction classes introduced in *SynDB.pas*.

We tried to implement all best-practice patterns detailed in the official *Building High Performance Drivers for Oracle* reference document.

Resulting speed is quite impressive: for all requests, *SynDBOracle* is 3 to 5 times faster than a *SynOLEDB* connection using the native *OLEDB Provider* supplied by Oracle. A similar (even worse) speed penalty has been observed in comparison with the official ODBC driver from Oracle, via a *SynDBODBC*-based connection. For more detailed numbers, see *Data access benchmark* (page 199).

8.2.3.1. Optimized client library

It is worth saying that, when used in a *mORMot* Client-Server architecture, object persistence using an *Oracle* database expects only the Oracle instance to be reachable on the Server side, just like with *OLEDB* or *ODBC*.

Here are the main features of this *SynDBOracle* unit:

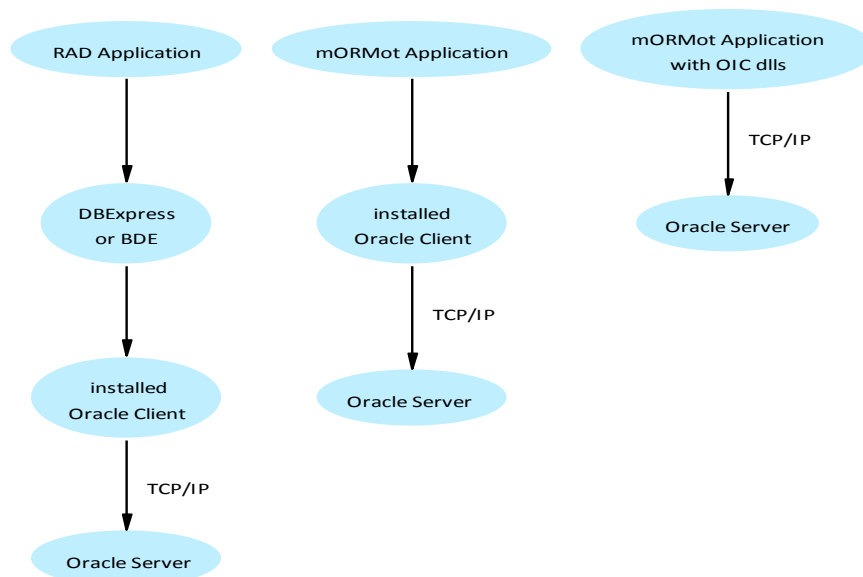

- *Direct access* to the *Oracle Call Interface* (OCI) client, with no BDE, Midas, DBExpress, nor *OLEDB* / *ODBC* provider necessary;
- Dedicated to work with *any version* of the Oracle OCI interface, starting from revision 8;
- *Optimized for the latest features* of Oracle 11g/12c (e.g. using native `Int64` for retrieving `NUMBER` fields with no decimal);

- Able to work with the *Oracle Instant Client for No Setup* applications (installation via file/folder copy);
- *Natively Unicode* (uses internal UTF-8 encoding), for all version of *Delphi*, with special handling of each database char-set;
- Tried to achieve *best performance available* from every version of the Oracle client;
- Designed to work under *any version of Windows*, either in 32 or 64-bit architecture (but the OCI library must be installed in the same version than the compiled *Delphi* application, i.e. only 32-bit for this current version);
- *Late-binding* access to column names, using a new dedicated Variant type (similar to Ole Automation runtime properties);
- Connections are *multi-thread ready* with low memory and CPU resource overhead;
- Can use connection strings like ' '//host[:port]/[service_name]', avoiding use of the TNSNAME.ORA file;
- Use *Rows Array* and *BLOB fetching*, for best performance (ZEOS/ZDBC did not handle this, for instance);
- Handle *Prepared Statements* - on both client and server side, if available - server side caching lead to up a 3 times speed boost, from our experiment;
- Implements *Array Binding* for very fast bulk modifications - insert, update or deletion of a lot of rows at once;
- Implements binding of a TInt64DynArray or TRawUTF8DynArray as parameter, e.g. within a SELECT .. IN where clause;
- *Cursor support*, which is pretty common when working with stored procedures and legacy code.

Of course, this unit is perfectly integrated with the *External SQL database access* (page 240) process. For instance, it features native *export to JSON* methods, which will be the main entry point for our ORM framework. And *Array binding* is handled directly during BATCH sequences - see below (page 351).

8.2.3.2. Direct connection without Client installation

You can use the latest version of the *Oracle Instant Client* (OIC) provided by Oracle - see <http://www.oracle.com/technetwork/database/features/instant-client..> - which allows to run client applications without installing the standard (huge) Oracle client or having an ORACLE_HOME.

Oracle Connectivity with SynDBOracle

Just deliver the few dll files in the same directory than the application (probably a *mORMot* server), and it will work at amazing speed, with all features of Oracle (other stand-alone direct Oracle access library rely on deprecated Oracle 8 protocol).

8.2.3.3. Oracle Wallet support

Password credentials for connecting to databases can now be stored in a client-side *Oracle Wallet*, a secure software container used to store authentication and signing credentials.

This wallet usage can simplify large-scale deployments that rely on password credentials for connecting to databases. When this feature is configured, application code, batch jobs, and scripts no longer need embedded user names and passwords. Risk is reduced because such passwords are no longer exposed in the clear, and password management policies are more easily enforced without changing application code whenever user names or passwords change.

In order to use this feature, set `TSQldbOracleConnectionProperties.UseWallet` to true before connecting to the database.

Wallet configuration is performed on the computer where server is running. You must perform a full Oracle client setup: OIC - see *Direct connection without Client installation* (page 258) - does not give access to wallet authentication.

Steps to create a Wallet:

1) Create a folder for you wallet:

```
> mkdir c:\OraWallets
```

2) Create a wallet on the client by using the following syntax at the command line:

```
> mkstore -wr1 c:\OraWallets -create
```

Oracle will ask you for the main wallet password - remember it!

3) Create database connection credentials in the wallet by using the following syntax at the command line:

```
mkstore -wr1 c:\OraWallets -createCredential TNS_alias_name_from_tnsnames_ora username password
```

where password is the password of database user. Oracle will ask you the wallet password - use the main password from previous step.

4) In the client `sqlnet.ora` file, add the `WALLET_LOCATION` parameter and set it to the directory location of the wallet and set `SQLNET.WALLET_OVERRIDE` parameter to TRUE:

```
SQLNET.WALLET_OVERRIDE = TRUE
WALLET_LOCATION =
(
  SOURCE =
    (METHOD = FILE)
    (METHOD_DATA =
      (DIRECTORY = c:\OraWallets)
    )
)
```

You can not drop a database while it has a wallet. You need to delete wallet credentials via the next command:

```
mkstore -wr1 wallet_location -deleteCredential db_alias
```

Oracle will ask to enter the wallet password - use the same password which you used during wallet

creation.

Note that there is also an *Oracle Wallet Manager* tool available with your database distribution, if you prefer to use a GUI tool for database administration.

See https://docs.oracle.com/cd/B28359_01/network.111/b28530/asowalet.htm..

8.2.4. SQLite3

For our ORM framework, we implemented an efficient *SQLite3* wrapper, joining the *SQLite3* engine either statically (i.e. within the main exe) or from external *sqlite3.dll*.

It was an easy task to let the *SynSQLite3.pas* unit be called from our *SynDB.pas* database abstract classes. Adding such another Database is just a very thin layer, implemented in the *SynDBSQLite3.pas* unit.

If you want to link the *SQLite3* engine to your project executable, ensure you defined the *SynSQLite3Static.pas* unit in your uses clause. Otherwise, define a *TSQLite3LibraryDynamic* instance to load an external *sqlite3.dll* library:

```
FreeAndNil(sqlite3); // release any previous instance (e.g. static)
sqlite3 := TSQLite3LibraryDynamic.Create;
```

To create a *connection property* to an existing *SQLite3* database file, call the *TSQLDBSQLite3ConnectionProperties*. Create constructor, with the actual *SQLite3* database file as *ServerName* parameter, and (optionally the proprietary encryption password in *Password* - available since rev. 1.16); others (*DataBaseName*, *UserID*) are just ignored.

These classes will implement an internal statement cache, just as the one used for *TSQLRestServerDB*. In practice, using the cache can make process up to two times faster (when processing small requests).

When used within the *mORMot* ORM, you have therefore two ways of accessing the *SQLite3* engine:

- Either directly from the ORM core;
- Either virtually, as external tables.

SynDB, mORMot and SQLite3

If your *mORMot*-based application purpose is to only use one centralized *SQLite3* database, it does not make sense to use *SynDBSQLite3* external tables. But if you want, in the future, to be able to connect to any external database, or to split your data in several database files, using those external *SQLite3* tables do make sense. Of course, the *SQLite3* engine library itself will be shared with both internal and external process.

8.2.5. DB.pas libraries

Since revision 1.18 of the framework, a new *SynDBDataset.pas* unit has been introduced, able to

interface any DB.pas based library to our SynDB.pas classes, using TDataset to retrieve the results. Due to the TDataset design, performance is somewhat degraded in respect to direct SynDB.pas connection (e.g. results for *SQLite3* or *Oracle*), but it also opens the potential database access.

Some dedicated providers have been published in the SynDBDataset sub-folder of the *mORMot* source code repository. Up to now, *FireDAC* (formerly *AnyDAC*), *UniDAC* and *BDE* libraries are interfaced, and a direct connection to the *NexusDB* engine is available.

Since there are a lot of potential combinations here - see *SynDB Architecture* (page 243) - feedback is welcome. Due to our Agile process, we will first stick to the providers we need and use. It is up to *mORMot* users to ask for additional features, and provide wrappers, if possible, or at least testing abilities. Of course, *DBExpress* will benefit to be integrated, even if *Embarcadero* just acquired *AnyDAC* and revamped/renamed it as *FireDAC* - to make it the new official platform.

8.2.5.1. NexusDB access

NexusDB is a "royalty-free, SQL:2003 core compliant, Client/Server and Embedded database system, with features that rival other heavily licensed products" (vendor's terms).

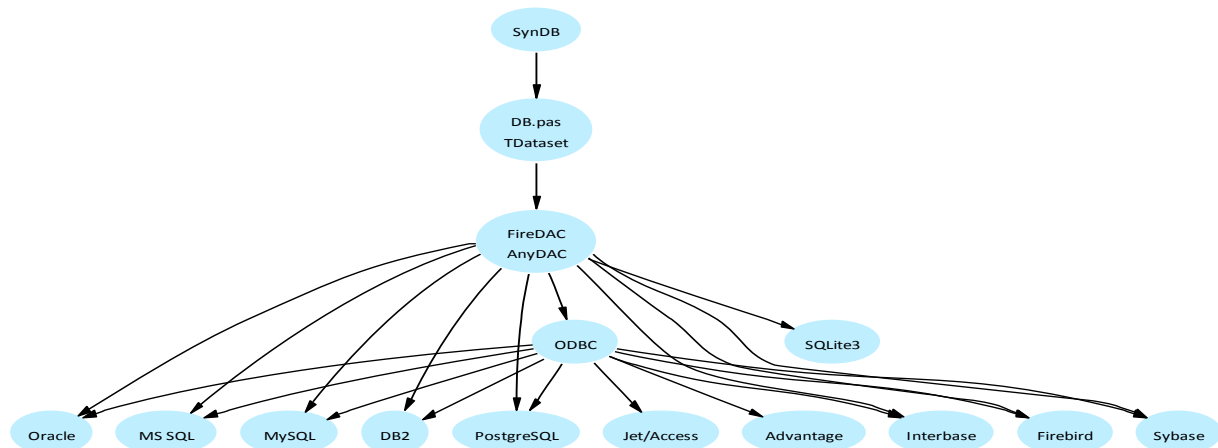

SynDB and NexusDB

We used and tested the free embedded edition, which is a perfect match for a Client-Server ORM framework like *mORMot* - see <http://www.nexusdb.com/support/index.php?q=FreeEmbedded..>

8.2.5.2. FireDAC / AnyDAC library

FireDAC is an unique set of *Universal Data Access* Components for developing cross platform database applications on *Delphi*. This was in fact a third-party component set, bought by *Embarcadero* to *DA-SOFT Technologies* (formerly known as *AnyDAC*), and included with several editions of *Delphi* XE3 and up. This is the new official platform for high-speed database development in *Delphi*, in favor to the now deprecated *DBExpress*.

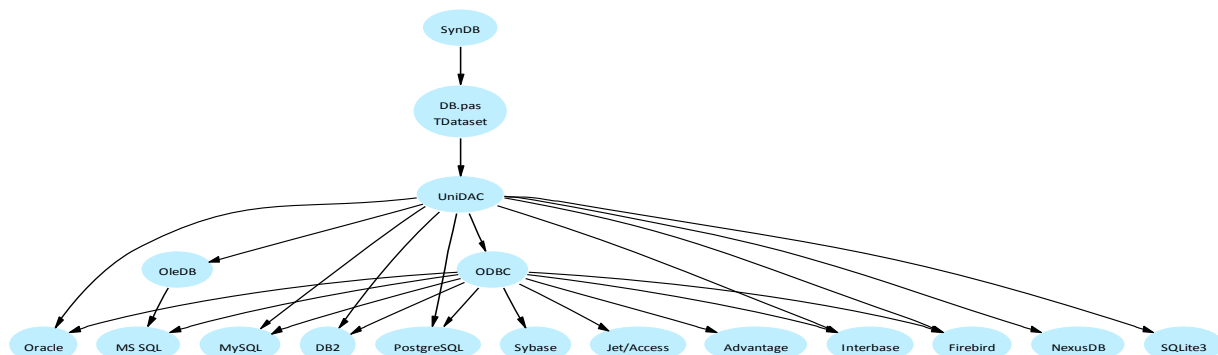

SynDB and FireDAC / AnyDAC

Our integration within SynDB.pas units and the *mORMot* persistence layer has been tuned. For instance, you can have direct access to high-speed FireDAC Array DML feature, via the ORM batch process, via so-called array binding - see below (page 357).

8.2.5.3. UniDAC library

Universal Data Access Components (UniDAC) is a cross-platform library of components that provides direct access to multiple databases from *Delphi*. See <http://www.devart.com/unidac..>

SynDB and UniDAC

For instance, to access to a MySQL remote database, you should be able to connect using:

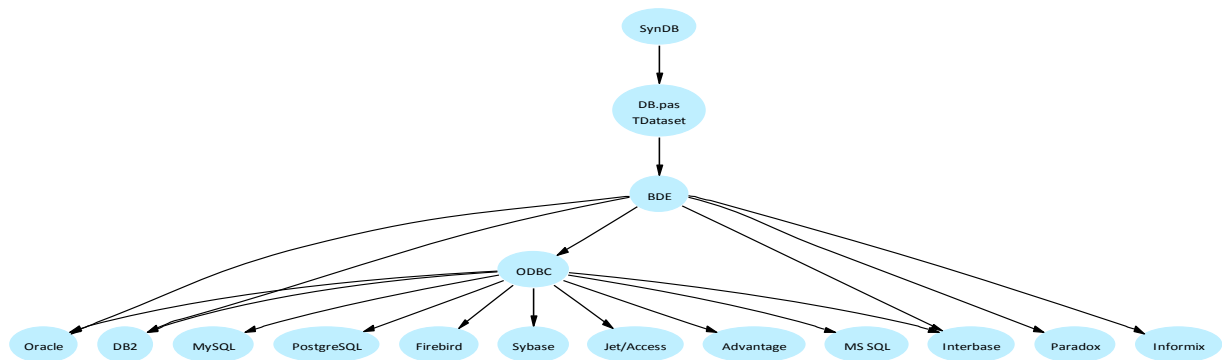

```

PropsMySQL := TSQLDBUniDACConnectionProperties.Create(
  TSQLDBUniDACConnectionProperties.URI(dMySQL, '192.168.2.60:3306'),
  'world', 'root', 'dev');
  
```

This library gives pretty stable results, but lack of the array binding feature, in comparison to *FireDAC*.

8.2.5.4. BDE engine

Borland Database Engine (BDE) is the Windows-based core database engine and connectivity software shipped with earlier versions of *Delphi*. Even if it is deprecated, and replaced by DBExpress since 2000, it is a working solution, easy to interface as a SynDB.pas provider.

SynDB and BDE

Please do not use the BDE on any new project!
You should better switch to another access layer.

8.2.6. Remote access via HTTP

The SynDBRemote.pas unit allows you to create database applications that perform SQL operations on a remote HTTP server, instead of a database server. You can create connections just like any other SynDB.pas database, but the transmission will take place over HTTP. As a result, no database client is to be deployed on the end user application: it will just use HTTP requests, even over Internet. You can use all the features of SynDB.pas classes, with the ease of one optimized HTTP connection.

SynDB Remote access Overview

This feature is *not* part of our RESTful ORM, so does not use the mORMot.pas unit, but its own optimized protocol, using enhanced security (transmission encryption with user authentication and optional HTTPS) and automatic data compression. Only the HTTP client and server classes, from the SynCrtSock.pas unit, are used.

Since your application can use both TDataSet - see *TDataset and SynDB* (page 251) - and emulated TQuery - see *TQuery emulation class* (page 251), this new mean of transmission may make it easy to convert existing Delphi client-server applications into *Multi-tier architecture* (page 88) with minimal changes in source code. Then, for your new code, you may switch to a SOA / ORM design, using mORMot's RESTful abilities - see below (page 296).

The transmission protocol uses an optimized binary format, which is compressed, encrypted and digitally signed on both ends, and the remote user authentication will be performed via a challenge validation scheme. You can also publish your server over HTTPS, if needed, in http.sys kernel mode.

8.2.6.1. Server and Client classes

To publish your SynDB.pas connection, you just need to initialize one of the TSQLDBServer* classes defined in SynDBRemote.pas:

SynDB Remote access Server classes hierarchy

You can define either a HTTP server based on the socket API - `TSQldbServerSockets` - or the more stable and fast `TSQldbServerHttpApi` class (under *Windows* only), which uses the `http.sys` kernel mode HTTP server available since Windows XP - see below (page 327).

For the client side, you could use one of the following classes also defined in `SynDBRemote.pas`:

SynDB Remote access Client classes hierarchy

Note that `TSQldbHttpRequestConnectionProperties` is an abstract parent class, so you should not instantiate it directly, but one of its inherited implementations.

As you can see, you may choose between a pure socket API client, others using WinINet or WinHTTP (under *Windows*), or the libcurl API (especially on *Linux*). The `TSQldbWinHTTPConnectionProperties` class is the more stable over the *Internet* on *Windows*, even if plain sockets tend to give better numbers on localhost as stated by our *Data access benchmark* (page 199). Please read below (page 330) for a comparison of the diverse APIs.

8.2.6.2. Publish a SynDB connection over HTTP

To define a HTTP server, you may write:

```

uses SynDB, // RDBMS core
    SynDBSQLite3, SynSQLite3Static, // static SQLite3 engine
    SynDBRemote; // for HTTP server
...
var Props: TSQldbConnectionProperties;
    HttpServer: TSQldbServerAbstract;
...
Props := TSQldbSQLite3ConnectionProperties.Create('data.db3','','');
HttpServer := TSQldbServerHttpApi.Create(Props,'syndbremote','8092','user','pass');
```

The above code will initialize a connection to a local `data.db3 SQLite3` database (in the `Props` variable), and then publish it using the `http.sys` kernel mode HTTP server to the `http://1.2.3.4:8092/syndbremote` URI - if the server's IP is `1.2.3.4`.

A first user is defined, with `'user' / 'pass'` credentials. Note that in our remote access, user management *does not* match the RDBMS user rights: you should better have your own set of users at application level, for higher security, and a better integration with your business logic. If creating a new user on a RDBMS could be painful, managing remote user authentication is pretty easy on the `SynDBRemote.pas` side, by using the `Protocol.Authenticate` property of the server:

```

HttpServer.Protocol.Authenticate.AuthenticateUser('toto','pipo');
HttpServer.Protocol.Authenticate.AuthenticateUser('toto2','pipo2');
...
```

You could also share *mORMot's* REST authentication users below (page 549), by replacing the default `TSynAuthentication` class instance with `TSynAuthenticationRest`, as defined in `mORMot.pas`. Note using at the same time `SynDBRemote` and *mORMot's* ORM/SOA sounds like a weak design, but may

have its benefits when dealing with legacy code, and a lot of existing SQL statements.

The URI should be registered to work as expected, just as expected by the `http.sys` API - see below (page 328). You may either run the server once with the system Administrator rights, or call the following method (as we do in `TestSQL3Register.dpr`) in your setup application:

```
THttpApiServer.AddUrlAuthorize('syndbremote','8092',false,'+');
```

8.2.6.3. SynDB client access via HTTP

On the client side, you can then write:

```
uses SynDB, // RDBMS core
    SynDBRemote; // for HTTP client
...
var Props: TSQLDBConnectionProperties;
...
Props := TSQLDBWinHTTPConnectionProperties.Create('1.2.3.4:8092','syndbremote','user','pass');
```

As you can see, there is no link to `SynDBSQLite3.pas` nor `SynSQLite3Static.pas` on the client side. Just the HTTP link is needed. No need to deploy the RDBMS client libraries with your application, nor setup the local network firewall.

We defined here a single user, with 'user' / 'pass' credentials, but you may manage more users on the server side, using the `Protocol.Authenticate` property of `TSQLDBServerAbstract`.

Then, you execute your favorite SQL using the connection just as usual:

```
procedure Test(Props: TSQLDBConnectionProperties);
var Stmt: ISQLDBRows;
begin
  Stmt := Props.Execute('select * from People where YearOfDeath=?',[1519]);
  while Stmt.Step do begin
    assert(Stmt.ColumnInt('ID')>0);
    assert(Stmt.ColumnInt('YearOfDeath')=1519);
  end;
end;
```

Or you may use it with VCL components, using the `SynDBVCL.pas` unit:

```
ds1.DataSet.Free; // release previous TDataSet
ds1.DataSet := ToDataSet(ds1,Props.Execute('select * from people',[]));
```

The `TSynSQLStatementDataSet` result set will map directly the raw binary data returned by the `TSQLDBServer*` class, avoiding any slow data marshalling in your client application, even for huge content. Note that all the whole data is computed and sent by the server: even if you display only the first rows in your `TDBGrid`, all the data has been transmitted. In fact, partial retrieval works well on a local network, but is not a good idea over the Internet, due to its much higher ping. So consider adding some filter fields, or some application-level paging, to reduce the number of rows retrieved from the `SynDBRemote` server.

If you defined your own `TSynAuthentication` class on the server class (e.g. to use REST users and groups via `TSynAuthenticationRest`), you should create your own class, and override the following method:

```
procedure TSQLDBWinHTTPConnectionPropertiesRest.SetInternalProperties;
begin
  if fProtocol=nil then
    fProtocol := TSQLDBRemoteConnectionProtocol.Create(
      TSynAuthenticationRest.Create(nil,[]));
  inherited;
end;
```

This overridden method will inherit from `TSQLDBWinHTTPConnectionProperties` all its behavior, but

use the ORM/SOA authentication scheme for validating its users on the server side.

8.2.6.4. Advanced use cases

You may use this remote connection feature e.g. to mutate a stand-alone shared *SQLite3* database into a high performance but low maintenance client-server database engine. You may create it as such on the server side:

```
var props: TSQLDBSQLite3ConnectionProperties;  
    server: TSQLDBServerHttpApi;  
...  
props := TSQLDBSQLite3ConnectionProperties.Create('database.db3','','');  
props.MainSQLite3DB.Synchronous := smOff;  
props.MainSQLite3DB.LockingMode := lmExclusive; // tune the performance  
server := TSQLDBServerHttpApi.Create(props,'syndbremote','8092','user','password');  
...
```

You could share an existing *SQLite3* database instance (e.g. a *TSQLRestServerDB* used for our RESTful ORM - see *Database layer* (page 196)) by creating the properties as such:

```
props := TSQLDBSQLite3ConnectionProperties.Create(aRestServerDB.DB);  
server := TSQLDBServerHttpApi.Create(props,'syndbremote','8092','user','password');
```

If you use the *http.sys* kernel-mode server, you could share the same IP port between regular ORM/SOA operations (which may be 80 for a "pure" HTTP server), and remote SynDB access, if the database name (i.e. here 'syndbremote') does not conflict with a ORM table nor a method service.

Note that you can also customize the transmission protocol by setting your own *TSQLDBProxyConnectionProtocol* class on both server and server sides.

8.2.6.5. Integration with SynDBExplorer

Our SynDBExplorer tool is able to publish in one click any SynDB connection as a HTTP server, or connect to it via HTTP. It could be very handy, even for debugging purposes.

To serve an existing database, just connect to it as usual. Then click on the "HTTP Server" button below the table lists (on left side). You can tune the server properties (HTTP port, database name used for URI, user credentials), then click on the "Start" button.

To connect to this remote connection, run another instance of SynDBExplorer. Create a new connection, using "Remote HTTP" as connection type, and set the other options with the values matching the server side, e.g. with the default "localhost:8092" (replacing localhost with the server IP for an access over the network) for the server name, "syndbremote" for the database name, and "synapse" for both user name and password.

You will be able to access the main server instance remotely, just as if the database was accessed via a regular client.

If the server side database is *SQLite3*, you just mutated this local engine into a true client-server database - you may be amazed by the resulting performance.

8.2.6.6. Do not forget the mORMot!

Even if you may be tempted to use such remote access to implement a *n-Tier architecture*, you should rather use *mORMot's* Client-Server ORM instead - see below (page 342) - which offers much better client-server integration - due to the *Persistence Ignorance* pattern of *Domain-Driven Design* (page 99), a better OOP and SOLID modeling design - see below (page 390), and even higher performance than raw SQL operations - see e.g. below (page 351) or below (page 360). Our little *mORMot* is not an

ORM on which we added a data transmission layer: it is a full RESTful system, with a true SOA design.

But for integrating some legacy SQL code into a new architecture, `SynDBRemote.pas` may have its benefits, used in conjunction with *mORMot*'s higher level features.

Note that for cross-platform clients, *mORMot*'s ORM/SOA patterns are a much better approach: do not put SQL in your mobile application, but use services, so that you will not need to re-validate and re-publish the app to the store after any small fix of your business logic!

8.3. SynDB ORM Integration

8.3.1. Code-first or database-first

When working with any *Object-Relational Mapping (ORM)* (page 92), you have mainly two possibilities:

- Start from scratch, i.e. write your classes and let the ORM create all the database structure, which will reflect directly the object properties - it is also named "code-first";
- Use an existing database, and then define in your model how your classes map the existing database structure - this is the "database-first" option.

Our *mORMot* framework implements both paths, even if, like for other ORMs, code-first sounds like a more straight option.

8.3.2. Code-first ORM

An *external* record can be defined as such, as expected by *mORMot*'s ORM:

```
type
  TSQLRecordPeopleExt = class(TSQLRecord)
  private
    fData: TSQLRawBlob;
    fFirstName: RawUTF8;
    fLastName: RawUTF8;
    fYearOfBirth: integer;
    fYearOfDeath: word;
    fLastChange: TModTime;
    fCreatedAt: TCreateTime;
  published
    property FirstName: RawUTF8 index 40 read fFirstName write fFirstName;
    property LastName: RawUTF8 index 40 read fLastName write fLastName;
    property Data: TSQLRawBlob read fData write fData;
    property YearOfBirth: integer read fYearOfBirth write fYearOfBirth;
    property YearOfDeath: word read fYearOfDeath write fYearOfDeath;
    property LastChange: TModTime read fLastChange write fLastChange;
    property CreatedAt: TCreateTime read fCreatedAt write fCreatedAt;
  end;
```

As you can see, there is no difference with an *internal* ORM class: it inherits from *TSQLRecord*, but you may want it to inherit from *TSQLRecordMany* to use *ORM implementation via pivot table* (page 165) for instance.

The only difference is this `index 40` attribute in the definition of `FirstName` and `LastName` published properties: this will define the length (in *UTF-16 WideChar* or *UTF-8* bytes) to be used when creating the external field for TEXT column. See above e.g.:

```
property FirstName: RawUTF8
  index 40
  read fFirstName write fFirstName;
```

In fact, *SQLite3* does not care about textual field length, but almost all other database engines expect a maximum length to be specified when defining a *VARCHAR* column in a table. If you do not specify any length in your field definition (i.e. if there is no `index ???` attribute), the ORM will create a column with an unlimited length (e.g. `varchar(max)` for *MS SQL Server*). In this case, code will work, but performance and disk usage may be highly degraded, since access via a *CLOB* is known to be notably slower. The only exceptions to this performance penalty are *SQLite3* and *PostgreSQL*, for which the size unlimited TEXT columns are as fast to process than `varchar(#)`.

By default, no check will be performed by the ORM to ensure that the field length is compliant with the column size expectation in the external database. You can use `TSQLRecordProperties`'s `SetMaxLengthValidatorForTextFields()` or `SetMaxLengthFilterForTextFields()` method to create a validation or filter rule to be performed before sending the data to the external database - see *Filtering and Validating* (page 172).

Here is an extract of the regression test corresponding to external databases:

```
var RExt: TSQLRecordPeopleExt;
(...)
fProperties := TSQldbSQLite3ConnectionProperties.Create(SQLITE_MEMORY_DATABASE_NAME, '', '', '');
VirtualTableExternalRegister(fExternalModel, TSQLRecordPeopleExt, fProperties, 'PeopleExternal');
aExternalClient := TSQLRestClientDB.Create(fExternalModel, nil, 'testExternal.db3', TSQLRestServerDB);
try
  aExternalClient.Server.StaticVirtualTableDirect := StaticVirtualTableDirect;
  aExternalClient.Server.CreateMissingTables;
  Check(aExternalClient.Server.CreateSQLMultiIndex(
    TSQLRecordPeopleExt, ['FirstName', 'LastName'], false));
  (...)
  Start := aExternalClient.Server.Timestamp;
  (...)
  aID := aExternalClient.Add(RExt, true);
  (...)
  aExternalClient.Retrieve(aID, RExt);
  (...)
  aExternalClient.BatchStart(TSQLRecordPeopleExt);
  aExternalClient.BatchAdd(RExt, true);
  (...)
  Check(aExternalClient.BatchSend(BatchID)=HTTP_SUCCESS);
  Check(aExternalClient.TableHasRows(TSQLRecordPeopleExt));
  Check(aExternalClient.TableRowCount(TSQLRecordPeopleExt)=n);
  (...)
  RExt.FillPrepare(aExternalClient, 'FirstName=? and LastName=?',
    [RInt.FirstName, RInt.LastName]); // query will use index -> fast :)
  while RExt.FillOne do ...
  (...)
  Updated := aExternalClient.Server.Timestamp;
  (...)
  aExternalClient.Update(RExt);
  aExternalClient.Unlock(RExt);
  (...)
  aExternalClient.BatchStart(TSQLRecordPeopleExt);
  aExternalClient.BatchUpdate(RExt);
  (...)
  aExternalClient.BatchSend(BatchIDUpdate);
  (...)
  aExternalClient.Delete(TSQLRecordPeopleExt, i)
  (...)
  aExternalClient.BatchStart(TSQLRecordPeopleExt);
  aExternalClient.BatchDelete(i);
  (...)
  aExternalClient.BatchSend(BatchIDUpdate);
  (...)
  for i := 1 to BatchID[high(BatchID)] do begin
    RExt.fLastChange := 0;
    RExt.CreatedAt := 0;
    RExt.YearOfBirth := 0;
    ok := aExternalClient.Retrieve(i, RExt, false);
    Check(ok=(i and 127<>0), 'deletion');
    if ok then begin
      Check(RExt.CreatedAt>=Start);
      Check(RExt.CreatedAt<=Updated);
      if i mod 100=0 then begin
        Check(RExt.YearOfBirth=RExt.YearOfDeath, 'Update');
        Check(RExt.LastChange>=Updated);
      end else begin
```

```

    Check(RExt.YearOfBirth<>RExt.YearOfDeath, 'Update');
    Check(RExt.LastChange>=Start);
    Check(RExt.LastChange<=Updated);
  end;
end;
end;
(...)
```

As you can see, there is no difference with using the local *SQLite3* engine or a remote database engine. From the Client point of view, you just call the usual RESTful CRUD methods, i.e. `Add()` `Retrieve()` `Update()` `UnLock()` `Delete()` - or their faster `Batch*()` revision - and you can even handle advanced methods like a `FillPrepare` with a complex `WHERE` clause, or `CreateSQLMultiIndex` / `CreateMissingTables` on the server side.

Even the creation of the table in the remote database (the `'CREATE TABLE...'` SQL statement) is performed by the framework when the `CreateMissingTables` method is called, with the appropriate column properties according to the database expectations (e.g. a `TEXT` for *SQLite3* will be a `NVARCHAR2` field for *Oracle*).

The resulting table layout on the external database will be the following:

TSQLEntityPeopleExt Code-First Field/Column Mapping

The only specific instruction is the global `VirtualTableExternalRegister()` function, which has to be run on the server side (it does not make any sense to run it on the client side, since for the client there is no difference between any tables - in short, the client do not care about storage; the server does).

In order to work as expected, `VirtualTableExternalRegister()` shall be called *before* `TSQLEntityServer.Create` constructor: when the server initializes, the ORM server must know whenever an *internal* or *external* database shall be managed. In the above code, `TSQLEntityClientDB.Create()` will instantiate its own embedded `TSQLEntityServerDB` instance.

Note that the `TSQLEntityRecordExternal.LastChange` field was defined as a `TModTime`: in fact, the current date and time will be stored each time the record is updated, i.e. for each `aExternalClient.Add` or `aExternalClient.Update` calls. This is tested by both `RExt.LastChange>=Start` and `RExt.LastChange<=Updated` checks in the latest loop. The time used is the "server-time", i.e. the current time and date on the server (not on the client), and, in the case of external databases, the time of the remote server (it will execute e.g. a `select getdate()` under MS SQL to synchronize the date to be inserted for `LastChange`). In order to retrieve this server-side time stamp, we use `Start := aExternalClient.ServerTimestamp` instead of the local `TimeLogNow` function.

A similar feature is tested for the `CreatedAt` published field, which was defined as `TCreateTime`: it will be set automatically to the current server time at record creation (and not changed on modifications). This is the purpose of the `RExt.CreatedAt<=Updated` check in the above code.

8.3.3. Database-first ORM

As we have just seen, the following line initializes the ORM to let `TSQLEntityRecordPeopleExt` data be

accessed via SQL, over an external database connection fProperties:

```
VirtualTableExternalRegister(fExternalModel, TSQLRecordPeopleExt, fProperties, 'PeopleExternal');
```

We also customized the name of the external table, from its default 'PeopleExt' (computed by trimming TSQLRecord prefix from TSQLRecordPeopleExt) into 'PeopleExternal'.

In addition to table name mapping, the ORM is also able to map the TSQLRecord published properties names to any custom database column name. It is in fact very common that most tables on existing databases do not have very explicit column naming, which may sound pretty weird when mapped directly as TSQLRecord property names. Even the primary keys of your existing database won't match the ORM's requirement of naming it as ID. All this should be setup as expected.

By default, for a *code-driven* approach, internal property names will match the external table column names - see *TSQLRecordPeopleExt Code-First Field/Column Mapping* (page 271)

You can customize this default mapping, writing e.g.

```
fProperties := TSQLDBSQLite3ConnectionProperties.Create(SQLITE_MEMORY_DATABASE_NAME, '', '', '');
VirtualTableExternalRegister(fExternalModel, TSQLRecordPeopleExt, fProperties, 'PeopleExternal');
fExternalModel.Props[TSQLRecordPeopleExt].ExternalDB.
  MapField('ID', 'Key');
  MapField('YearOfDeath', 'YOD');
(...) // the remaining code stays the same
```

As an alternative, you can use the VirtualTableExternalMap function and its fluent interface:

```
fProperties := TSQLDBSQLite3ConnectionProperties.Create(SQLITE_MEMORY_DATABASE_NAME, '', '', '');
VirtualTableExternalMap(fExternalModel, TSQLRecordPeopleExt, fProperties, 'PeopleExternal').
  MapField('ID', 'Key');
  MapField('YearOfDeath', 'YOD');
```

Then you use your TSQLRecordPeopleExt table as usual from *Delphi* code, with ID and YearOfDeath fields.

But, under the hood, the mORMot ORM will do the mapping when creating all needed SQL statements:

- The "internal" TSQLRecord class will be stored within the PeopleExternal external table;
- The "internal" TSQLRecord.ID field will be an external "Key: INTEGER" column;
- The "internal" TSQLRecord.YearOfDeath field will be an external "YOD: INTEGER" column;
- Other internal published properties will be mapped by default with the same name to external column.

The resulting mapping will therefore be the following:

TSQLRecordPeopleExt Database-First Field/Column Mapping

Note that only the ID and YearOfDeath column names were customized.

Due to the design of *SQLite3* virtual tables, and *mORMot* internals in its current state, the database primary key must be an INTEGER field to be mapped as expected by the ORM. But you can specify any secondary key, e.g. a TEXT field, via stored *AS_UNIQUE* definition in code.

8.3.4. Sharing the database with legacy code

It is pretty much possible that you will have to maintain and evolve a legacy project, based on an existing database, with a lot of already written SQL statements - see *Legacy code and existing projects* (page 77). For instance, you would like to use *mORMot* for new features, and/or add mobile or HTML clients - see below (page 482).

In this case, the ORM advanced features - like *ORM Cache* (page 174) or BATCH process, see below (page 351) - may conflict with the legacy code, for the tables which may have to be shared. Here are some guidelines when working on such a project.

To be exhaustive about this question, we need to consider each ORM CRUD operation. We may have to divide them in three kinds: read queries, insertions, and modifications of existing data.

About **ORM read queries**, i.e. `Retrieve()` methods, the ORM cache can be tuned per table, and you will definitely lack of some cache, but remember :

- That you can set a "time out" period for this cache, so that you may still benefit of it in most cases;
- That you have a cache at server level and another at client level, so you can tune it to be less aggressive on the client, for instance;
- That you can tune the ORM cache *per ID*, so some items which are not likely to change can still be cached.

About **ORM insertions**, i.e. `Add()` or `BatchAdd()` methods, when using the external engine, if any external process is likely to INSERT new rows, ensure you set the `TSQLRestStorageExternal.EngineAddUseSelectMaxID` property to `TRUE`, so that it will compute the next maximum ID by hand.

But it still may be an issue, since the external process may do an INSERT *during* the ORM insertion.

So the best is perhaps to NOT use the ORM `Add()` or `BatchAdd()` methods, but rely on dedicated INSERT SQL statement, e.g. hosted in an interface-based service on the server side.

About **ORM modifications**, i.e. `Update()` `Delete()` `BatchUpdate()` `BatchDelete()` methods, they sound safe to be used in conjunction with external process modifying the DB, as soon as you use transactions to let the modifications be atomic, and won't conflict any concurrent modifications in the legacy code.

Perhaps the safer pattern, when working with external tables which are to be modified in the background by some legacy code, may be to by-pass those ORM methods, and define server-side *interface-based services* - see below (page 420). Those services may contain manual SQL, instead of using the ORM "magic". But it will depend on your business logic, and you will fail to benefit from the ORM features of the framework.

Nevertheless, introducing *Service-Oriented Architecture (SOA)* (page 90) into your application will be very beneficial: ORM is not mandatory, especially if you are "fluent" in SQL queries, know how to make them as standard as possible, and have a lot of legacy code, perhaps with already tuned SQL statements.

Introducing SOA is mandatory to interface new kind of clients to your applications, like mobile apps or AJAX modern sites. To be fair, you should not access directly the database any more, as you did with your legacy Delphi application and RAD DB components.

All new features, involving new tables to store new data, will still benefit of the *mORMot*'s ORM, and could still be hosted in the very same external database, shared by your existing code.

Then, you will be able to identify *seams* - see *Legacy code and existing projects* (page 77) - in your legacy code, and move them to your new *mORMot* services, then let your application evolve into a newer SOA/MVC architecture, without breaking anything, nor starting from scratch.

8.3.5. Auto-mapping of SQL conflictual field names

If your application is likely to be run on several databases, it may be difficult to handle any potential field name conflict, when you switch from one engine to another. The ORM allows you therefore to ensure that no field name will conflict with a SQL keyword of the underlying database.

In code-first mode, you can use the following method to ensure that no such conflict occurs:

```
fExternalModel.Props[TSQlRecordPeopleExt].ExternalDB.MapAutoKeywordFields;
```

For a database-first database, the following syntax is to be used so that field names will be checked:

```
fExternalModel.Props[TSQlRecordPeopleExt].ExternalDB. // custom field mapping
  MapField('ID','Key').
  MapField('YearOfDeath','YOD').
  MapAutoKeywordFields;
```

or, if you want to full fluent interface definition:

```
VirtualTableExternalMap(fExternalModel,TSQlRecordPeopleExt,fProperties,'PeopleExternal').
  MapField('ID','Key').
  MapField('YearOfDeath','YOD').
  MapAutoKeywordFields
```

It is a good idea to call the `MapAutoKeywordFields` method after any manual field mapping for a database-first database, since even your custom field names may conflict with a SQL keyword.

If any field name is likely to conflict with a SQL keyword, it will be mapped with a trailing '_'. For instance, a 'Select' published property will be mapped into a `SELECT_` column in the table.

Even if this option is disabled by default, a warning message will appear in the log proposing to use this `MapAutoKeywordFields` method, and will help you to identify such issues.

8.3.6. External database ORM internals

The `mORMotDB.pas` unit implements Virtual Tables access for any `SynDB.pas`-based external database for the framework.

In fact, this feature will use `TSQlRestStorageExternal`, `TSQlVirtualTableCursorExternal` and `TSQlVirtualTableExternal` classes, defined as such:

External Databases classes hierarchy

The registration of the class is done by a call to the following new global procedure:

```
procedure VirtualTableExternalRegister(aModel: TSQlModel; aClass: TSQlRecordClass;
  aExternalDB: TSQlDBConnectionProperties; const aExternalTableName: RawUTF8);
```

This procedure will register on the Server-side an external database for an ORM class:

- It will define the supplied class to behave like a `TSQlRecordVirtualTableAutoID` class (i.e. its `TSQlModelRecordProperties.Kind` property will be overwritten to `rCustomAutoID` in this ORM

- model);
- It will associate the supplied class with a `TSQLVirtualTableExternal` module;
 - The `TSQLDBConnectionProperties` instance should be shared by all classes, and released globally when the ORM is no longer needed;
 - The full table name, as expected by the external database, should be provided here (`SQLTableName` will be used internally as table name when called via the associated *SQLite3* Virtual Table) - if no table name is specified (''), will use `SQLTableName` (e.g. 'Customer' for a class named `TSQLCustomer`);
 - Internal adjustments will be made to convert SQL on the fly from internal ORM representation into the expected external SQL format (e.g. table name or ID property) - see `TSQLRestStorage.AdaptSQLForEngineList` method.

Typical usage may be for instance:

```
aProps := ToleDBMSSQLConnectionProperties.Create('.\SQLEXPRESS','AdventureWorks2008R2','','');
aModel := TSQLModel.Create([TSQLCustomer],'root');
VirtualTableExternalRegister(aModel,TSQLCustomer,aProps,'Sales.Customer');
aServer := TSQLRestServerDB.Create(aModel,'application.db'),true)
```

All the rest of the code will use the "regular" ORM classes, methods and functions, as stated by *Object-Relational Mapping* (page 130).

In order to be stored in an external database, the ORM records can inherit from any `TSQLRecord` class. Even if this class does not inherit from `TSQLRecordVirtualTableAutoID`, it will behave as such, once `VirtualTableExternalRegister` function has been called for the given class.

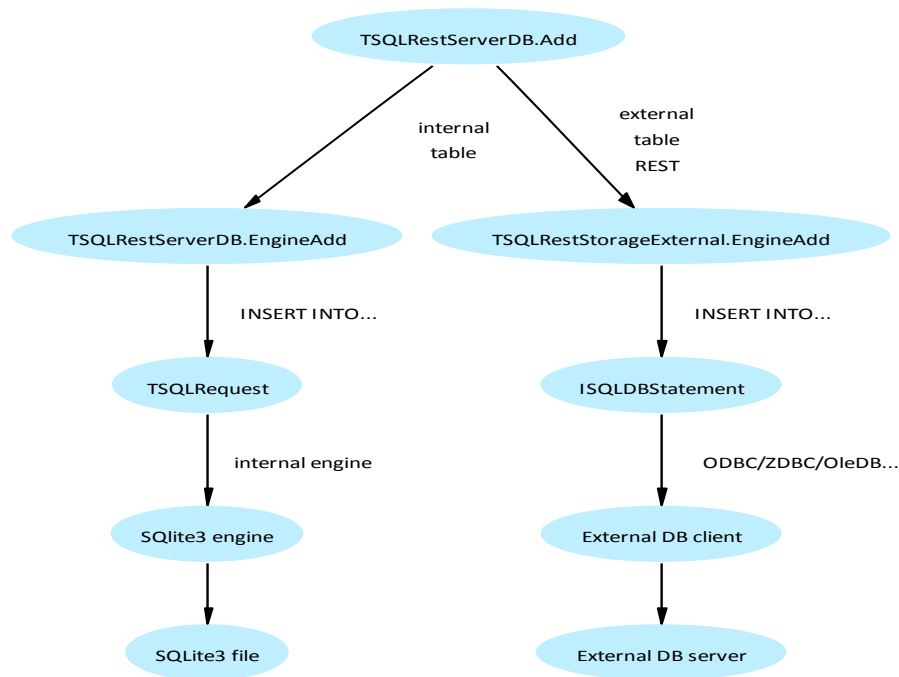

As with any regular `TSQLRecord` classes, the ORM core will expect external tables to map an Integer ID published property, auto-incremented at every record insertion. Since not all databases handle such fields - e.g. *Oracle* - auto-increment will be handled via a `select max(id) from tablename` statement run at initialization, then computed on the fly via a thread-safe cache of the latest inserted *RowID*.

You do not have to know where and how the data persistence is stored. The framework will do all the low-level DB work for you. And thanks to the *Virtual Table* feature of *SQLite3*, internal and external tables can be mixed within SQL statements. Depending on the implementation needs, classes could be persistent either via the internal *SQLite3* engine, or via external databases, just via a call to `VirtualTableExternalRegister()` before server initialization.

In fact, `TSQLVirtualTableCursorExternal` will convert any query on the external table into a proper optimized SQL query, according to the indexes existing on the external database. `TSQLVirtualTableExternal` will also convert individual SQL modification statements (like insert / update / delete) at the *SQLite3* level into remote SQL statements to the external database.

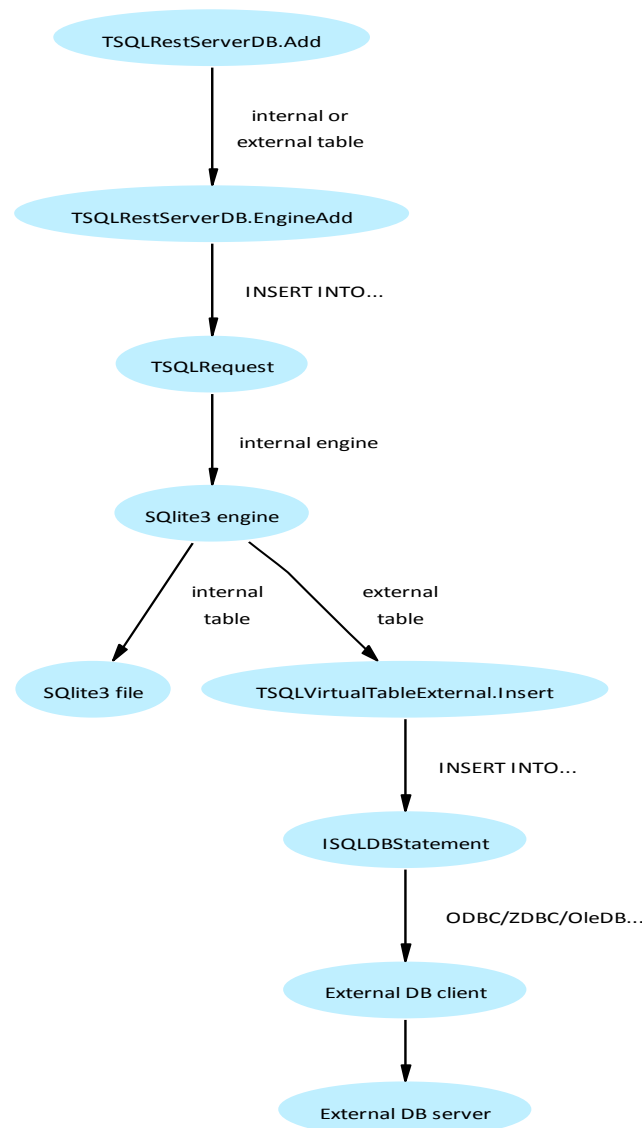

Most of the time, all RESTful methods (GET/POST/PUT/DELETE) will be handled directly by the `TSQLRestStorageExternal` class, and won't use the virtual table mechanism. In practice, most access to the external database will be as fast as direct access, but the virtual table will always be ready to interpret any cross-database complex request or statement.

Direct REST access will be processed as following - when adding an object, for instance:

ORM Access Via REST

Indirect access via virtual tables will be processed as following:

ORM Access Via Virtual Table

About speed, here is an extract of the test regression log file (see code above, in previous paragraph), which shows the difference between RESTful call and virtual table call, working with more than 11,000 rows of data:

```
- External via REST: 133,666 assertions passed 409.82ms  
- External via virtual table: 133,666 assertions passed 1.12s
```

The first run is made with `TSQLRestServer.StaticVirtualTableDirect` set to `TRUE` (which is the default) - i.e. it will call directly `TSQLRestStorageExternal` for RESTful commands, and the second will set this property to `FALSE` - i.e. it will call the `SQLite3` engine and let its virtual table mechanism convert it into another SQL calls.

It is worth saying that this test is using an in-memory `SQLite3` database (i.e. instantiated via `SQLITE_MEMORY_DATABASE_NAME` as pseudo-file name) as its external DB, so what we test here is mostly the ORM overhead, not the external database speed. With real file-based or remote databases

(like MS SQL), the overhead of remote connection won't make noticeable the use of Virtual Tables.

In all cases, letting the default `StaticVirtualTableDirect=true` will ensure the best possible performance. As stated by *Data access benchmark* (page 199), using a virtual or direct call won't affect the CRUD operation speed: it will by-pass the virtual engine whenever possible.

8.3.7. Tuning the process

Multi-threading abilities of the server, and all available settings, will be detailed below (page 336).

By default, all ORM read operations will be run in concurrent mode, and all ORM write operations will be executed in blocking mode. This is expected to be both safe and fast, with our internal *SQLite3* engine, or most of the external databases. But you may need to change this default behavior, depending on the external engine you are connected to.

Most `TSQLDBConnectionProperties` will inherit from `TSQLDBConnectionPropertiesThreadSafe`, so will create one connection per thread. This is efficient, but some providers may have issues with it.

First of all, some database client libraries may not allow transactions to be shared among several threads - for instance MS SQL. Other clients may consume a lot of resources for each connection, or may not have good multi-thread scaling abilities. Some database servers do fork their process for each connected client - for instance *PostgreSQL*: you may want to reduce the server resources by using only one connection, so only one process on the server. To avoid such problems, you can force all ORM write operations to be executed in a dedicated thread, i.e. by setting `amMainThread` (which is not very opportune on a server without UI), or even better via `amBackgroundThread` or a `amBackgroundORMSharedThread`:

```
aServer.AcquireExecutionMode[execORMWrite] := amBackgroundThread;
```

Secondly, especially on a long-running n-Tier *mORMot* server, you may suffer from broken connection exceptions. For instance, after a night without any activity, the attempts to access to the external database may fail in the morning, since the connection may have been disconnected by the database server in the meanwhile.

You can use the `TSQLDBConnectionProperties.ConnectionTimeOutMinutes` property to specify a maximum period of inactivity after which all connections will be flushed and recreated, to avoid potential broken connections issues.

In practice, recreating the connections after a while is safe and won't slow down the process - on the contrary, it may help reducing the consumed resources, and stabilize long running n-Tier servers.

`ThreadSafeConnection` method will check for the last activity on its `TSQLDBConnectionProperties` instance, and then call `ClearConnectionPool` to release all active connections if the idle time elapsed was too long.

As a consequence, if you use this `ConnectionTimeOutMinutes` property, you should ensure that no other connection is still active on the background, otherwise some unexpected issues may occur.

For instance, you should ensure that your *mORMot* ORM server runs all its statements in blocking mode for both read and write:

```
aServer.AcquireExecutionMode[execORMGet] := am***;  
aServer.AcquireExecutionMode[execORMWrite] := am***;
```

Here above, safe blocking `am***` modes are any mode *but* `amUnlocked`, i.e. either `amLocked`, `amBackgroundThread`, `amBackgroundORMSharedThread` or `amMainThread`.

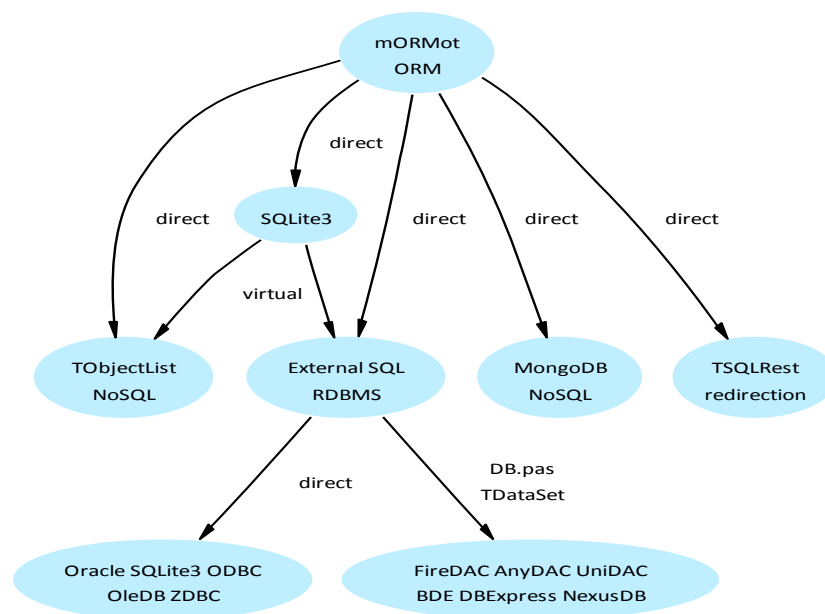

9. External NoSQL database access

Adopt a mORMot

Our ORM RESTful framework is able to access not only regular SQL database engines, via *SynDB direct RDBMS access* (page 242), but also NoSQL engines - see *NoSQL and Object-Document Mapping (ODM)* (page 96).

Remember the diagram introducing *mORMot's Database layer* (page 196):

mORMot Persistence Layer Architecture

The following *NoSQL* engines can be accessed from *mORMot's Object Document Mapping (ODM)* abilities:

NoSQL Engine	Description
TObjectList	In memory storage, with JSON or binary disk persistence
MongoDB	#1 NoSQL database engine

We can in fact consider our *TSQLRestStorageInMemory* instance, and its *TObjectList* storage, as a *NoSQL* very fast in-memory engine, written in pure Delphi. See *In-Memory "static" process* (page 231) for details about this feature.

MongoDB (from "humongous") is a cross-platform document-oriented database system, and certainly the best known *NoSQL* database.

According to <http://db-engines.com..> in December 2015, *MongoDB* is at 4th place of the most popular types of database management systems, and at first place for *NoSQL* database management systems. Our *mORMot* gives premium access to this database, featuring full *NoSQL and Object-Document Mapping (ODM)* (page 96) abilities to the framework.

Integration is made at two levels:

- Direct low-level access to the *MongoDB* server, in the *SynMongoDB.pas* unit;
- Close integration with our ORM (which becomes *defacto* an ODM), in the *mORMotMongoDB.pas* unit.

MongoDB eschews the traditional table-based relational database structure in favor of JSON-like documents with dynamic schemas (*MongoDB* calls the format BSON), which match perfectly *mORMot's* RESTful approach.

9.1. SynMongoDB client

The *SynMongoDB.pas* unit features direct optimized access to a *MongoDB* server.

It gives access to any BSON data, including documents, arrays, and *MongoDB's* custom types (like *ObjectID*, dates, binary, regex, *Decimal128* or *Javascript*):

- For instance, a *TBSONObjectID* can be used to create some genuine document identifiers on the client side (*MongoDB* does not generate the IDs for you: a common way is to generate unique IDs on the client side);
- Generation of BSON content from any *Delphi* types (via *TBSONWriter*);
- Fast in-place parsing of the BSON stream, without any memory allocation (via *TBSONElement*);
- A *TBSONVariant* custom variant type, to store *MongoDB's* custom type values;
- Interaction with the *SynCommons.pas' TDocVariant custom variant type* (page 112) as document storage and late-binding access;
- Marshalling BSON to and from JSON, with the *MongoDB* extended syntax for handling its custom types.

This unit defines some objects able to connect and manage databases and collections of documents on any *MongoDB* servers farm:

- Connection to one or several servers, including secondary hosts, via the *TMongoClient* class;
- Access to any database instance, via the *TMongoDatabase* class;
- Access to any collection, via the *TMongoCollection* class;
- It features some nice abilities about speed, like BULK insert or delete mode, and explicit *Write Concern* settings.

At collection level, you can have direct access to the data, with high level structures like TDocVariant/TBSONVariant, with easy-to-read JSON, or low level BSON content. You can also tune most aspects of the client process, e.g. about error handling or *write concerns* (i.e. how remote data modifications are acknowledged).

9.1.1. Connecting to a server

Here is some sample code, which is able to connect to a *MongoDB* server, and returns the server time:

```
var Client: TMongoClient;  
    DB: TMongoDatabase;  
    serverTime: TDateTime;  
    res: variant; // we will return the command result as TDocVariant  
    errmsg: RawUTF8;  
begin  
    Client := TMongoClient.Create('localhost',27017);  
    try  
        DB := Client.Database['mydb'];  
        writeln('Connecting to ',DB.Name); // will write 'mydb'  
        errmsg := DB.RunCommand('hostInfo',res); // run a command  
        if errmsg<>'' then  
            exit; // quit on any error  
        serverTime := res.system.currentTime; // direct conversion to TDateTime  
        writeln('Server time is ',DateTimeToStr(serverTime));  
    finally  
        Client.Free; // will release the DB instance  
    end;  
end;
```

Note that for this low-level command, we used a TDocVariant, and its late-binding abilities.

In fact, if you put your mouse over the res variable during debugging, you will see the following JSON content:

```
{ "system": { "currentTime": "2014-05-06T15:24:25", "hostname": "Acer", "cpuAddrSize": 64, "memSizeMB": 3934, "numCores": 4, "cpuArch": "x86_64", "numaEnabled": false }, "os": { "type": "Windows", "name": "Microsoft Windows 7", "version": "6.1 SP1 (build 7601)" }, "extra": { "pageSize": 4096 }, "ok": 1 }
```

And we simply access to the server time by writing res.system.currentTime.

Here connection was made anonymously. It will work only if the mongod instance is running on the same computer. Safe remote connection, including user authentication, could be made via the TMongoClient.OpenAuth() method: it supports the latest SCRAM-SHA-1 challenge-response mechanism (supported since *MongoDB* 3.x), or the deprecated MONGODB-CR (for older versions).

```
...  
Client := TMongoClient.Create('localhost',27017);  
try  
    DB := Client.OpenAuth('mydb','mongouser','mongopwd');  
...  
end;
```

For safety reasons, never let a *MongoDB* server be remotely accessible without proper authentication, as stated by <http://docs.mongodb.org/manual/administration/security-access-control..> The TMongoDatabase.CreateUser(), CreateUserForThisDatabase() and DropUser() methods allow to easily manage credentials from your applications.

9.1.2. Adding some documents to the collection

We will now explain how to add documents to a given collection.

We assume that we have a DB: TMongoDatabase instance available. Then we will create the documents with a TDocVariant instance, which will be filled via late-binding, and via a doc.Clear

pseudo-method used to flush any previous property value:

```
var Coll: TMongoCollection;  
    doc: variant;  
    i: integer;  
begin  
    Coll := DB.CollectionOrCreate[COLL_NAME];  
    TDocVariant.New(doc);  
    for i := 1 to 10 do  
        begin  
            doc.Clear;  
            doc.Name := 'Name '+IntToStr(i+1);  
            doc.Number := i;  
            Coll.Save(doc);  
            writeln('Inserted with _id=', doc._id);  
        end;  
    end;
```

Thanks to TDocVariant late-binding abilities, code is pretty easy to understand and maintain.

This code will display the following on the console:

```
Inserted with _id=5369029E4F901EE8114799D9  
Inserted with _id=5369029E4F901EE8114799DA  
Inserted with _id=5369029E4F901EE8114799DB  
Inserted with _id=5369029E4F901EE8114799DC  
Inserted with _id=5369029E4F901EE8114799DD  
Inserted with _id=5369029E4F901EE8114799DE  
Inserted with _id=5369029E4F901EE8114799DF  
Inserted with _id=5369029E4F901EE8114799E0  
Inserted with _id=5369029E4F901EE8114799E1  
Inserted with _id=5369029E4F901EE8114799E2
```

It means that the Coll.Save() method was clever enough to understand that the supplied document does not have any _id field, so will compute one on the client side before sending the document data to the *MongoDB* server.

We may have written:

```
for i := 1 to 10 do  
begin  
    doc.Clear;  
    doc._id := ObjectID;  
    doc.Name := 'Name '+IntToStr(i+1);  
    doc.Number := i;  
    Coll.Save(doc);  
    writeln('Inserted with _id=', doc._id);  
end;  
end;
```

Which will compute the document identifier explicitly before calling Coll.Save().

In this case, we may have called directly Coll.Insert(), which is somewhat faster.

Note that you are not obliged to use a *MongoDB* ObjectID as identifier. You can use any value, if you are sure that it will be genuine. For instance, you can use an integer:

```
for i := 1 to 10 do  
begin  
    doc.Clear;  
    doc._id := i;  
    doc.Name := 'Name '+IntToStr(i+1);  
    doc.Number := i;  
    Coll.Insert(doc);  
    writeln('Inserted with _id=', doc._id);  
end;  
end;
```

The console will display now:

```
Inserted with _id=1
Inserted with _id=2
Inserted with _id=3
Inserted with _id=4
Inserted with _id=5
Inserted with _id=6
Inserted with _id=7
Inserted with _id=8
Inserted with _id=9
Inserted with _id=10
```

Note that the *mORMot* ORM will compute a genuine series of integers in a similar way, which will be used as expected by the `TSQLRecord.ID` primary key property.

The *TMongoCollection* class can also write a list of documents, and send them at once to the *MongoDB* server: this BULK insert mode - close to the *Array Binding* feature of some SQL providers, and implemented in our *SynDB.pas* classes - see below (page 351) - can increase the insertion by a factor of 10 times, even when connected to a local instance: imagine how much time it may save over a physical network!

For instance, you may write:

```
var docs: TVariantDynArray;
...
SetLength(docs, COLL_COUNT);
for i := 0 to COLL_COUNT-1 do begin
  TDocVariant.New(docs[i]);
  docs[i]._id := ObjectID; // compute new ObjectID on the client side
  docs[i].Name := 'Name '+IntToStr(i+1);
  docs[i].FirstName := 'FirstName '+IntToStr(i+COLL_COUNT);
  docs[i].Number := i;
end;
Coll.Insert(docs); // insert all values at once
...
```

You will find out later for some numbers about the speed increase due to such BULK insert.

9.1.3. Retrieving the documents

You can retrieve the document as a *TDocVariant* instance:

```
var doc: variant;
...
doc := Coll.FindOne(5);
writeln('Name: ', doc.Name);
writeln('Number: ', doc.Number);
```

Which will write on the console:

```
Name: Name 6
Number: 5
```

You have access to the whole Query parameter, if needed:

```
doc := Coll.FindDoc('{_id:?}', [5]);
doc := Coll.FindOne(5); // same as previous
```

This Query filter is similar to a WHERE clause in SQL. You can write complex search patterns, if needed - see <http://docs.mongodb.org/manual/reference/method/db.collection.find..> for reference.

You can retrieve a list of documents, as a dynamic array of *TDocVariant*:

```
var docs: TVariantDynArray;
...
```

```
Coll.FindDocs(docs);  
for i := 0 to high(docs) do  
  writeln('Name: ',docs[i].Name,' Number: ',docs[i].Number);
```

Which will output:

```
Name: Name 2 Number: 1  
Name: Name 3 Number: 2  
Name: Name 4 Number: 3  
Name: Name 5 Number: 4  
Name: Name 6 Number: 5  
Name: Name 7 Number: 6  
Name: Name 8 Number: 7  
Name: Name 9 Number: 8  
Name: Name 10 Number: 9  
Name: Name 11 Number: 10
```

In a GUI application, you could fill a VCL grid using a TDocVariantArrayDataSet as defined in SynVirtualDataSet.pas, for instance:

```
ds1.DataSet.Free; // release previous TDataSet  
ds1.DataSet := ToDataSet(self,FindDocs({'name:?',age:{>?}}',['John',21],null));
```

This overloaded FindDocs() method takes a query filter as JSON and parameters (following the MongoDB syntax), and a Projection mapping (null to retrieve all properties). Its returns a TVariantDynArray result, which was mapped to an optimized read-only TDataSet using the overloaded ToDataSet() function. So in our case, the DB grid has been filled with all people named 'John', with age greater than 21.

If you want to retrieve the documents directly as JSON, we can write:

```
var json: RawUTF8;  
...  
  json := Coll.FindJSON(null,null);  
  writeln(json);  
...
```

This will append the following to the console:

```
[{"_id":1,"Name":"Name 2","Number":1},{"_id":2,"Name":"Name 3","Number":2},{"_id":  
":3,"Name":"Name 4","Number":3},{"_id":4,"Name":"Name 5","Number":4},{"_id":5,"N  
ame":"Name 6","Number":5},{"_id":6,"Name":"Name 7","Number":6},{"_id":7,"Name":  
Name 8","Number":7},{"_id":8,"Name":"Name 9","Number":8},{"_id":9,"Name":"Name 1  
0","Number":9},{"_id":10,"Name":"Name 11","Number":10}]
```

You can note that FindJSON() has two properties, which are the Query filter, and a Projection mapping (similar to the column names in a SELECT col1,col2).

So we may have written:

```
json := Coll.FindJSON({'_id:?'},[5]);  
writeln(json);
```

Which outputs:

```
[{"_id":5,"Name":"Name 6","Number":5}]
```

We used here an overloaded FindJSON() method, which accept the *MongoDB* extended syntax (here, the field name is unquoted), and parameters as variables.

We can specify a projection:

```
json := Coll.FindJSON({'_id:?'},[5,{'Name:1'}]);  
writeln(json);
```

Which will only return the "Name" and "_id" fields (since _id is, by *MongoDB* convention, always returned:

```
[{"_id":5,"Name":"Name 6"}]
```

To return only the "Name" field, you can specify `'_id:0,Name:1'` as JSON in extended syntax for the *projection* parameter.

```
[{"Name": "Name 6"}]
```

There are other methods able to retrieve data, also directly as BSON binary data. They will be used for best speed e.g. in conjunction with our ORM, but for most end-user code, using `TDocVariant` is safer and easier to maintain.

9.1.3.1. Updating or deleting documents

The `TMongoCollection` class has some methods dedicated to alter existing documents.

At first, the `Save()` method can be used to update a document which has been first retrieved:

```
doc := Coll.FindOne(5);
doc.Name := 'New!';
Coll.Save(doc);
writeln('Name: ', Coll.FindOne(5).Name);
```

Which will write:

```
Name: New!
```

Note that we used here an integer value (5) as key, but we may use an *ObjectID* instead, if needed.

The `Coll.Save()` method could be changed into `Coll.Update()`, which expects an explicit Query operator, in addition to the updated document content:

```
doc := Coll.FindOne(5);
doc.Name := 'New!';
Coll.Update(BSONVariant(['_id', 5]), doc);
writeln('Name: ', Coll.FindOne(5).Name);
```

Note that by *MongoDB*'s design, any call to `Update()` will *replace* the whole document.

For instance, if you write:

```
writeln('Before: ', Coll.FindOne(3));
Coll.Update({'_id:?'}, [3], {'Name:?'}, ['New Name!']);
writeln('After: ', Coll.FindOne(3));
```

Then the *Number* field will disappear!

```
Before: {"_id":3,"Name":"Name 4","Number":3}
After: {"_id":3,"Name":"New Name!"}
```

If you need to update only some fields, you will have to use the `$set` modifier:

```
writeln('Before: ', Coll.FindOne(4));
Coll.Update({'_id:?'}, [4], {'$set:{Name:?'}}, ['New Name!']);
writeln('After: ', Coll.FindOne(4));
```

Which will write on the console the value as expected:

```
Before: {"_id":4,"Name":"Name 5","Number":4}
After: {"_id":4,"Name":"New Name!","Number":4}
```

Now the *Number* field remains untouched.

You can also use the `Coll.UpdateOne()` method, which will update the supplied fields, and leave the non specified fields untouched:

```
writeln('Before: ', Coll.FindOne(2));
Coll.UpdateOne(2, Obj(['Name', 'NEW']));
writeln('After: ', Coll.FindOne(2));
```

Which will output as expected:

```
Before: {"_id":2,"Name":"Name 3","Number":2}  
After: {"_id":2,"Name":"NEW","Number":2}
```

You can refer to the documentation of the SynMongoDB.pas unit, to find out all functions, classes and methods available to work with *MongoDB*.

Some very powerful features are available, including Aggregation (available since *MongoDB* 2.2), which offers a good alternative to standard Map/Reduce pattern.

See <http://docs.mongodb.org/manual/reference/command/aggregate..> for reference.

9.1.4. Write Concern and Performance

You can take a look at the MongoDBTests.dpr sample - located in the SQLite3\Samples\24 - MongoDB sub-folder of the source code repository, and the TTestDirect classes, to find out some performance information.

In fact, this TTestDirect is inherited twice, to run the same tests with diverse write concern:

MongoDB TTestDirect classes hierarchy

The difference between the two classes will take place at client initialization:

```
procedure TTestDirect.ConnectToLocalServer;  
...  
  fClient := TMongoClient.Create('localhost',27017);  
  if ClassType=TTestDirectWithAcknowledge then  
    fClient.WriteConcern := wcAcknowledged else  
  if ClassType=TTestDirectWithoutAcknowledge then  
    fClient.WriteConcern := wcUnacknowledged;  
...
```

wcAcknowledged is the default safe mode: the *MongoDB* server confirms the receipt of the write operation. Acknowledged write concern allows clients to catch network, duplicate key, and other errors. But it adds an additional round-trip from the client to the server, and wait for the command to be finished before returning the error status: so it will slow down the write process.

With wcUnacknowledged, *MongoDB* does not acknowledge the receipt of write operation. Unacknowledged is similar to errors ignored; however, drivers attempt to receive and handle network errors when possible. The driver's ability to detect network errors depends on the system's networking configuration.

The speed difference between the two is worth mentioning, as stated by the regression tests status, running on a local *MongoDB* instance:

1. Direct access

1.1. Direct with acknowledge:

- Connect to local server: 6 assertions passed 4.72ms
- Drop and prepare collection: 8 assertions passed 9.38ms
- Fill collection: 15,003 assertions passed 558.79ms
5000 rows inserted in 548.83ms i.e. 9110/s, aver. 109us, 3.1 MB/s
- Drop collection: no assertion 856us
- Fill collection bulk: 2 assertions passed 74.59ms

```
5000 rows inserted in 64.76ms i.e. 77204/s, aver. 12us, 7.2 MB/s
- Read collection: 30,003 assertions passed 2.75s
  5000 rows read at once in 9.66ms i.e. 517330/s, aver. 1us, 39.8 MB/s
- Update collection: 7,503 assertions passed 784.26ms
  5000 rows updated in 435.30ms i.e. 11486/s, aver. 87us, 3.7 MB/s
- Delete some items: 4,002 assertions passed 370.57ms
  1000 rows deleted in 96.76ms i.e. 10334/s, aver. 96us, 2.2 MB/s
Total failed: 0 / 56,527 - Direct with acknowledge PASSED 4.56s
```

1.2. Direct without acknowledge:

```
- Connect to local server: 6 assertions passed 1.30ms
- Drop and prepare collection: 8 assertions passed 8.59ms
- Fill collection: 15,003 assertions passed 192.59ms
  5000 rows inserted in 168.50ms i.e. 29673/s, aver. 33us, 4.4 MB/s
- Drop collection: no assertion 845us
- Fill collection bulk: 2 assertions passed 68.54ms
  5000 rows inserted in 58.67ms i.e. 85215/s, aver. 11us, 7.9 MB/s
- Read collection: 30,003 assertions passed 2.75s
  5000 rows read at once in 9.99ms i.e. 500150/s, aver. 1us, 38.5 MB/s
- Update collection: 7,503 assertions passed 446.48ms
  5000 rows updated in 96.27ms i.e. 51933/s, aver. 19us, 7.7 MB/s
- Delete some items: 4,002 assertions passed 297.26ms
  1000 rows deleted in 19.16ms i.e. 52186/s, aver. 19us, 2.8 MB/s
Total failed: 0 / 56,527 - Direct without acknowledge PASSED 3.77s
```

As you can see, the reading speed is not affected by the *Write Concern* settings.

But data writing can be multiple times faster, when each write command is not acknowledged.

Since there is no error handling, `wcUnacknowledged` is not to be used on production. You may use it for replication, or for data consolidation, e.g. feeding a database with a lot of existing data as fast as possible.

9.2. MongoDB + ORM = ODM

The `mORMotMongoDB.pas` unit is able to let any `TSQLRecord` class be persisted on a remote *MongoDB* server.

As a result, our ORM is able to be used as a *NoSQL and Object-Document Mapping (ODM)* (page 96) framework, with almost no code change. Any *MongoDB* database can be accessed via RESTful commands, using JSON over HTTP - see below (page 296).

This integration benefits from the other parts of the framework (e.g. our UTF-8 dedicated process, which is also the native encoding for BSON), so you can easily mix SQL and NoSQL databases with the exact same code, and are still able to tune any SQL or *MongoDB* request in your code, if necessary.

From the client point of view, there is no difference between a ORM or an ODM: you may use a SQL engine as a storage for ODM - via *Shared nothing architecture (or sharding)* (page 155) - or even a NoSQL database as a regular ORM, with denormalization (even if it may void most advantages of NoSQL).

9.2.1. Define the TSQLRecord class

In the database model, we define a `TSQLRecord` class, as usual:

```
TSQLORM = class(TSQLRecord)
private
  fAge: integer;
  fName: RawUTF8;
  fDate: TDateTime;
  fValue: variant;
  fInts: TIntegerDynArray;
  fCreateTime: TCreateTime;
  fData: TSQLRawBlob;
published
  property Name: RawUTF8 read fName write fName stored AS_UNIQUE;
  property Age: integer read fAge write fAge;
  property Date: TDateTime read fDate write fDate;
  property Value: variant read fValue write fValue;
  property Ints: TIntegerDynArray index 1 read fInts write fInts;
  property Data: TSQLRawBlob read fData write fData;
  property CreateTime: TCreateTime read fCreateTime write fCreateTime;
end;
```

Note that we did not define any **index** ... values for the `RawUTF8` property, as we need for external SQL databases, since *MongoDB* does not expect any restriction about text fields length (as far as I know, the only SQL engines which allow this natively without any performance penalty are *SQLite3* and *PostgreSQL*).

The property values will be stored in the native *MongoDB* layout, i.e. with a better coverage than the SQL types recognized by our `SynDB*` unit:

Delphi	MongoDB	Remarks
byte	int32	
word	int32	
integer	int32	
cardinal	N/A	You should use Int64 instead

Int64	int64	
boolean	boolean	<i>MongoDB</i> has a boolean type
enumeration	int32	store the ordinal value of the enumerated item(i.e. starting at 0 for the first element)
set	int64	each bit corresponding to an enumerated item (therefore a set of up to 64 elements can be stored in such a field)
single	double	
double	double	
extended	double	stored as double (precision lost)
currency	double	stored as double (<i>MongoDB</i> does not have a BSD type)
RawUTF8	UTF-8	this is the preferred field type for storing some textual content in the ORM
WinAnsiString	UTF-8	<i>WinAnsi</i> char-set (code page 1252) in <i>Delphi</i>
RawUnicode	UTF-8	<i>UCS2</i> char-set in <i>Delphi</i> , as <i>AnsiString</i>
WideString	UTF-8	<i>UCS2</i> char-set, as COM BSTR type (Unicode in all version of <i>Delphi</i>)
SynUnicode	UTF-8	Will be either <i>WideString</i> before <i>Delphi</i> 2009, or <i>UnicodeString</i> later
string	UTF-8	Not to be used before <i>Delphi</i> 2009 (unless you may loose some data during conversion) - <i>RawUTF8</i> is preferred in all cases
TDateTime TDateTimeMS	datetime	ISO 8601 encoded date time
TTimeLog	int64	as proprietary fast Int64 date time
TModTime	int64	the server date time will be stored when a record is modified (as proprietary fast Int64)
TCreateTime	int64	the server date time will be stored when a record is created (as proprietary fast Int64)
TUnixTime	datetime	seconds since Unix epoch
TUnixMSTime	datetime	milliseconds since Unix epoch
TSQLRecord	int32	32-bit RowID pointing to another record (warning: the field value contains pointer(RowID), not a valid object instance - the record content must be retrieved with late-binding via its ID using a <i>PtrInt(Field)</i> typecast or the <i>Field.ID</i> method), or by using e.g. <i>CreateJoined()</i> - is 64-bit on <i>Win64</i>

TID	int32/int64	RowID pointing to another record - this kind of property is 64-bit compatible, so can handle values up to 9,223,372,036,854,775,808
TSQLRecordMany	nothing	data is stored in a separate <i>pivot</i> table; for MongoDB, you should better use <i>data sharding</i> , and an embedded sub-document
TRecordReference TRecordReferenceToBeDeleted	int32/int64	store both ID and TSQLRecord type in a RecordRef-like value - with proper synchronization when the record is deleted
TPersistent	object	BSON object (from ObjectToJSON)
TCollection	array	BSON array of objects (from ObjectToJSON)
TObjectList	array	BSON array of objects (from ObjectToJSON) - see TJSONSerializer. RegisterClassForJSON below (page 310)
TStrings	array	BSON array of strings (from ObjectToJSON)
TRawUTF8List	array	BSON array of string (from ObjectToJSON)
any TObject	object	See TJSONSerializer.RegisterCustomSerializer below (page 307)
TSQLRawBlob	binary	This type is an alias to RawByteString - those properties are not retrieved by default: you need to use RetrieveBlobFields() or set ForceBlobTransfert / ForceBlobTransertTable[] properties
TByteDynArray	binary	Used to embed a BLOB property stored as BSON binary within a document - so that TSQLRawBlob may be restricted in the future to GridFS external content
<i>dynamic arrays</i>	array binary	if the dynamic array can be saved as true JSON, will be stored as BSON array - otherwise, will be stored in the TDynArray.SaveTo BSON binary format
variant	value array object	BSON number, text, date, object or array, depending on TDocVariant custom variant type (page 112) - or TBSONVariant stored value (e.g. to store native MongoDB types like ObjectID or Decimal128)
record	binary object	BSON as defined in code by overriding TSQLRecord.InternalRegisterCustomProperties to produce true JSON

You can share the same TSQLRecord definition with *MongoDB* and other storage means, like external SQL databases. Unused information (like the index attribute) will just be ignored.

Note that TSQLRecord, TID and TRecordReference* published properties will automatically create an index on the corresponding field, and that a kind of ON DELETE SET DEFAULT tracking will take place for TSQLRecord and TRecordReference properties, and ON DELETE CASCADE for TRecordReferenceToBeDeleted - but not for TID, since we do not know which table to track.

9.2.2. Register the TSQLRecord class

On the server side (there won't be any difference for the client), you define a TMongoDBClient, and assign it to a given TSQLRecord class, via a call to StaticMongoDBRegister():

```
MongoClient := TMongoClient.Create('localhost',27017);
DB := MongoClient.Database['dbname'];
Model := TSQLModel.Create([TSQLORM]);
Client := TSQLRestClientDB.Create(Model,nil,':memory:',TSQLRestServerDB);
if StaticMongoDBRegister(TSQLORM,fClient.Server,fDB,'collectionname')=nil then
  raise Exception.Create('Error');
```

And... that's all!

If all the tables of a *mORMot* server should be hosted on a *MongoDB* server, you could call the StaticMongoDBRegisterAll() function instead:

```
StaticMongoDBRegisterAll(aServer,aMongoClient.Open(collectionname'));
```

If you want TSQLRecord.InitializeTable method to be called for void tables (and for instance create TSQLAuthGroup and TSQLAuthUser default content), you can execute the following command:

```
Client.Server.InitializeTables(INITIALIZETABLE_NOINDEX);
```

You can then execute any ORM command, as usual:

```
writeln(Client.TableRowCount(TSQLORM)=0);
```

As with external databases, you can specify the field names mapping between the objects and the *MongoDB* collection.

By default, the TSQLRecord.ID property is mapped to the *MongoDB*'s `_id` field, and the ORM will populate this `_id` field with a sequence of integer values, just like any TSQLRecord table.

You can specify your own mapping, using e.g.:

```
aModel.Props[aClass].ExternalDB.MapField(..)
```

Since the field names are stored within the document itself, it may be a good idea to use shorter naming for the *MongoDB* collection. It may save some storage space, when working with a huge number of documents.

Once the TSQLRecord is mapped to a *MongoDB* collection, you can always have direct access to the corresponding TMongoCollection instance later on, using a simple transtyping:

```
(aServer.StaticDataServer[aClass] as TSQLRestStorageMongoDB).Collection
```

This may allow any specific task, including any tuned query or process.

9.2.3. ORM/ODM CRUD methods

You can add documents with the standard CRUD methods of the ORM, as usual:

```
R := TSQLORM.Create;
try
  for i := 1 to COLL_COUNT do begin
    R.Name := 'Name '+Int32ToUTF8(i);
    R.Age := i;
    R.Date := 1.0*(30000+i);
    R.Value := _ObjFast(['num',i]);
    R.Ints := nil;
    R.DynArray(1).Add(i);
    assert(Client.Add(R,True)=i);
  end;
finally
  R.Free;
end;
```

As we already saw, the framework is able to handle any kind of properties, including complex types like *dynamic arrays* or *variant*.

In the above code, a *TDocVariant* document has been stored in *R.Value*, and a dynamic array of integer values is accessed via its index *1* shortcut and the *TSQLRecord.DynArray()* method.

The usual Retrieve / Delete / Update methods are available:

```
R := TSQLORM.Create;
try
  for i := 1 to COLL_COUNT do begin
    Check(Client.Retrieve(i,R));
    // here R instance contains all values of one document, excluding BLOBs
  end;
finally
  R.Free;
end;
```

You can define a WHERE clause, as if the back-end where a regular SQL database:

```
R := TSQLORM.CreateAndFillPrepare(Client, 'ID=?',[i]);
try
  ...
```

9.2.4. ODM complex queries

To perform a query and retrieve the content of several documents, you can use regular *CreateAndFillPrepare* or *FillPrepare* methods:

```
R := TSQLORM.CreateAndFillPrepare(Client,WHERE_CLAUSE,[WHERE_PARAMETERS]);
try
  n := 0;
  while R.FillOne do begin
    // here R instance contains all values of one document, excluding BLOBs
    inc(n);
  end;
  assert(n=COLL_COUNT);
finally
  R.Free;
end;
```

A WHERE clause can also be defined for *CreateAndFillPrepare* or *FillPrepare* methods. This WHERE clause could contain several expressions, joined with AND / OR.

Each of those expressions could use:

- The simple comparators = < <= <> > >=,
- An IN (....) clause,
- IS NULL / IS NOT NULL tests,
- A LIKE operation,
- Or even any ...*DynArrayContains()* specific function.

The *mORMot* ODM will convert this SQL-like statement into the optimized *MongoDB* query expression, using e.g. a regular expression for the LIKE operator.

The LIMIT, OFFSET and ORDER BY clauses will also be handled as expected. A special care should be taken for an ORDER BY on textual values: by design, *MongoDB* will always sort text with case-sensitivity, which is not what we expect: so our ODM will sort such content on client side, after having been retrieved from the *MongoDB* server. For numerical fields, *MongoDB* sorting features will be processed on the server side.

The COUNT(*) function will also be converted into the proper *MongoDB* API call, so that such operations will be as costless as possible. DISTINCT() MAX() MIN() SUM() AVG() functions and the

GROUP BY clause will also be converted into optimized *MongoDB* aggregation pipelines, on the fly. You could even set aliases for the columns (e.g. max(RowID) as first) and perform simple addition/subtraction of an integer value.

Here are some typical WHERE clauses, and the corresponding *MongoDB* query document as generated by the ODM:

WHERE clause	MongoDB Query
'Name=?', ['Name 43']	{Name:"Name 43"}
'Age<?', [51]	{Age:{\$lt:51}}
'Age in (1,10,20)'	{Age:{\$in:[1,10,20]}}
'Age in (1,10,20) and ID=?', [10]	{Age:{\$in:[1,10,20]},_id:10}
'Age in (10,20) or ID=?', [30]	{\$or:[{Age:{\$in:[10,20]}},{_id:30}]}
'Name like ?', ['name 1%']	{Name:/^name 1/i}
'Name like ?', ['name 1']	{Name:/^name 1\$/i}
'Name like ?', ['%ame 1%']	{Name:/ame 1/i}
'Data is null'	{Data:null}
'Data is not null'	{Data:{\$ne:null}}
'Age<? limit 10', [51]	{Age:{\$lt:51}} + limit 10
'Age in (10,20) or ID=? order by ID desc', [30]	{\$query:{\$or:[{Age:{\$in:[10,20]}},{_id:30}]},\$orderby:{_id:-1}}
'order by Name'	{ } + client side text sort by Name
'Age in (1,10,20) and IntegerDynArrayContains(Ints,?)', [10])	{Age:{\$in:[1,10,20]},Ints:{\$in:[10]}}
Distinct(Age),max(RowID) as first,count(Age) as count group by age	{\$group:{_id:"\$Age",f1:{\$max:"\$_id"},f2:{\$sum:1}},{\$project:{_id:0,"Age":"\$_id","first":"\$f1","count":"\$f2"}}
min(RowID),max(RowID),Count(RowID)	{\$group:{_id:null,f0:{\$min:"\$_id"},f1:{\$max:"\$_id"},f2:{\$sum:1}},{\$project:{_id:0,"min(RowID)":"\$f0","max(RowID)":"\$f1","Count(RowID)":"\$f2"}}
min(RowID) as a,max(RowID)+1 as b,Count(RowID) as c	{\$group:{_id:null,f0:{\$min:"\$_id"},f1:{\$max:"\$_id"},f2:{\$sum:1}},{\$project:{_id:0,"a":"\$f0","b":{\$add:["\$f1",1]},{"c":"\$f2"}}

Note that parenthesis and mixed AND OR expressions are not handled yet. You could always execute any complex *NoSQL* query (e.g. using aggregation functions or the *Map/Reduce* pattern) by using directly the *TMongoCollection* methods.

But for most business code, *mORMot* allows to share the same exact code between your regular SQL databases or *NoSQL* engines. You do not need to learn the *MongoDB* query syntax: the ODM will compute the right expression for you, depending on the database engine it runs on.

9.2.5. BATCH mode

In addition to individual CRUD operations, our *MongoDB* is able to use BATCH mode for adding or deleting documents.

You can write the exact same code as with any SQL back-end:

```
Client.BatchStart(TSQLORM);
R := TSQLORM.Create;
try
  for i := 1 to COLL_COUNT do begin
    R.Name := 'Name '+Int32ToUTF8(i);
    R.Age := i;
    R.Date := 1.0*(30000+i);
    R.Value := _ObjFast(['num',i]);
    R.Ints := nil;
    R.DynArray(1).Add(i);
    assert(Client.BatchAdd(R,True)>=0);
  end;
finally
  R.Free;
end;
assert(Client.BatchSend(IDs)=HTTP_SUCCESS);
```

Or for deletion:

```
Client.BatchStart(TSQLORM);
for i := 5 to COLL_COUNT do
  if i mod 5=0 then
    assert(fClient.BatchDelete(i)>=0);
assert(Client.BatchSend(IDs)=HTTP_SUCCESS);
```

Speed benefit may be huge in regard to individual Add/Delete operations, even on a local *MongoDB* server. We will see some benchmark numbers now.

9.2.6. ORM/ODM performance

You can take a look at *Data access benchmark* (page 199) to compare *MongoDB* as back-end for our ORM classes.

In respect to external SQL engines, it features very high speed, low CPU use, and almost no difference in use. We interfaced the BatchAdd() and BatchDelete() methods to benefit of *MongoDB* BULK process, and avoided most memory allocation during the process.

Here are some numbers, extracted from the MongoDBTests.dpr sample, which reflects the performance of our ORM/ODM, depending on the *Write Concern* mode used:

2. ORM

2.1. ORM with acknowledge:

- Connect to local server: 6 assertions passed 18.65ms
- Insert: 5,002 assertions passed 521.25ms
5000 rows inserted in 520.65ms i.e. 9603/s, aver. 104us, 2.9 MB/s
- Insert in batch mode: 5,004 assertions passed 65.37ms
5000 rows inserted in 65.07ms i.e. 76836/s, aver. 13us, 8.4 MB/s
- Retrieve: 45,001 assertions passed 640.95ms
5000 rows retrieved in 640.75ms i.e. 7803/s, aver. 128us, 2.1 MB/s
- Retrieve all: 40,001 assertions passed 20.79ms
5000 rows retrieved in 20.33ms i.e. 245941/s, aver. 4us, 27.1 MB/s
- Retrieve one with where clause: 45,410 assertions passed 673.01ms
5000 rows retrieved in 667.17ms i.e. 7494/s, aver. 133us, 2.0 MB/s
- Update: 40,002 assertions passed 681.31ms
5000 rows updated in 660.85ms i.e. 7565/s, aver. 132us, 2.4 MB/s
- Blobs: 125,003 assertions passed 2.16s

```
5000 rows updated in 525.97ms i.e. 9506/s, aver. 105us, 2.4 MB/s
- Delete: 38,003 assertions passed 175.86ms
  1000 rows deleted in 91.37ms i.e. 10944/s, aver. 91us, 2.3 MB/s
- Delete in batch mode: 33,003 assertions passed 34.71ms
  1000 rows deleted in 14.90ms i.e. 67078/s, aver. 14us, 597 KB/s
Total failed: 0 / 376,435 - ORM with acknowledge PASSED 5.00s

2.2. ORM without acknowledge:
- Connect to local server: 6 assertions passed 16.83ms
- Insert: 5,002 assertions passed 179.79ms
  5000 rows inserted in 179.15ms i.e. 27908/s, aver. 35us, 3.9 MB/s
- Insert in batch mode: 5,004 assertions passed 66.30ms
  5000 rows inserted in 31.46ms i.e. 158891/s, aver. 6us, 17.5 MB/s
- Retrieve: 45,001 assertions passed 642.05ms
  5000 rows retrieved in 641.85ms i.e. 7789/s, aver. 128us, 2.1 MB/s
- Retrieve all: 40,001 assertions passed 20.68ms
  5000 rows retrieved in 20.26ms i.e. 246718/s, aver. 4us, 27.2 MB/s
- Retrieve one with where clause: 45,410 assertions passed 680.99ms
  5000 rows retrieved in 675.24ms i.e. 7404/s, aver. 135us, 2.0 MB/s
- Update: 40,002 assertions passed 231.75ms
  5000 rows updated in 193.74ms i.e. 25807/s, aver. 38us, 3.6 MB/s
- Blobs: 125,003 assertions passed 1.44s
  5000 rows updated in 150.58ms i.e. 33202/s, aver. 30us, 2.6 MB/s
- Delete: 38,003 assertions passed 103.57ms
  1000 rows deleted in 19.73ms i.e. 50668/s, aver. 19us, 2.4 MB/s
- Delete in batch mode: 33,003 assertions passed 47.50ms
  1000 rows deleted in 364us i.e. 2747252/s, aver. 0us, 23.4 MB/s
Total failed: 0 / 376,435 - ORM without acknowledge PASSED 3.44s
```

As for direct *MongoDB* access, the *wcUnacknowledged* is not to be used on production, but may be very useful in some particular scenarios. As expected, the reading process is not impacted by the *Write Concern* mode set.

10. JSON RESTful Client-Server

Adopt a mORMot

Before describing the Client-Server design of this framework, we may have to detail some standards it is based on:

- JSON as its internal data storage and transmission format;
- REST as its Client-Server architecture.

10.1. JSON

10.1.1. Why use JSON?

As we just stated, the JSON format is used internally in this framework. By definition, the *JavaScript Object Notation* (JSON) is a standard, open and lightweight computer data interchange format.

JSON's basic types are - as retrieved from <http://en.wikipedia.org/wiki/JSON..>

Type	Description
Number	Double precision floating-point format in <i>JavaScript</i> , generally depends on implementation. There is no specific integer type
String	Double-quoted Unicode, with backslash escaping
Boolean	true or false
Array	An ordered sequence of values, comma-separated and enclosed in square brackets; the values do not need to be of the same type

Object	An unordered collection of key:value pairs with the ':' character separating the key and the value, comma-separated and enclosed in curly braces; the keys must be strings and should be distinct from each other
--------	---

null	Empty/undefined value
------	-----------------------

Non-significant white space may be added freely around the "structural characters" (i.e. brackets "{ } []", colons ":" and commas ",").

The following example shows the JSON representation of an object that describes a person. The object has string fields for first name and last name, a number field for age, an object representing the person's address and an array of phone number objects.

```
{
  "firstName": "John",
  "lastName": "Smith",
  "age": 25,
  "address": {
    "streetAddress": "21 2nd Street",
    "city": "New York",
    "state": "NY",
    "postalCode": 10021
  },
  "phoneNumbers": [
    {
      "type": "home",
      "number": "212 555-1234"
    },
    {
      "type": "fax",
      "number": "646 555-4567"
    }
  ]
}
```

Usage of this layout, instead of other like XML or any proprietary format, results in several particularities:

- Like XML, it is a text-based, human-readable format for representing simple data structures and associative arrays (called objects);
- It's easier to read (for both human beings and machines), quicker to implement, and much smaller in size than XML for most use;
- It's a very efficient format for data caching;
- Its layout allows to be rewritten in place into individual zero-terminated UTF-8 strings, with almost no wasted space: this feature is used for very fast JSON to text conversion of the tables results, with no memory allocation nor data copy;
- It's natively supported by the *JavaScript* language, making it a perfect serialization format in any AJAX (i.e. Web 2.0) or HTML5 Mobile application;
- The JSON format is simple, and specified in a short and clean RFC document;
- The default text encoding for both JSON and *SQLite3* is UTF-8, which allows the full Unicode char-set to be stored and communicated;
- It is the default data format used by ASP.NET AJAX services created in Windows Communication Foundation (WCF) since .NET framework 3.5; so it's Microsoft officially "ready";
- For binary BLOB transmission, we simply encode the binary data as *Base64*; please note that, by default, BLOB fields are not transmitted over REST with other fields in JSON objects, see below (page 314) (only exception are *dynamic array* fields, which are transmittest within the other fields).

REST JSON serialization will indeed be used in our main ORM to process of any TSQLRecord published properties, and in the interface-based SOA architecture of the framework, for content transmission.

In the framework, the whole <http://json.org..> standard is implemented, with some exceptions/extensions:

- #0 characters will indicate the end of input, as with almost all JSON libraries - so if your text input contains a #0 char, please handle it as binary (note that other control chars are escaped as expected);
- You may use an "extended syntax" (used e.g. by MongoDB) by unquoting ASCII-only property names;
- Floating point numbers are sometimes limited to currency (i.e. 4 decimals), to ensure serialization/unserialization won't lose precision; but in such cases, it can be extended to the double precision via a set of options;
- There is no 53-bit limitation for integers, as with JavaScript: the framework handles 64-bit integer values - when using a JavaScript back-end, you may have to transmit huge values as text.

In practice, JSON has been found out to be very easy to work with and stable. A binary format is not used for transmission yet, but is available at other level of the framework, e.g. as a possible file format for in-memory TObjectList database engine (with our SynLZ compression - see *Virtual Tables magic* (page 226)).

10.1.2. Values serialization

Standard *Delphi* value types are serialized directly within the JSON content, in their textual representation. For instance, integer or Int64 are stored as numbers, and double values are stored as their corresponding floating-point representation.

All string content is serialized as standard JSON text field, i.e. nested with double quotes ("). Since JSON uses UTF-8 encoding, it is one of the reasons why we introduced the RawUTF8 type, and use it everywhere in our framework.

10.1.3. Record serialization

In *Delphi*, the record has some nice advantages:

- record are *value* objects, i.e. accessed by value, not by reference - this can be very convenient, e.g. when defining *Domain-Driven Design* (page 99);
- record can contain any other record or *dynamic array*, so are very convenient to work with (no need to define sub-classes or lists);
- record variables can be allocated on stack, so won't solicit the global heap;
- record instances automatically freed by the compiler when they come out of scope, so you won't need to write any `try..finally Free; end` block.

Serialization of record values are therefore a must-have for a framework like *mORMot*. In practice, the record types should be defined as packed record, so that low-level access will be easier to manage by the serializers.

10.1.3.1. Automatic serialization via Enhanced RTTI

Since *Delphi* 2010, the compiler generates additional RTTI at compilation, so that all record fields are described, and available at runtime.

By the way, this enhanced RTTI is one of the reasons why executables did grow so much in newer versions of the compiler.

Our SynCommons.pas unit is able to use this enhanced information, and let any record be serialized via RecordLoad() and RecordSave() functions, and all internal JSON marshalling process.

In short, you have nothing to do. Just use your record as parameters, and, with *Delphi 2010* and up, they will be serialized as valid JSON objects. The only restriction is that the records should be defined as packed record.

10.1.3.2. Serialization for older Delphi versions

Sadly, the information needed to serialize a record is available only since *Delphi 2010*.

If your application is developed on any older revision (e.g. *Delphi 7*, *Delphi 2007* or *Delphi 2009*), you won't be able to automatically serialize records as plain JSON objects directly.

You have several paths available:

- By default, the record will be serialized as binary, and encoded as *Base64* text;
- Or you can define method callbacks which will write or read the data as you expect;
- Or you can define the record layout as plain text.

Note that any custom serialization (either via callbacks, or via text definition), will override any previous registered method, even the mechanism using the enhanced RTTI. You can change the default serialization to easily meet your requirements. For instance, this is what `SynCommons.pas` does for any `TGUID` content, which is serialized as the standard JSON text layout (e.g. `"C9A646D3-9C61-4CB7-BFCD-EE2522C8F633"`), and not following the `TGUID` record layout as defined in the RTTI, i.e. `{"D1":12345678,"D2":23023,"D3":9323,"D4":"0123456789ABCDEF"}` - which is far from convenient.

10.1.3.2.1. Default Binary/Base64 serialization

On any version of the compiler prior to *Delphi 2010*, any record value will be serialized by default with a proprietary binary (and optimized) layout - i.e. via `RecordLoad` and `RecordSave` functions - then encoded as *Base64*, to be stored as plain text within the JSON stream.

A special UTF-8 prefix (which does not match any existing *Unicode* glyph) is added at the beginning of the resulting JSON string to identify this content as a BLOB, as such:

```
{ "MyRecord": "ï¿°w6nDoM0nYQ==" }
```

You will find in `SynCommons.pas` unit both `BinToBase64` and `Base64ToBin` functions, very optimized for speed. *Base64* encoding was chosen since it is standard, much more efficient than hexadecimal, and still JSON compatible without the need to escape its content.

When working with most part of the framework, you do not have anything to do: any record will by default follow this *Base64* serialization, so you will be able e.g. to publish or consume interface-based services with records.

10.1.3.2.2. Custom serialization

Base64 encoding is pretty convenient for a computer (it is a compact and efficient format), but it is very limited about its interoperability. Our format is proprietary, and will use the internal *Delphi* serialization scheme: it means that it won't be readable nor writable outside the scope of your own *mORMot* applications. In a RESTful/SOA world, this sounds not like a feature, but a limitation.

Custom record JSON serialization can therefore be defined, as with any `class` - see below (page 307). It will allow writing and parsing record variables as regular JSON objects, ready to be consumed by any client or server. Internally, some callbacks will be used to perform the serialization.

In fact, there are two entry points to specify a custom JSON serialization for record:

- When setting a custom *dynamic array* JSON serializer - see below (page 304) - the associated record will also use the same Reader and Writer callbacks;
- By setting explicitly serialization callbacks for the `TypeInfo()` of the record, with the very same `TTextWriter`. `RegisterCustomJSONSerializer` method used for dynamic arrays.

Then the Reader and Writer callbacks can be defined by two means:

- By hand, i.e. coding the methods with manual conversion to JSON text or parsing;
- Via some text-based type definition, which will follow the record layout, but will do all the marshalling (including memory allocation) on its own.

10.1.3.2.3. Defining callbacks

For instance, if you want to serialize the following record:

```
TSQLEstCacheEntryValue = record
  ID: TID;
  Timestamp: cardinal;
  JSON: RawUTF8;
end;
```

With the following code:

```
TTextWriter.RegisterCustomJSONSerializer(TypeInfo(TSQLEstCacheEntryValue),
  TTestServiceOrientedArchitecture.CustomReader,
  TTestServiceOrientedArchitecture.CustomWriter);
```

The expected format will be as such:

```
{"ID":1786554763,"Timestamp":323618765,"JSON":"D:\\TestSQL3.exe"}
```

Therefore, the writer callback could be:

```
class procedure TTestServiceOrientedArchitecture.CustomWriter(
  const aWriter: TTextWriter; const aValue);
var V: TSQLEstCacheEntryValue absolute aValue;
begin
  aWriter.AddJSONEscape(['ID',V.ID,'Timestamp',Int64(V.Timestamp),'JSON',V.JSON]);
end;
```

In the above code, the cardinal field named `Timestamp` is type-casted to a `Int64`: in fact, as stated by the documentation of the `AddJSONEscape` method, an array of `const` will handle by default any cardinal as an integer value (this is a limitation of the *Delphi* compiler). By forcing the type to be an `Int64`, the expected cardinal value will be transmitted, and not a wrongly negative versions for numbers > \$7fffffff.

On the other side, the corresponding reader callback will be like:

```
class function TTestServiceOrientedArchitecture.CustomReader(P: PUTF8Char;
  var aValue; out aValid: Boolean; aCustomVariantOptions: PDocVariantOptions): PUTF8Char;
var V: TSQLEstCacheEntryValue absolute aValue;
  Values: array[0..2] of TValuePUTF8Char;
begin
  result := JSONDecode(P,['ID','Timestamp','JSON'],@Values);
  if result=nil then
    aValid := false else begin
      V.ID := GetInt64(Values[0].Value);
      V.Timestamp := GetCardinal(Values[1].Value);
      Values[2].ToUTF8(V.JSON);
      aValid := true;
    end;
end;
```

Here `JSONDecode()` is used for fast deserialization of a JSON object.

10.1.3.2.4. Text-based definition

Writing those callbacks by hand could be error-prone, especially for the Reader event.

You can use the `TTextWriter.RegisterCustomJSONSerializerFromText` method to define the record layout in a convenient text-based format. Once more, those types need to be defined as packed record, so that the text layout definition will not depend on compiler-specific field alignment.

The very same `TSQLRestCacheEntryValue` can be defined as with a typical *pascal* record:

```
const
__TSQLRestCacheEntryValue = 'ID: Int64; Timestamp: cardinal; JSON: RawUTF8';
```

Or with a shorter syntax:

```
const
__TSQLRestCacheEntryValue = 'ID Int64 Timestamp cardinal JSON RawUTF8';
```

Both declarations will do the same definition. Note that the supplied text should match *exactly* the original record type definition: do not swap or forget any property!

By convention, we use two underscore characters (`__`) before the record type name, to easily identify the layout definition. It may indeed be convenient to write it as a constant, close to the record type definition itself, and not in-lined at `RegisterCustomJSONSerializerFromText()` call level.

Then you register your type as such:

```
TTextWriter.RegisterCustomJSONSerializerFromText(
  TypeInfo(TSQLRestCacheEntryValue), __TSQLRestCacheEntryValue);
```

Now you are able to serialize any record value directly:

```
Cache.ID := 10;
Cache.Timestamp := 200;
Cache.JSON := 'test';
U := RecordSaveJSON(Cache, TypeInfo(TSQLRestCacheEntryValue));
Check(U='{ "ID":10, "Timestamp":200, "JSON":"test" }');
```

You can also unserialize some existing JSON content:

```
U := '{ "ID":210, "Timestamp":2200, "JSON":"test2" }';
RecordLoadJSON(Cache, @U[1], TypeInfo(TSQLRestCacheEntryValue));
Check(Cache.ID=210);
Check(Cache.Timestamp=2200);
Check(Cache.JSON='test2');
```

Note that this text-based definition is very powerful, and is able to handle any level of nested record or *dynamic arrays*.

By default, it will write the JSON content in a compact form, and will expect only existing fields to be available in the incoming JSON. You can specify some options at registration, to ignore all non defined fields. It can be very useful when you want to consume some remote service, and are interested only in a few fields.

For instance, we may define a client access to a RESTful service like `api.github.com`:

```
type
TTestCustomJSONGitHub = packed record
  name: RawUTF8;
  id: cardinal;
  description: RawUTF8;
  fork: boolean;
  owner: record
    login: RawUTF8;
    id: cardinal;
  end;
```

```
end;
TTestCustomJSONGitHubs = array of TTestCustomJSONGitHub;

const
  __TTestCustomJSONGitHub = 'name RawUTF8 id cardinal description RawUTF8 '+'
    'fork boolean owner{login RawUTF8 id cardinal}';
```

Note the { } format to define a nested record, as a shorter alternative to a nested record .. end syntax.

It is also mandatory that you declare the record as packed. Otherwise, you may have unexpected access violation issues, since alignment may vary, depending on local setting, and compiler revision.

Now we can register the record layout, and provide some additional options:

```
TTextWriter.RegisterCustomJSONSerializerFromText(TypeInfo(TTestCustomJSONGitHub),
  __TTestCustomJSONGitHub).Options := [soReadIgnoreUnknownFields, soWriteHumanReadable];
```

Here, we defined:

- soReadIgnoreUnknownFields to ignore any non defined field in the incoming JSON;
- soWriteHumanReadable to let the output JSON be more readable.

Then the JSON can be parsed then emitted as such:

```
var git: TTestCustomJSONGitHubs;
...
U := zendframeworkJson;
Check(DynArrayLoadJSON(git,@U[1],TypeInfo(TTestCustomJSONGitHubs))<>nil);
U := DynArraySaveJSON(git,TypeInfo(TTestCustomJSONGitHubs));
```

You can see that the record serialization is auto-magically available at dynamic array level, which is pretty convenient in our case, since the `api.github.com` RESTful service returns a JSON array.

It will convert 160 KB of very verbose JSON information:

```
[{"id":8079771,"name":"Component_ZendAuthentication","full_name":"zendframework/Component_ZendAuth
entication","owner":{"login":"zendframework","id":296074,"avatar_url":"https://1.gravatar.com/avat
ar/460576a0866d93fdacb597da4b90f233?d=https%3A%2F%2Fidenticons.github.com%2F292b7433472e2946c926bd
ca195cec8c.png&r=x","gravatar_id":"460576a0866d93fdacb597da4b90f233","url":"https://api.github.com
/users/zendframework","HTTP_url":"https://github.com/zendframework","followers_url":"https://api.g
ithub.com/users/zendframework/followers","following_url":"https://api.github.com/users/zendframewo
rk/following{/other_user}","gists_url":"https://api.github.com/users/zendframework/gists{/gist_id}
","starred_url":"https://api.github.com/users/zendframework/starred{/owner}/{repo}"},"...]
```

Into the much smaller (6 KB) and readable JSON content, containing only the information we need:

```
[
{
  "name": "Component_ZendAuthentication",
  "id": 8079771,
  "description": "Authentication component from Zend Framework 2",
  "fork": true,
  "owner":
  {
    "login": "zendframework",
    "id": 296074
  }
},
{
  "name": "Component_ZendBarcode",
  "id": 8079808,
  "description": "Barcode component from Zend Framework 2",
  "fork": true,
  "owner":
  {
    "login": "zendframework",
```

```
"id": 296074
}
},
...
```

During the parsing process, all unneeded JSON members will just be ignored. The parser will jump the data, without doing any temporary memory allocation. This is a huge difference with other existing *Delphi* JSON parsers, which first create a tree of all JSON values into memory, then allow to browse all the branches on request.

Note also that the fields have been ordered following the `TTestCustomJSONGitHub` record definition, which may not match the original JSON layout (here `name/id` fields order is inverted, and `owner` is set at the end of each item, for instance).

With *mORMot*, you can then access directly the content from your *Delphi* code as such:

```
if git[0].id=8079771 then begin
  Check(git[0].name='Component_ZendAuthentication');
  Check(git[0].description='Authentication component from Zend Framework 2');
  Check(git[0].fork=true);
  Check(git[0].owner.login='zendframework');
  Check(git[0].owner.id=296074);
end;
```

Note that we do not need to use intermediate objects (e.g. via some obfuscated expressions like `gitarray.Value[0].Value['owner'].Value['login']`). Your code will be much more readable, will complain at compilation if you misspell any field name, and will be easy to debug within the IDE (since the record layout can be easily inspected).

The serialization is able to handle any kind of nested record or *dynamic arrays*, including *dynamic arrays* of simple types (e.g. array of integer or array of `RawUTF8`), or *dynamic arrays* of record:

```
type
  TTestCustomJSONRecord = packed record
    A,B,C: integer;
    D: RawUTF8;
    E: record E1,E2: double; end;
    F: TDateTime;
  end;
  TTestCustomJSONArray = packed record
    A,B,C: integer;
    D: RawByteString;
    E: array of record E1: double; E2: string; end;
    F: TDateTime;
  end;
  TTestCustomJSONArraySimple = packed record
    A,B: Int64;
    C: array of SynUnicode;
    D: RawUTF8;
  end;
```

The corresponding text definitions may be:

```
const
  __TTestCustomJSONRecord = 'A,B,C integer D RawUTF8 E{E1,E2 double} F TDateTime';
  __TTestCustomJSONArray = 'A,B,C integer D RawByteString E[E1 double E2 string] F TDateTime';
  __TTestCustomJSONArraySimple = 'A,B Int64 C array of synunicode D RawUTF8';
```

The following types are handled by this feature:

Delphi type	Remarks
boolean	Serialized as JSON boolean

byte word integer cardinal Int64 single double currency TUnixTime	Serialized as JSON number
string RawUTF8 SynUnicode WideString	Serialized as JSON string
DateTime TTimeLog	Serialized as JSON text, encoded as ISO 8601
RawByteString	Serialized as JSON null or Base64-encoded JSON string
RawJSON	Stored as un-serialized raw JSON content (e.g. any value, object or array)
TGUID	GUID serialized as JSON text
nested record	Serialized as JSON object Identified as record ... end; or { ... } with its nested definition
nested registered record	Serialized as JSON corresponding the the defined callbacks
<i>dynamic array</i> of record	Serialized as JSON array Identified as array of ... or [...]
<i>dynamic array</i> of simple types	Serialized as JSON array Identified e.g. as array of integer
<i>static array</i>	Serialized as JSON array Handled with enhanced RTTI, not via text definition yet
variant	Serialized as JSON, with full support of <i>TDocVariant custom variant type</i> (page 112)

For other types (like enumerations or sets), you can simply use the unsigned integer types corresponding to the binary value, e.g. byte word cardinal Int64 (depending on the sizeof() of the initial value).

For instance, void TTestCustomJSONRecord may be serialized as:

```
{"A":0,"B":0,"C":0,"D":"","E":{"E1":0,"E2":0},"F":""}
```

Or void TTestCustomJSONArray may be serialized as:

```
{"A":0,"B":0,"C":0,"D":null,"E":[],"F":""}
```

Or void TTestCustomJSONArraySimple may be serialized as:

```
{"A":0,"B":0,"C":[],"D":""}
```

You can refer to the supplied regression tests (in TTestLowLevelTypes.EncodeDecodeJSON) for some more examples of custom JSON serialization.

10.1.4. Dynamic array serialization

10.1.4.1. Standard JSON arrays

Note that dynamic arrays are handled in two separated contexts:

- Within the ORM part of the framework, they are stored as BLOB and always transmitted after

Base64 encoding - see *TSQLRecord fields definition* (page 131);

- Within the scope of interface-based services, dynamic arrays values and parameters are using the advanced JSON serialization made available in the TDynArray wrapper, i.e. could be either a true JSON array, or, in default, use generic binary and *Base64* encoding, prior to *Delphi 2010*.

In fact, this TDynArray wrapper - see *TDynArray dynamic array wrapper* (page 107) - recognizes most common kind of *dynamic arrays*, like array of byte, word, integer, cardinal, Int64, double, currency, RawUTF8, SynUnicode, WinAnsiString, string. They will be serialized as a valid JSON array, i.e. a list of valid JSON elements of the matching type (number, floating-point value or string). If you have any ideas of standard *dynamic arrays* which should be handled, feel free to post your proposal in the forum!

Since *Delphi 2010*, the framework will use the enhanced RTTI to create a JSON array corresponding to the data layout of each *dynamic array* item, just as for *Record serialization* (page 298).

For version of the compiler up to *Delphi 2009*, not-known *dynamic arrays* (like any array of packed record) will be serialized by default as binary, then *Base64* encoded. This method will always work, but won't be easy to deal with from an AJAX client.

Of course, your applications can supply a custom JSON serialization for any other dynamic array, via the TTextWriter.RegisterCustomJSONSerializer() class method. Two callbacks are to be defined in association with dynamic array type information, in order to handle proper serialization and un-serialization of the JSON array.

As an alternative, you can call the RegisterCustomJSONSerializerFromText method to define the record layout in a convenient text-based format - see above.

In fact, if you register a *dynamic array* custom serializer, it will also be used for the associated internal record.

10.1.4.2. Customized serialization

As we already stated, it may be handy to change the default serialization.

For instance, we would like to serialize a dynamic array of the following record:

```
TFV = packed record
  Major, Minor, Release, Build: integer;
  Main, Detailed: string;
end;
TFVs = array of TFV;
```

With the default serialization, such a dynamic array will be serialized either:

- As a *Base64* encoded binary buffer, before *Delphi 2010* - this won't be easy to understand from an AJAX client, for instance;
- As a JSON array of JSON object, with all property names listed within each object, since *Delphi 2010* and its enhanced RTTI.

This default serialization can be overridden, by defining callbacks. It could be handy, e.g. if you do not like the fact that all field names are written in the data, which may be a waste of space:

```
{"Major":1,"Minor":2001,"Release":3001,"Build":4001,"Main":"1","Detailed":"1001"}
```

In order to add a custom serialization for this kind of record, we need to implement the two needed callbacks.

Our expected format will be a JSON array of all fields, i.e.:

```
[1,2001,3001,4001,"1","1001"]
```

This layout is more than two times shorter than the default JSON object format.

We may have used another layout, e.g. using `JSONEncode()` function and a JSON object layout, or any other valid JSON content.

Here comes the writer:

```
class procedure TCollTstDynArray.FVWriter(const aWriter: TTextWriter; const aValue);
var V: TFV absolute aValue;
begin
  aWriter.Add(['[%,%,%,%,"%", "%"]',
    [V.Major,V.Minor,V.Release,V.Build,V.Main,V.Detailed],twJSONEscape);
end;
```

This event will write one entry of the dynamic array, without the last ',' (which will be appended by `TTextWriter.AddDynArrayJSON`). In this method, `twJSONEscape` is used to escape the supplied string content as a valid JSON string (with double quotes and proper UTF-8 encoding).

Of course, the *Writer* is easier to code than the *Reader* itself:

```
class function TCollTstDynArray.FVReader(P: PUTF8Char; var aValue;
  out aValid: Boolean): PUTF8Char;
var V: TFV absolute aValue;
begin // '[1,2001,3001,4001,"1","1001"],[2,2002,3002,4002,"2","1002"],...'
  aValid := false;
  result := nil;
  if (P=nil) or (P^<>'[') then
    exit;
  inc(P);
  V.Major := GetNextItemCardinal(P);
  V.Minor := GetNextItemCardinal(P);
  V.Release := GetNextItemCardinal(P);
  V.Build := GetNextItemCardinal(P);
  V.Main := UTF8ToString(GetJSONField(P,P));
  V.Detailed := UTF8ToString(GetJSONField(P,P));
  if P=nil then
    exit;
  aValid := true;
  result := P; // ', ' or ']' for last item of array
end;
```

The reader method shall return a pointer to the next separator of the JSON input buffer just after this item (either ', ' or ']').

The registration process itself is as simple as:

```
TTextWriter.RegisterCustomJSONSerializer(TypeInfo(TFVs),
  TCollTstDynArray.FVReader, TCollTstDynArray.FVWriter);
```

Then, from the user code point of view, this dynamic array handling won't change: once registered, the JSON serializers are used everywhere in the framework, as soon as this type is globally registered.

Here is a *Writer* method using a JSON object layout, which may be used for *Delphi* up to 2009, to obtain a serialization similar to the one generated via the enhanced RTTI.

```
class procedure TCollTstDynArray.FVWriter2(const aWriter: TTextWriter; const aValue);
var V: TFV absolute aValue;
begin
  aWriter.AddJSONEscape(['Major',V.Major,'Minor',V.Minor,'Release',V.Release,
    'Build',V.Build,'Main',V.Main,'Detailed',V.Detailed]);
end;
```

This will create some JSON content as such:

```
{"Major":1,"Minor":2001,"Release":3001,"Build":4001,"Main":"1","Detailed":"1001"}
```

We may also use similar callbacks, e.g. if we want the property names to be changed, or ignored

depending on some default values.

Then the corresponding *Reader* callback could be written as:

```
class function TCollTstDynArray.FVReader2(P: PUTF8Char; var aValue;
  out aValid: Boolean): PUTF8Char;
var V: TFV absolute aValue;
    Values: array[0..5] of TValuePUTF8Char;
begin
  aValid := false;
  result := JSONDecode(P, ['Major', 'Minor', 'Release', 'Build', 'Main', 'Detailed'], @Values);
  if result=nil then
    exit; // result^ = ',' or ']' for last item of array
  V.Major := Values[0].ToInteger;
  V.Minor := Values[1].ToInteger;
  V.Release := Values[2].ToInteger;
  V.Build := Values[3].ToInteger;
  V.Main := Values[4].ToString;
  V.Detailed := Values[5].ToString;
  aValid := true;
end;
```

Most of the JSON decoding process is performed within the `JSONDecode()` function, which will let `Values[].Value/ValueLen` couples point to null-terminated un-escaped content within the `P^` buffer. In fact, unserialization will do no memory allocation, and will therefore be very fast.

If you want to go back to the default binary + *Base64* encoding serialization, you may run the registering method as such:

```
TTextWriter.RegisterCustomJSONSerializer(TypeInfo(TFVs), nil, nil);
```

Or calling the text-based registration with a void definition:

```
TTextWriter.RegisterCustomJSONSerializerFromText(TypeInfo(TTestCustomJSONGitHub), '');
```

You can define now your custom JSON serializers, starting for the above code as reference, or via the `RegisterCustomJSONSerializerFromText()` method text-based definition.

Note that if the *record* corresponding to its item dynamic array has some associated RTTI (i.e. if it contains some reference-counted types, like any string), it will be serialized as JSON during the *mORMot* service process, just as stated with *Record serialization* (page 298).

10.1.5. TSQLRecord TPersistent TStringList TRawUTF8List

Classes with published properties, i.e. every class inheriting from `TPersistent` or our ORM-dedicated `TSQLRecord` class will be serialized as a true JSON object, containing all their published properties values. See *TSQLRecord fields definition* (page 131) for a corresponding table with the ORM database types and the JSON content.

List of *Delphi* strings, i.e. `TStrings` kind of classes will be serialized as a JSON array of strings. This is the reason why we also introduced a dedicated `TRawUTF8List` class, for direct UTF-8 content storage, via our dedicated `RawUTF8` type, reducing the need of encoding conversion, therefore increasing process speed.

10.1.6. TObject serialization

In fact, any `TObject` can be serialized as JSON in the whole framework: not only for the ORM part (for published properties), but also for SOA (as parameters of interface-based service methods). All JSON serialization is centralized in `ObjectToJSON()` and `JSONToObject()` (aka `TJSONSerializer.WriteObject()`) functions.

10.1.6.1. Custom class serialization

In some cases, it may be handy to have a custom serialization, for instance if you want to manage some third-party classes, or to adapt the serialization scheme to a particular purpose, at runtime.

You can add a customized serialization of any class, by calling the `TJSONSerializer.RegisterCustomSerializer` class method. Two callbacks are to be defined for a specific class type, and will be used to serialize or un-serialize the object instance. The callbacks are class methods (procedure() of object), and not plain functions (for some evolved objects, it may have sense to use a context during serialization).

In the current implementation of this feature, callbacks expect low-level implementation. That is, their implementation code shall follow function `JSONToObject()` patterns, i.e. calling low-level `GetJSONField()` function to decode the JSON content, and follow function `TJSONSerializer.WriteObject()` patterns, i.e. `aSerializer.Add/AddInstanceName/AddJSONEscapeString` to encode the class instance as JSON.

Note that the process is called outside the "{...}" JSON object layout, allowing any serialization scheme: even a class content can be serialized as a JSON string, JSON array or JSON number, on request.

For instance, we'd like to customize the serialization of this class (defined in `SynCommons.pas`):

```
TFileVersion = class
protected
  fDetailed: string;
  fBuildDateTime: TDateTime;
public
  Major: Integer;
  Minor: Integer;
  Release: Integer;
  Build: Integer;
  BuildYear: integer;
  Main: string;
published
  property Detailed: string read fDetailed write fDetailed;
  property BuildDateTime: TDateTime read fBuildDateTime write fBuildDateTime;
end;
```

By default, since it has been defined within `{M+} ... {M-}` conditionals, RTTI is available for the published properties (just as if it were inheriting from `TPersistent`). That is, the default JSON serialization will be for instance:

```
{"Detailed": "1.2.3.4", "BuildDateTime": "1911-03-14T00:00:00"}
```

This is what is expected when serialized within a `TSynLog` content - see below (page 632) - or for current AJAX use.

We would like to serialize this class as such:

```
{"Major":1,"Minor":2001,"Release":3001,"Build":4001,"Main":"1","BuildDateTime":"1911-03-14"}
```

We will therefore define the *Writer* callback, as such:

```
class procedure TCollTstDynArray.FVClassWriter(const aSerializer: TJSONSerializer;
  aValue: TObject; aOptions: TTextWriterWriteObjectOptions);
var V: TFileVersion absolute aValue;
begin
  aSerializer.AddJSONEscape(['Major',V.Major,'Minor',V.Minor,'Release',V.Release,
    'Build',V.Build,'Main',V.Main,'BuildDateTime',DateTimeToIso8601Text(V.BuildDateTime)]);
end;
```

Most of the JSON serialization work will be made within the `AddJSONEscape` method, expecting the

JSON object description as an array of name/value pairs.

Then the associated *Reader* callback could be, for instance:

```
class function TCollTstDynArray.FVClassReader(const aValue: TObject; aFrom: PUTF8Char;
  var aValid: Boolean; aOptions: TJSONToObjectOptions): PUTF8Char;
var V: TFileVersion absolute aValue;
  Values: array[0..5] of TValuePUTF8Char;
begin
  result := JSONDecode(aFrom, ['Major', 'Minor', 'Release', 'Build', 'Main', 'BuildDateTime'], @Values);
  aValid := (result <> nil);
  if aValid then begin
    V.Major := Values[0].ToInteger;
    V.Minor := Values[1].ToInteger;
    V.Release := Values[2].ToInteger;
    V.Build := Values[3].ToInteger;
    V.Main := Values[4].ToString;
    V.BuildDateTime := Iso8601ToDateTimePUTF8Char(Values[5].Value, Values[5].ValueLen);
  end;
end;
```

Here, the JSONDecode function will un-serialize the JSON object into an array of PUTF8Char values, without any memory allocation (in fact, Values[].Value will point to un-escaped and #0 terminated content within the aFrom memory buffer. So decoding is very fast.

Then, the registration step will be defined as such:

```
TJSONSerializer.RegisterCustomSerializer(TFileVersion,
  TCollTstDynArray.FVClassReader, TCollTstDynArray.FVClassWriter);
```

If you want to disable the custom serialization, you may call the same method as such:

```
TJSONSerializer.RegisterCustomSerializer(TFileVersion, nil, nil);
```

This will reset the JSON serialization of the specified class to the default serializer (i.e. writing of published properties).

The above code uses some low-level functions of the framework (i.e. AddJSONEscape and JSONDecode) to implement serialization as a JSON object, but you may use any other serialization scheme, on need. That is, you may serialize the whole class instance just as one JSON string or numerical value, or even a JSON array. It will depend of the implementation of the *Reader* and *Writer* registered callbacks.

10.1.6.2. Custom field names serialization

If your customization just expect changing some property names, you may use TJSONSerializer.RegisterCustomSerializerFieldNames class method.

For instance, given the following class:

```
type
  TMyClass = class(TSynPersistent)
  private
    FLength: Integer;
    FColor: Integer;
    FName: RawUTF8;
  published
    property Color: Integer read FColor write FColor;
    property Length: Integer read FLength write FLength;
    property Name: RawUTF8 read FName write FName;
  end;
```

You may use default serialization as such:

```
var
```

```
O: TMyClass;  
json: RawUTF8;  
begin  
  O := TMyClass.Create;  
  O.Color := 10;  
  O.Length := 20;  
  O.Name := 'one';  
  json := ObjectToJSON(O);  
  writeln(json); // {"Color":10,"Length":20,"Name":"one"}
```

Then switch to customized serialization:

```
TJSONSerializer.RegisterCustomSerializerFieldNames(TMyClass, ['name','length'], ['n','len']);  
json := ObjectToJSON(O);  
writeln(json); // {"Color":10,"Len":20,"n":"one"}
```

And back to normal/default serialization:

```
TJSONSerializer.RegisterCustomSerializerFieldNames(TMyClass, [], []);  
json := ObjectToJSON(O);  
writeln(json); // {"Color":10,"Length":20,"Name":"one"}
```

You could ignore some fields, by setting the destination name to '':

```
TJSONSerializer.RegisterCustomSerializerFieldNames(TMyClass, ['length'], ['']);  
json := ObjectToJSON(O);  
writeln(json); // {"Color":10,"Name":"one"}  
O.Free;  
end;
```

This method may therefore help working with pre-existing JSON objects, for instance retrieved from a third-party REST server.

Note that the `TJSONSerializer.RegisterCustomSerializerFieldNames` method won't accept `TSQLRecord` classes, since ORM serialization is handled in its own (optimized) set - and you could use ORM-level mapping if needed - see *Database-first ORM* (page 271).

10.1.6.3. TObjectList serialization

You can even serialize `TObjectList` instances as a valid JSON array, with the ability to store each instance class name, so allowing the storage of non uniform lists of objects.

Calling `TJSONSerializer.RegisterClassForJSON()` is just needed to register each `TObject` class in its internal tables, and be able to create instances from a class name serialized in each JSON object.

In fact, if `ObjectToJSON()` or `TJSONWriter.WriteObject()` have their `woStoreClassName` option defined, a new "ClassName": field will be written as first field of the serialized JSON object.

This new "ClassName" field will be recognized:

- by `JSONToObject()` for `TObjectList` members,
- and by the new `JSONToNewObject()` method.

Note that all `TSQLRecord` classes of a model are automatically registered via a call to `TJSONSerializer.RegisterClassForJSON()`: you do not have to register them, and can directly serialize `TObjectList` of `TSQLRecords`.

As a consequence, this kind of code can now work:

```
// register the type (but Classes.RegisterClass list is also checked)  
TJSONSerializer.RegisterClassForJSON([TComplexNumber]);  
// create an instance by reading the textual class name field  
J := '{"ClassName":"TComplexNumber", "Real": 10.3, "Imaginary": 7.92 }';  
P := @J[1]; // make local copy of constant  
Comp := TComplexNumber(JSONToNewObject(P,Valid));  
// here Comp is a valid unserialized object :)
```

```
Check(Valid);
Check(Comp.ClassType=TComplexNumber);
CheckSame(Comp.Real,10.3);
CheckSame(Comp.Imaginary,7.92);
// do not forget to free the memory (Comp can be nill if JSON was not valid)
Comp.Free;
```

Internal TObjectList process will therefore rely on a similar process, creating the proper class instances on the fly. You can even have several classes appearing in one TObjectList: the only prerequisite is that all class types shall have been previously registered on both sides, by a call to TJSONSerializer.RegisterClassForJSON().

10.2. REST

10.2.1. What is REST?

Representational state transfer (REST) is a style of software architecture for distributed hypermedia systems such as the World Wide Web. As such, it is not just a method for building "web services". The terms "representational state transfer" and "REST" were introduced in 2000 in the doctoral dissertation of Roy Fielding, one of the principal authors of the Hypertext Transfer Protocol (HTTP) specification, on which the whole Internet rely.

There are 5 basic fundamentals of web which are leveraged to create REST services:

- Everything is a Resource;
- Every Resource is Identified by a Unique Identifier;
- Use Simple and Uniform Interfaces;
- Communication is Done by Representation;
- Every Request is Stateless.

10.2.1.1. Resource-based

Internet is all about getting data. This data can be in a format of web page, image, video, file, etc. It can also be a dynamic output like get customers who are newly subscribed. The first important point in REST is start thinking in terms of resources rather than physical files.

You access the resources via some URI, e.g.

- <http://www.mysite.com/pictures/logo.png> - Image Resource;
- <http://www.mysite.com/index.html> - Static Resource;
- <http://www.mysite.com/Customer/1001> - Dynamic Resource returning XML or JSON content;
- <http://www.mysite.com/Customer/1001/Picture> - Dynamic Resource returning an image.

10.2.1.2. Unique Identifier

Older web techniques, e.g. *aspx* or *ColdFusion*, did request a resource by specifying parameters, e.g.

```
http://www.mysite.com/Default.aspx?a=1;a=2&b=1&a=3
```

In REST, we add one more constraint to the current URI: in fact, every URI should uniquely represent every item of the data collection.

For instance, you can see the below unique URI format for customer and orders fetched:

Customer data	URI
Get Customer details with name "dupont"	http://www.mysite.com/Customer/dupont
Get Customer details with name "smith"	http://www.mysite.com/Customer/smith
Get orders placed by customer "dupont"	http://www.mysite.com/Customer/dupont/Orders
Get orders placed by customer "smith"	http://www.mysite.com/Customer/smith/Orders

Here, "dupont" and "smith" are used as unique identifiers to specify a customer. In practice, a name is far from unique, therefore most systems use an unique ID (like an integer, a hexadecimal number or a GUID).

10.2.1.3. Interfaces

To access those identified resources, basic CRUD activity is identified by a set of HTTP verbs:

HTTP method	Action
GET	List the members of the collection (one or several)
PUT	Update a member of the collection
POST	Create a new entry in the collection
DELETE	Delete a member of the collection

Then, at URI level, you can define the type of collection, e.g. `http://www.mysite.com/Customers` to identify the customers or `http://www.mysite.com/Customers/1234/Orders` to access a given order.

This combinaison of HTTP method and URI replace a list of English-based methods, like `GetCustomer` / `InsertCustomer` / `UpdateOrder` / `RemoveOrder`.

10.2.1.4. By Representation

What you are sending over the wire is in fact a representation of the actual resource data.

The main representation schemes are XML and JSON.

For instance, here is how a customer data is retrieved from a GET method:

```
<Customer>
  <ID>1234</ID>
  <Name>Dupond</Name>
  <Address>Tree street</Address>
</Customer>
```

Below is a simple JSON snippet for creating a new customer record with name and address (since we create a new record, here we named him "Dupond" - with an ending D - not "Dupont"):

```
{"Customer": {"Name": "Dupond", "Address": "Tree street"}}
```

As a result to this data transmitted with a POST command, the RESTful server will return the just-created ID.

See *JSON* (page 296) for the reasons why in *mORMot*, we prefer to use JSON format.

10.2.1.5. Stateless

Every request should be an independent request so that we can scale up using load balancing techniques.

Independent request means with the data also send the state of the request so that the server can carry forward the same from that level to the next level.

See below (page 315) for more details.

10.2.2. RESTful mORMot

The *Synapse mORMot Framework* was designed in accordance with Fielding's REST architectural style without using HTTP and without interacting with the World Wide Web. Such Systems which follow REST principles are often referred to as "RESTful". Optionally, the Framework is able to serve standard HTTP/1.1 pages over the Internet (by using the `mORMotHttpClient` / `mORMotHttpServer` units and the `TSQLHttpServer` and `TSQLHttpClient` classes), in an embedded low resource and fast HTTP server.

The standard RESTful methods are implemented, i.e. GET/PUT/POST/DELETE.

The following methods were added to the standard REST definition, for locking individual records and for handling database transactions (which speed up database process):

- LOCK to lock a member of the collection;
- UNLOCK to unlock a member of the collection;
- BEGIN to initiate a transaction;
- END to commit a transaction;
- ABORT to rollback a transaction.

The GET method has an optional pagination feature, compatible with the YUI DataSource Request Syntax for data pagination - see `TSQLRestServer.URI` method and <http://developer.yahoo.com/yui/datatable/#data..> . Of course, this breaks the "Every Resource is Identified by a Unique Identifier" RESTful principle - but it is much more easy to work with, e.g. to implement paging or custom filtering.

From the *Delphi* code point of view, a RESTful Client-Server architecture is implemented by inheriting some common methods and properties from a main class.

TSQLRestClient classes hierarchy

This diagram states how the `TSQLRest` class implements a common ancestor for both Client and Server classes.

10.2.2.1. BLOB fields

BLOB fields are defined as `TSQLRawBlob` published properties in the classes definition - which is an alias to the `RawByteString` type (defined in `SynCommons.pas` for *Delphi* up to 2007, since it appeared only with *Delphi* 2009). But their content is not included in standard RESTful methods of the framework, to spare network bandwidth.

The RESTful protocol allows BLOB to be retrieved (GET) or saved (PUT) via a specific URL, like:

`ModelRoot/TableName/TableID/BlobFieldName`

This is even better than the standard JSON encoding, which works well but convert BLOB to/from hexadecimal values, therefore need twice the normal size of it. By using such dedicated URL, data can be transferred as full binary.

Some dedicated methods of the generic TSQLRest class handle BLOB fields: RetrieveBlob and UpdateBlob.

10.2.2.2. JSON representation

The "04 - HTTP Client-Server" sample application available in the framework source code tree can be used to show how the framework is AJAX-ready, and can be proudly compared to any other REST server (like *CouchDB*) also based on JSON.

First deactivate the authentication - see below (page 547) - by changing the parameter from true to false in Unit2.pas:

```
DB := TSQLRestServerDB.Create(Model,ChangeFileExt(paramstr(0),'.db3'),  
false);
```

and by commenting the following line in Project04Client.dpr:

```
Form1.Database := TSQLHttpClient.Create(Server,'8080',Form1.Model);  
// TSQLHttpClient(Form1.Database).SetUser('User','synapse');  
Application.Run;
```

Then you can use your browser to test the JSON content:

- Start the Project04Server.exe program: the background HTTP server, together with its *SQLite3* database engine;
- Start any Project04Client.exe instances, and add/find any entry, to populate the database a little;
- Close the Project04Client.exe programs, if you want;
- Open your browser, and type into the address bar:

```
http://localhost:8080/root
```

- You'll see an error message:

```
TSQLHttpServer Server Error 400
```

- Type into the address bar:

```
http://localhost:8080/root/SampleRecord
```

- You'll see the result of all SampleRecord IDs, encoded as a JSON list, e.g.

```
[{"ID":1}, {"ID":2}, {"ID":3}, {"ID":4}]
```

- Type into the address bar:

```
http://localhost:8080/root/SampleRecord/1
```

- You'll see the content of the SampleRecord of ID=1, encoded as JSON, e.g.

```
{"ID":1,"Time":"2010-02-08T11:07:09","Name":"AB","Question":"To be or not to be"}
```

- Type into the address bar any other REST command, and the database will reply to your request...

You have got a full HTTP/SQLite3 RESTful JSON server in less than 400 KB.

Note that *Internet Explorer* or old versions of *FireFox* do not recognize the application/json; charset=UTF-8 content type to be viewed internally. This is a limitation of those softwares, so above requests will download the content as .json files, but won't prevent AJAX requests to work as expected.

10.2.2.3. Stateless ORM

Our framework is implementing REST as a stateless protocol, just as the HTTP/1.1 protocol it could use as its communication layer.

A *stateless* server is a server that treats each request as an independent transaction that is unrelated to any previous request.

At first, you could find it a bit disappointing from a classic Client-Server approach. In a stateless world, you are never sure that your Client data is up-to-date. The only place where the data is safe is the server. In the web world, it's not confusing. But if you are coming from a rich Client background, this may concern you: you should have the habit of writing some synchronization code from the server to replicate all changes to all its clients. This is not necessary in a stateless architecture any more.

The main rule of this architecture is to ensure that the Server is the only reference, and that the Client is able to retrieve any pending update from the Server side. That is, always modify a record content on a server side, then refresh the client to retrieve the modified value. Do *not* modify the client side directly, but always pass through the Server. The UI components of the framework follow these principles. Client-side modification could be performed, but must be made in a separated autonomous table/database. This will avoid any synchronization problem in case of concurrent client modification.

10.3. REST and JSON

10.3.1. JSON format density

Most common RESTful JSON used a verbose format for the JSON content: see for example http://bitworking.org/news/restful_json.. which proposed to put whole URI in the JSON content;

```
[  
  "http://example.org/coll/1",  
  "http://example.org/coll/2",  
  "http://example.org/coll/3",  
  ...  
  "http://example.org/coll/N",  
]
```

The REST implementation of the framework will return most concise JSON content, containing an array of objects:

```
[{"ID":1}, {"ID":2}, {"ID":3}, {"ID":4}]
```

Depending on a setting, *mORMot* servers may in fact returns this alternative (see below *non expanded format*), which can be shorter, since it does not replicate field names:

```
{"fieldCount":1, "values":["ID",1,2,3,4,5,6,7]}
```

which preserves bandwidth and human readability: if you were able to send a GET request to the URI <http://example.org/coll> you will be able to append this URI at the beginning of every future request, doesn't it make sense?

In all cases, the *Synapse mORMot Framework* always returns the JSON content just as a pure response of a SQL query, with an array and field names.

10.3.2. JSON (not) expanded layouts

Note that our JSON content has two layouts, which can be produced according to the `TSQLRestServer.NoAJAXJSON` property:

1. the *"expanded" or standard/AJAX layout*, which allows you to create pure *JavaScript* objects from the JSON content, because the field name / *JavaScript* object property name is supplied for every value:

```
[{"ID":0,"Int":0,"Test":"abcde+-ef+á+-","Unicode":"abcde+-ef+á+-","Ansi":"abcde+-ef+á+-","ValFloat":3.14159265300000E+0000,"ValWord":1203,"ValDate":"2009-03-10T21:19:36","Next":0},{..}]
```

2. the *"not expanded" layout*, which reflects exactly the layout of the SQL request: first line/row are the field names, then all next lines.row are the field content:

```
{"fieldCount":9,"values":["ID","Int","Test","Unicode","Ansi","ValFloat","ValWord","ValDate","Next",  
0,0,"abcde+-ef+á+-","abcde+-ef+á+-","abcde+-ef+á+-",3.14159265300000E+0000,1203,"2009-03-10T21:19:  
36",0,..]}
```

By default, the `NoAJAXJSON` property is set to `true` when the `TSQLRestServer.ExportServerNamedPipe` is called: if you use named pipes for communication, you probably won't use a *JavaScript* client since all browsers communicate via HTTP only!

But otherwise, `NoAJAXJSON` property is set to `false`. You could force its value to `true` and you will save some bandwidth if *JavaScript* is never executed: even the parsing of the JSON Content will be faster with *Delphi* if JSON content is not expanded.

In this "not expanded" layout, the following JSON content:

```
[{"ID":1}, {"ID":2}, {"ID":3}, {"ID":4}, {"ID":5}, {"ID":6}, {"ID":7}]
```

will be transfered as shorter:

```
{"fieldCount":1, "values":["ID",1,2,3,4,5,6,7]}
```

10.3.3. JSON global cache

A global cache, at *SQLite3* level, is used to enhance the framework scaling, featuring JSON storage for its result encoding.

In order to speed-up the server response time, especially in a concurrent client access, the internal database engine is not to be called on every request. In fact, a global cache has been introduced to store in memory the latest SQL SELECT statements results, directly in JSON.

The *SQLite3* engine access is protected at SQL/JSON cache level, via `DB.LockJSON()` calls in most `TSQLRestServerDB` methods.

A `TSynCache` instance is instantiated within the `TSQLDataBase` internal global instance, with the following line:

```
constructor TSQLRestServerDB.Create(aModel: TSQLModel; aDB: TSQLDataBase;  
  aHandleUserAuthentication: boolean);  
begin  
  fStatementCache.Init(aDB.DB);  
  aDB.UseCache := true; // we better use caching in this JSON oriented use  
  (...)
```

This will enable a global JSON cache at the SQL level. This cache will be reset on every INSERT, UPDATE or DELETE SQL statement, whatever the corresponding table is.

If you need to disable the JSON cache for a particular request, add the `SQLDATABASE_NOCACHE` text, i.e. the `'/*nocache*/'` text comment, anywhere in the SQL statement, e.g. in the ORM WHERE clause. It will indicate to `TSQLDataBase` to not cache the returned JSON content. It may be usefull e.g. if you pass a pointer as `PtrInt(aVariable)` bound parameter, which may have the very same integer reference value, but diverse content.

In practice, this global cache was found to be efficient, even if its implementation is some kind of "naive". It is in fact much more tuned than other HTTP-level caching mechanisms used in most client-server solutions (using e.g. a *Squid* proxy) - since our caching is at the SQL level, it is shared among all CRUD / Restful queries, and is also independent from the authentication scheme, which pollutes the URI. Associated with the other levels of cache - see *ORM Cache* (page 174) - the framework scaling was found to be very good.

11. Client-Server process

Adopt a mORMot

11.1. Client-Server cheat sheet

Before deeping into the details, and presenting all the *mORMot* framework Client-Server abilities, let's step back, and look at the big picture.

In practice, for your project, you will have several possibilities to create a Client-Server system. ORM, SOA and MVC can all be accessed remotely, and it may not be easy to find out which method is preferred to implement, in the context of a production system.

Method	Best for	Beware
SOA Interfaces	RPC REST	RPC
SOA Methods	Full REST/HTTP	Verbose
MVC Web	Web site + AJAX	HTML-oriented
ORM REST	Tests or internal use	Security/design flaws

In a nutshell,

- *SOA Interfaces* - see below (page 420) - is the preferred way to build both public and private services: both client and server code will be defined from interface types, including sessions management, stubbing/mocking, documentation generation, and security features.
- *SOA Methods* - see below (page 374) - will open full access to REST/HTTP details of each request, so may be needed to conform to a more REST, less RPC implementation - but the client side will need to be written by hand, and the server side could be more verbose to implement.

- *MVC Web* - see below (page 520) - is the way to go if you expect to develop mostly dynamic web pages, and sometimes consume some JSON content from JavaScript if needed, by accessing its `url/json` sub path.
- *ORM REST* - see below (page 342) - exposes all data automatically, but should better not be used on production for public APIs for architecture and security reasons, since it is directly tied to the datastore. It could be exposed internally, or for debugging/testing.
- remember that *any combination of the four previous framework features* could be defined in the same `TSQLRestServer` instance, so you can just pickup what fits best your needs.

We will now present all those communication features, but you may focus on *SOA Interfaces*, and its associated samples, when implementing your project, and go back to other details of this exhaustive documentation, only if needed.

11.2. Protocols

The *mORMot* framework can be used either stand-alone, or in a Client-Server model, via several communication layers:

- Fast in-process access (an executable file using a common library, for instance);
- Windows Messages, only locally on the same computer, which are very fast for small content;
- Named pipes, which can be used locally between a Server running as a Windows service and some Client instances;
- HTTP/1.1 over TCP/IP, for remote access.

See *General mORMot architecture - Client / Server* (page 74) about this Client-Server architecture.

The framework allow you to create either a `TSQLHttpClient`, `TSQLRestClientURIDll`, `TSQLRestClientURINamedPipe` or `TSQLRestClientURIMessage` instance to access to your data according to the communication protocol used for the server.

Abilities will depend on the protocol used. For instance, HTTP may sounds slower than alternatives, but it is the best protocol for remote access of concurrent clients, even running locally. For instance, *mORMot's* `http.sys` based server is able to serve 50,000 concurrent connections without any problem, but you should better not attempt connecting more than a dozen clients via named pipes or messages...

Here are some general information about available communication layers:

	In-process	Windows Messages	Named pipes	HTTP
Unit	mORMot.pas	mORMot.pas	mORMot.pas	mORMotHttpServer.pas mORMotHttpClient.pas
Speed	****	***	**	*
Scaling	****	*	*	***
Hosting	In-process	Local	Local	Remote
Protocol	Method call	WM_COPYDATA	\\.\pipe\mORMot_	Standard
Data	JSON	JSON	JSON	JSON
Run as service	Stand alone	No	Yes	Yes

Note that you can have *several* protocols exposing the same TSQLRestServer instance. You may expose the same server over HTTP and over named pipes, at the same time, depending on your speed requirements.

11.3. TSQLRest classes

This architecture is implemented by a hierarchy of classes, implementing the RESTful pattern - see *REST* (page 312) - for either stand-alone, client or server side, all inheriting from a TSQLRest common ancestor, as two main branches:

RESTful Client-Server classes

All ORM operations (aka CRUD process) are available from the abstract TSQLRest class definition, which is overridden to implement either a Server (via TSQLRestServer classes), or a Client (via TSQLRestClientURI classes) access to the data.

You should instantiate the classes corresponding to the needed transmission protocol, but should better rely on abstraction, i.e. implement your whole code logic relying on abstract TSQLRestClient / TSQLRestServer classes. It will then help changing from one protocol or configuration at runtime, depending on your customer's expectations.

11.3.1. Server classes

The following classes are available to implement a *Server* instance:

RESTful Server classes

In practice, in order to implement the business logic, you should better create a new class, inheriting from one of the above TSQLRestServer classes. Having your own inherited class does make sense, especially for implementing your own method-based services - see below (page 374), or override internal methods.

The TSQLRestServerDB class is the main kind of Server of the framework. It will host a *SQLite3* engine, as its core *Database layer* (page 196).

If your purpose is not to have a full *SQLite3* engine available, you may create your server from a TSQLRestServerFullMemory class instead of TSQLRestServerDB: this will implement a fast in-memory engine (using TSQLRestStorageInMemory instances), with basic CRUD features (for ORM), and persistence on disk as JSON or optimized binary files - this kind of server is enough to handle authentication, and host services in a stand-alone way.

If your services need to have access to a remote ORM server, it may use a `TSQLRestServerRemoteDB` class instead: this server will use an internal `TSQLRestClient` instance to handle all ORM operations - it can be used e.g. to host some services on a stand-alone server, with all ORM and data access retrieved from another server: it will allow to easily implement a proxy architecture (for instance, as a DMZ for publishing services, but letting ORM process stay out of scope). See below (page 537) for some hosting scenarios.

Another option may be to use `TSQLRestClientRedirect` - see below (page 325) - which does something similar, but inheriting from `TSQLRestClientURI`.

11.3.2. Storage classes

In the *mORMot* units, you may also find those classes also inheriting from `TSQLRestStorage`:

RESTful storage classes

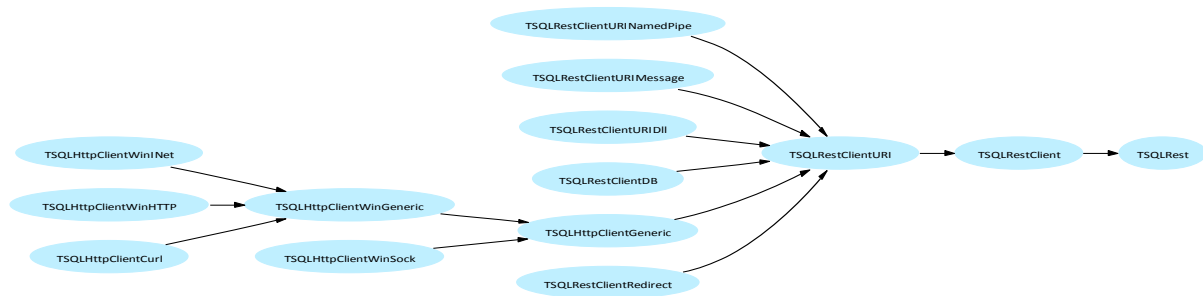

In the above class hierarchy, the `TSQLRestStorage[InMemory][External]` classes are in fact used to store some `TSQLRecord` tables in any non-SQL backend:

- `TSQLRestStorageExternal` maps tables stored in an external database - see *External SQL database access* (page 240);
- `TSQLRestStorageInMemory` stores the data in a `TObjectList` - see *In-Memory "static" process* (page 231);
- `TSQLRestStorageRemote` will redirect the CRUD operations of a given table to an external `TSQLRest` instance (client or server) - see *Redirect to an external TSQLRest* (page 234);
- `TSQLRestStorageMongoDB` will connect to a remote *MongoDB* server to store the tables as a NoSQL collection of documents - see *External NoSQL database access* (page 279).

Those classes are used within a main `TSQLRestServer` to host some given `TSQLRecord` classes, either in-memory, or on external databases. They do not enter in account in our Client-Server presentation, but are implementation details, on the server side.

11.3.3. Client classes

A full set of *client* classes will implement a RESTful access to a remote database, with associated services and business logic:

RESTful Client classes

Of course, all those TSQRestClient* classes expect a TSQRestServer to be available, via the corresponding transmission protocol.

11.4. In-process/stand-alone application

For a stand-alone application, create a `TSQLRestClientDB`. This particular class will initialize an internal `TSQLRestServerDB` instance, and you'll have full access to the *SQLite3* database in the same process, with no speed penalty.

Content will still be converted to and from JSON, but there will be no delay due to the transmission of the data. Having JSON at hand will enable internal cache - see below (page 360) - and allow to combine this in-process direct process with other transmission protocols (like named pipes or HTTP).

Another option may be to use `TSQLRestClientRedirect`, which allows redirection from any `TSQLRest` class, either inheriting from `TSQLRestClient` or `TSQLRestServer`. Any `TSQLRestClientURI.URI` request will be passed to the redirected `TSQLRest` instance, which may be local or remote. The `TSQLRestClientRedirect.RedirectTo` method allows to enable or disable the redirection at runtime (by setting `aRedirected=nil`), or change the redirected `TSQLRest` instance on the fly, without creating a new `TSQLRestClientRedirect` instance.

You may also directly work with a `TSQLRestServerDB` instance, but you will miss some handy features of the `TSQLRestClientURI` class, like User-Interface interaction, or advanced ORM/SOA abilities, based on `TSQLRestServer.URI` process.

11.5. Local access via named pipes or Windows messages

For a Client-Server local application, that is some executable running on the same physical machine, create a `TSQLRestServerDB` instance, then use the corresponding `ExportServer`, `ExportServerNamedPipe`, `ExportServerMessage` method to instantiate either a in-process, Named-Pipe or Windows Messages server.

The Windows Messages layer has the lowest overhead and is the fastest transport layer available between several applications on the same computer. But it has the problem of being reserved to desktop applications (since Windows Vista), so you a Windows Messages server won't be accessible when run as a background service.

A named pipe communication is able to be served from a Windows service, and is known to be more efficient when transmitting big messages. So it is the preferred mean of communication for a local application sharing data between clients.

Due to security restriction of newer versions of Windows (i.e. starting with Vista), named pipes are not available by default over a network. This is the reason why this protocol is listed as local access mean only.

11.6. Network and Internet access via HTTP

For publishing a server via HTTP/1.1 over TCP/IP, creates a `TSQLHttpServer` instance, and associate your running `TSQLRestServerDB` to it.

Typical initialization code, as extracted from sample "04 - HTTP Client-Server", may be:

```
Model := CreateSampleModel;
DBServer := TSQLRestServerDB.Create(Model, ChangeFileExt(paramstr(0), '.db3'), true);
DBServer.CreateMissingTables;
HttpServer := TSQLHttpServer.Create('8080', [DBServer], '+', HTTP_DEFAULT_MODE);
```

The following options is usually defined:

```
HttpServer.AccessControlAllowOrigin := '*'; // allow cross-site AJAX queries
```

And you can optionally define some per domain / per sub-domain hosting redirection:

```
HttpServer.DomainHostRedirect('project.com', 'root'); // 'root' is current Model.Root
HttpServer.DomainHostRedirect('blog.project.com', 'root/blog'); // MVC application
```

In all cases, even if HTTP protocol is very network friendly (especially over the 80 port), you shall always acquire IT approval and advices before any deployment over a corporate network, at least to negotiate firewall settings.

11.6.1. HTTP server(s)

The `TSQLHttpServer` class is able to use any of two HTTP server classes, as defined in `SynCrtSock` unit - and `SynBidirSock` for *WebSockets*:

- `THttpServer` which is a light and tuned server featuring a thread pool and IOCP implementation pattern, on the raw Sockets API;
- `THttpApiServer` which is based on *http.sys* API;
 - `TWebSocketServer` which is a `THttpServer` server, able to upgrade to the *WebSockets* protocol for asynchronous and bidirectional callbacks - see below (page 445).

THttpServerGeneric classes hierarchy

On production, `THttpApiServer` seems to give the best results, and has a proven and secure implementation. It is also the only one class implementing HTTPS / SSL secure communication, if needed. That's why `TSQLHttpServer` will first try to use fastest *http.sys* kernel-mode server, then fall-back to the generic sockets-based `THttpServer` class in case of failure.

You can specify which kind of HTTP server class is to be used, via the `aHttpServerKind`: `TSQLHttpServerOptions` of the `TSQLHttpServer.Create` constructor. By default, it will be

HTTP_DEFAULT_MODE (i.e. useHttpApi over Windows), but you may specify useHttpApiRegisteringURI for automatic registration of the URI - see below (page 328) - or useHttpSocket to use the socket-based THttpServer, or useBidirSocket for TWebsocketServer.

The THttpServerGeneric abstract class provides one OnRequest property event, in which all high level process is to take place - it expects some input parameters, then will compute the output content to be sent as response:

```
TOnHttpRequest = function(Ctxt: THttpRequest): cardinal of object;
```

This event handler prototype is shared by both TThread classes instances able to implement a HTTP/1.1 server.

Both THttpApiServer and THttpServer classes will receive any incoming request, pass it to the TSQLRestServer instance matching the incoming URI request, via the OnRequest event handler.

If the request is a remote ORM operation, a JSON response will be retrieved from the internal cache of the framework, or computed using the *SQLite3* database engine. In case of a remote service access - see below (page 373) - the request will be computed on the server side, also marshalling the data as JSON. If you specified useBidirSocket kind of server, you may use remote service access via interfaces, with asynchronous callbacks - see below (page 445).

The resulting JSON content will be compressed using our very optimized *SynLZ* algorithm (20 times faster than Zip/Deflate for compression), if the client is a *Delphi* application knowing about *SynLZ* - for an AJAX client, it won't be compressed by default (even if you can enable the deflate algorithm - which may slow down the server).

Then the response will be marked as to be sent back to the Client...

11.6.2. High-performance http.sys server

Since *Windows XP SP2* and *Windows Server 2003*, the Operating System provides a kernel stack to handle HTTP requests. This *http.sys* driver is in fact a full featured HTTP server, running in kernel mode. It is part of the networking subsystem of the *Windows* operating system, as a core component.

The SynCrtSock unit can implement a HTTP server based on this component. Of course, the *Synapse mORMot framework* will use it. If it's not available, it will launch our pure *Delphi* optimized HTTP server, using I/O completion ports and a Thread Pool.

What's good about *https.sys*?

- *Kernel-mode request queuing*: Requests cause less overhead in context switching, because the kernel forwards requests directly to the correct worker process. If no worker process is available to accept a request, the kernel-mode request queue holds the request until a worker process picks it up.
- *Enhanced stability*: When a worker process fails, service is not interrupted; the failure is undetectable by the user because the kernel queues the requests while the WWW service starts a new worker process for that application pool.
- *Faster process*: Requests are processed faster because they are routed directly from the kernel to the appropriate user-mode worker process instead of being routed between two user-mode processes, i.e. the good old *WinSock* library and the worker process;
- *Embedded SSL process*, when secure HTTPS communication is needed.

11.6.2.1. Use the http.sys server

Take a look at sample "04 - HTTP Client-Server", which is able to serve a *SQLite3* database content

over HTTP, using our RESTful ORM server.

By default, it will try to use the `http.sys` server, then fall-back to plain socket server, in case of failure.

In fact, two steps are performed by the `TSQLHttpServer` constructor:

- The HTTP Server API is first initialized (if needed) during `THttpApiServer.Create` constructor call. The `HttpApi.dll` library (which is the wrapper around `http.sys`) is loaded dynamically: so if you are running an old system (*Windows XP SP1* for instance), you could still be able to use the server.
- It then tries to register the URI matching the RESTful model - *REST* (page 312) - via the `THttpApiServer.AddUrl` method. In short, the `TSQLModel.Root` property is used to compute the RESTful URI needed, just by the book. You can register several `TSQLRestServer` instances, each with its own `TSQLModel.Root`, if you need it.

As we already stated, if any of those two steps fails (e.g. if `http.sys` is not available, or if it was not possible to register the URLs), the `TSQLHttpServer` class will fall back into using the other `THttpServer` class, which is a plain *Delphi* multi-threaded server. It won't be said that we will let you down!

Inside `http.sys` all the magic is made... it will listen to any incoming connection request, then handle the headers, then check against any matching URL.

`http.sys` will handle all the communication by itself, leaving the server threads free to process the next request.

You can even use a special feature of *http.sys* to serve a file content as fast as possible. In fact, if you specify `HTTP_RESP_STATICFILE` as `Ctxt.OutContentType`, then `Ctxt.OutContent` is the UTF-8 file name of a file which must be sent to the client. Note that it will work only with `THttpApiServer` kind of server (i.e. using high performance *http.sys* API). But whole file access and sending will occur in background, at the kernel level, so with best performance. See sample "*09 - HttpApi web server*" and `HttpApiServer.dpr` file.

If you use a `TSQLHttpServer`, the easiest is to define a method-based service - see below (page 374) - and call `Ctxt.ReturnFile()` to return a file content from its name. We will see details about this below. Another possibility may be to override `TSQLHttpServer.Request()` method, as stated by `Project04ServerStatic.dpr` sample: but we think that a method-based service and `Ctxt.ReturnFile()` is preferred.

11.6.2.2. URI authorization as Administrator

This works fine under XP. Performances are very good, and stability is there. But... here comes the UAC nightmare again.

Security settings have changed since XP. Now only applications running with Administrator rights can register URLs to `http.sys`. That is, no real application. So the URI registration step will always fail with the default settings, under Vista and Seven.

The only case when authorization will be possible is when the application launched as a Windows Service, with default services execution user. By default, Windows services are launched with a User which has the Administrator rights.

11.6.2.2.1. Secure specific authorization

Standard security policy, as requested by Windows for all its *http.sys* based systems (i.e. IIS and WCF services) is to explicitly register the URI.

Depending on the system it runs on (i.e. Windows XP or Vista and up), a diverse command line tool is to be used. Can be confusing.

To keep it simple, our `SynCrtSock` unit provides a dedicated method to authorize a particular URI prefix to be registered by any user.

Therefore, a program can be easily created and called once with administrator rights to make `http.sys` work with our framework. This could be done, for instance, as part of your *Setup* program.

Then when your server application will be launched (for instance, as an application in tray icon with normal user rights, or a background Windows service with tuned user rights), it will be able to register all needed URL.

Here is a sample program which can be launched to allow our `TestSQL3.dpr` to work as expected - it will allow any connection via the 888 port, using `TSQLModel1`. Root set as 'root'- that is, an URI prefix of `http://+:888/root/` as expected by the kernel server:

```
program TestSQL3Register;
uses
  SynCrtSock,
  SysUtils;

// force elevation to Administrator under Vista/Seven
{$R VistaAdm.res}

begin
  THttpApiServer.AddUrlAuthorize('root','888',false,'+');
end.
```

Take also a look at the `Project04ServerRegister.dpr` sample, in the context of a whole client/server RESTful solution over HTTP.

Note that you still need to open the IP port for incoming TCP traffic, in the Windows firewall, if you want your server to be accessible to the outer world, as usual.

11.6.2.2.2. Automatic authorization

An easier possibility could be to run the server application at least once as system Administrator.

The `TSQLHttpServer.Create()` constructor has a `aHttpServerKind: TSQLHttpServerOptions` parameter. By default, it will be set to `useHttpApi`. If you specify `useHttpApiRegisteringURI`, the class will register the URI before launching the server process.

All *mORMot* samples are compiled with this flag, as such:

```
aHTTPServer := TSQLHttpServer.Create(PORT_NAME,[aServer],'+',useHttpApiRegisteringURI);
```

Note this does not follow default security policy of Windows. But it will make your application development easier.

11.6.2.2.3. Manual URI authorization

If you configured several `http.sys` servers on a given computer, you may have URI registration conflicts after some time.

You can use the `netsh` tool to list all registered URL with:

```
netsh http show urlacl
```

You can optionally specify the fully qualified URL, for instance:

```
netsh http show urlacl url=http://+:80/MyUri
netsh http show urlacl url=http://www.contoso.com:80/MyUri
```

Then you can delete any url registration with:

```
netsh http delete urlacl http://host:port/[URI]
```

The [URI] is the registered URL path or domain. For instance:

```
netsh delete urlacl url=http://+:80/MyUri
netsh delete urlacl url=http://www.contoso.com:80/MyUri
```

Note that all those commands should be run with administrator user rights.

You can consult the corresponding documentation of netsh http commands for HTTP context available to query and configure http.sys settings and parameters at <https://msdn.microsoft.com/en-us/library/windows/desktop/cc307236..>

11.6.2.3. HTTP API 2.0 Features

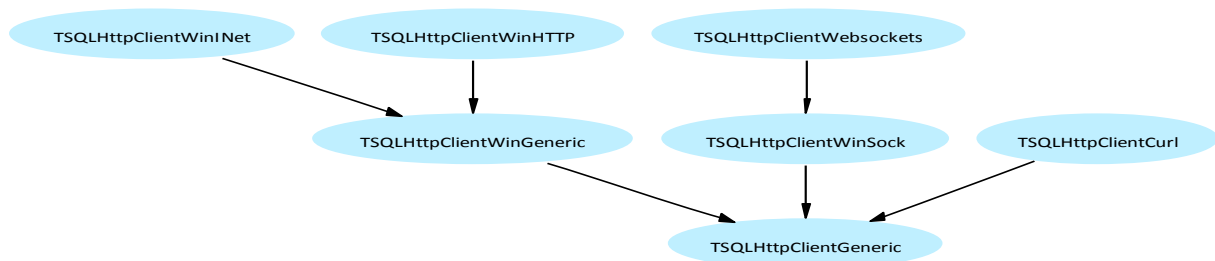

Some THttpApiServer methods are available with the HTTP Server 2.0 API, provided since Windows Vista and Windows Server 2008:

Method	Description
HasAPI2	check if the HTTP API 2.0 is available
SetTimeoutLimits()	advanced timeout settings
LogStart() and LogStop	HTTP level standard logging
SetAuthenticationSchemes()	kernel-mode authentication

Please see the corresponding documentation of SynCrtSock.pas for further details, and <https://msdn.microsoft.com/en-us/library/windows/desktop/aa364703..> as low-level reference of these features. Note that our implementation of http.sys is more complete than the one currently included in the official .Net WCF framework. Not bad for a third-party library, isn't it?

11.6.3. HTTP client(s)

In fact, there are several implementation of a HTTP/1.1 clients, according to this class hierarchy:

HTTP/1.1 Client RESTful classes

So you can select either TSQLHttpClientWinSock, TSQLHttpClientWinINet or TSQLHttpClientWinHTTP for a HTTP/1.1 client, under *Windows*. By design, TSQLHttpClientWinINet or TSQLHttpClientWinHTTP are not available outside of Windows, but TSQLHttpClientCurl is a great option under Linux, if the libcurl library is installed, especially if you want to use HTTPS - it will call SynCurl.pas.

The `TSQLHttpClientWebsockets` class has the ability to *upgrade* the HTTP connection to the *WebSockets* protocol, which will be used for dual ways callbacks - see below (page 445).

Each class has its own architecture, and attaches itself to a Windows communication library, all based on *WinSock* API. As stated by their name, `TSQLHttpClientWinSock` will call directly the *WinSock* API, `TSQLHttpClientWinINet` will call *WinINet* API (as used by IE 6) and `TSQLHttpClientWinHTTP` will call the latest *WinHTTP* API:

- *WinSock* is the common user-space API to access the sockets stack of Windows, i.e. IP connection - it's able to handle any IP protocol, including TCP/IP, UDP/IP, and any protocol over it (including HTTP);
- *WinINet* was designed as an HTTP API client platform that allowed the use of interactive message dialogs such as entering user credentials - it's able to handle HTTP and FTP protocols;
 - *WinHTTP*'s API set is geared towards a non-interactive environment allowing for use in service-based applications where no user interaction is required or needed, and is also much faster than *WinINet* - it only handles HTTP protocol.

HTTP/1.1 Client architecture

Here are some PROs and CONSs of the available solutions, under *Windows*:

Criteria	WinSock	WinINet	WinHTTP
API Level	Low	High	Medium
Local speed	Fastest	Slow	Fast
Network speed	Slow	Medium	Fast
Minimum OS	Win95/98	Win95/98	Win2000
HTTPS	Not available	Available	Available
Integration with IE	None	Excellent (proxy)	Available (see below)
User interactivity	None	Excellent (authentication, dial-up)	None

As stated above, there is still a potential performance issue to use the direct `TSQLHttpClientWinSock` class over a network. It has been reported on our forum, and root cause was not identified yet.

Therefore, the `TSQLHttpClient` class maps by default to the `TSQLHttpClientWinHTTP` class. This is the recommended usage from a *Delphi* client application.

Note that even if *WinHTTP* does not share by default any proxy settings with Internet Explorer, it can import the current IE settings. The *WinHTTP* proxy configuration is set by either `proxycfg.exe` on Windows XP and Windows Server 2003 or earlier, or `netsh.exe` on Windows Vista and Windows

Server 2008 or later; for instance, you can run "proxycfg -u" or "netsh winhttp import proxy source=ie" to use the current user's proxy settings for Internet Explorer. Under 64-bit Vista/Seven, to configure applications using the 32 bit *WinHttp* settings, call netsh or proxycfg bits from %SystemRoot%\SysWOW64 folder explicitly.

Note that by design, the *TSQLHttpClient** classes, like other *TSQLRestClientURI* implementations, were designed to be thread safe, since their *URI()* method is protected by a lock. See below (page 336).

11.6.4. HTTPS server

The *http.sys* kernel mode server can be defined to serve HTTPS secure content, i.e. the SSL protocol over HTTP.

When the *aHttpServerSecurity* parameter is set to *secSSL* for the *TSQLHttpServer.Create()* constructor, the SSL layer will be enabled within *http.sys*. Note that *useHttpSocket* kind of server does not offer SSL/TLS encryption yet.

In order to let the SSL layer work as expected, you need first to create and import a set of certificates.

11.6.4.1. Certificates

You need one *certificate* (cert) to act as your root authority, and one to act as the actual certificate to be used for the SSL, which needs to be signed by your root authority. If you don't set up the root authority your single certificate won't be trusted, and you will start to discover this through a series of extremely annoying exceptions, long after the fact. To get a free certificate, i.e. for testing purposes, you may use an online service like <http://www.startssl.com..>

Depending on the *Windows* revision you are using, you can run the *Internet Information Services (IIS) Manager*: from the *Windows* Start menu, click Administrative Tools > Internet Information Services (IIS) Manager. See <http://support.microsoft.com/kb/299875..>

You could also install the needed certificate by using some command lines - this may be handy for fast installation using a *.bat* file. Here are the needed steps, as detailed in <http://www.codeproject.com/Articles/24027/SSL-with-Self-hosted-WCF-Service..> and <http://msdn.microsoft.com/en-us/library/ms733791..>

The following command (run in a *Visual Studio* command prompt) will create your root certificate:

```
makecert -sv SignRoot.pvk -cy authority -r signroot.cer -a  
sha1 -n "CN=Dev Certification Authority" -ss my -sr localmachine
```

Take a look at the above links to see what each of these arguments mean, it isn't terribly important, but it's nice to know.

The *MakeCert* tool is available as part of the *Windows* SDK, which you can download from <http://go.microsoft.com/fwlink/p/?linkid=84091..> if you do not want to download the whole *Visual Studio* package. Membership in *Administrators*, or equivalent, on the local computer is the minimum required to complete this procedure.

Once this command has been run and succeeded, you need to make this certificate a trusted authority. You do this by using the MMC snap in console. Go to the run window and type "mmc", hit enter. Then in the window that opens (called the "*Microsoft Management Console*", for those who care) perform the following actions:

```
File -> Add/Remove Snap-in -> Add... -> Double click Certificates -> Select Computer Account and Click
```

Next -> Finish -> Close -> OK

Then select the Certificates (Local Computer) -> Personal -> Certificates node.

You should see a certificate called "Dev Certificate Authority" (or whatever else you decided to call it as parameter in the above command line). Move this certificate from the current node to Certificates (Local Computer) -> Trusted Root Certification Authorities -> Certificates node, drag and drop works happily.

Now you have NOT the cert you need :)

You have made yourself able to create trusted certs though, which is nice.

Now you have to create another cert, which you are actually going to use.

Run makecert again, but run it as follows...

```
makecert -iv SignRoot.pvk -ic signroot.cer -cy end -pe -n  
CN="localhost" -eku 1.3.6.1.5.5.7.3.1 -ss my -sr  
localmachine -sky exchange -sp  
"Microsoft RSA SChannel Cryptographic Provider" -sy 12
```

Note that you are using the first certificate as the author for this latest one. This is important... where I have localhost you need to put the DNS name of your box. In other words, if you deploy your service such that its endpoint reads `http://bob:10010/Service` then the name needs to be bob. In addition, you are going to need to do this for each host you need to run as (yes, so one for bob and another one for localhost).

Get the signature of your cert by double clicking on the cert (Select the Certificates (Local Computer) ' Personal ' Certificates), opening the details tab, and scrolling down to the "Thumbprint" option.

Select the thumbprint and copy it. Put it in Notepad or any other text editor and replace the spaces with nothing. *Keep this thumbprint hexadecimal value safe*, since we will need it soon.

You have your certs set up. Congrats!

But we are not finished yet.

11.6.4.2. Configure a Port with an SSL certificate

Now you get to use another fun tool, `httpcfg` (for XP/2003), or its newer version, named aka `netsh http` (for Vista/Seven/Eight).

Firstly run the command below to check that you don't have anything running on a port you want.

```
httpcfg query ssl
```

(under XP)

```
netsh http show sslcert
```

(under Vista/Seven/Eight)

If this is your first time doing this, it should just return a newline. If there is already SSL set up on the exact IP you want to use (or if later on you need to delete any mistakes) you can use the following command, where the IP and the port are displayed as a result from the previous query.

Now we have to bind an SSL certificate to a port number, as such (here below, `0000000000003ed9cd0c315bbb6dc1c08da5e6` is the *thumbprint* of the certificate, as you copied it into the notepad in the previous paragraph):

```
httpcfg set ssl -i 0.0.0.0:8012 -h 0000000000003ed9cd0c315bbb6dc1c08da5e6
```

(under XP)

```
netsh http add sslcert ipport=0.0.0.0:8000 certhash=000000000003ed9cd0c315bbb6dc1c08da5e6  
appid={00112233-4455-6677-8899-AABBCCDDEEFF}
```

(under Vista/Seven/Eight)

Here the `appid=` parameter is a GUID that can be used to identify the owning application.

To delete an SSL certificate from a port number previously registered, you can use one of the following commands:

```
httpcfg delete ssl -i 0.0.0.0:8005 -h 000000000003ed9cd0c315bbb6dc1c08da5e6  
httpcfg delete ssl -i 0.0.0.0:8005
```

(under XP)

```
netsh http delete sslcert ipport=0.0.0.0:8005
```

(under Vista/Seven/Eight)

Note that this is mandatory to first delete an existing certificate for a given port before replacing it with a new one.

11.6.5. Custom Encodings

11.6.5.1. SynLZ/deflate compression

On the client side, the `TSQLHttpClientGeneric.Compression` property is by default set as such:

```
MyClient.Compression := [hcSynLZ];
```

It will enable *SynLZ* compression in the HTTP headers:

```
ACCEPT-ENCODING: synlz
```

Our *SynLZ* is efficient, especially on JSON content, and very fast on the server side. It will therefore use less resources than *hcDeflate*, so may be preferred when balancing the resource / concurrent client ratio.

You may include *hcDeflate* to the property, if you want to support this zip-derived compression algorithm, e.g. from browsers or any HTTP library. In terms of CPU resources, *hcDeflate* will be more consuming than *hcSynLZ*, but will obtain a slightly better compression ratio.

If both `[hcSynLZ, hcDeflate]` are defined, *mORMot* clients will use *SynLZ* compression, while other clients (e.g. browsers which do not know about the *SynLZ* encoding), will use the standard *deflate* compression.

11.6.5.2. AES encryption over HTTP

In addition to regular HTTPS flow encryption, which is not easy to setup due to the needed certificates, *mORMot* proposes a proprietary encryption scheme. It is based on SHA256 and AES256-CFB algorithms, so is known to be secure. You do not need to setup anything on the server or the client configuration, just run the `TSQLHttpClient` and `TSQLHttpServer` classes with the corresponding parameters.

Note that this encryption uses a global key for the whole process, which should match on both Server and Client sides. You should better hard-code this public key in your Client and Server *Delphi* applications, with some variants depending on each end-user service. You can use `CompressShaAesSetKey()` as defined in `SynCrypto.pas` to set globally this Encryption Key, and an optional Initialization Vector. You can even customize the AES chaining mode, if the default `TAESCFB`

mode is not what you expect.

When the `aHttpServerSecurity` parameter is set to `secSynShaAes` for the `TSQLHttpServer.Create()` constructor, this proprietary encryption will be enabled on the server side. For instance:

```
MyServer := TSQLHttpServer.Create('888',[DataBase],'+',useHttpApi,32,secSynShaAes);
```

On the client side, you can just set the `TSQLHttpClientGeneric.Compression` property as expected:

```
MyClient.Compression := [hcSynShaAes];
```

Once those parameters have been set, a new proprietary encoding will be defined in the HTTP headers:

```
ACCEPT-ENCODING: synshaaes
```

Then all HTTP body content will be compressed via our *SynLZ* algorithm, and encoded using the very secure AES256-CFB scheme.

On both client and server side, this encryption will use AES-NI hardware instructions, if available on the CPU it runs on. It ensures that security is enhanced not at the price of performance and scalability.

Since it is a proprietary algorithm, it will work only for *Delphi* clients. When accessing for a plain AJAX client, or a *Delphi* application with `TSQLHttpClientGeneric.Compression = []`, there won't be any encryption at all, due to way HTTP accepts its encoding. For safety, you should therefore use it in conjunction with per-URI Authentication - see below (page 547).

11.6.5.3. Prefer WebSockets between mORMot nodes

As we just saw, defining `hcSynShaAes` will only be available between *mORMot* nodes, if both do support the encoding. There is no insurance that content will be encrypted during transmission, e.g. if the client did not define `synshaaes`.

Therefore, for truly safe communication between *mORMot* nodes, you may consider our *WebSockets* client/server implementation instead - see below (page 445). It implements a proprietary binary protocol for its communication frames, using also *SynLZ* compression and AES256-CFB encryption. And, last but not least, it features real-time callbacks, if needed. This kind of access may in fact be considered as the safest available mean of remote connection to a *mORMot* server, from stable *mORMot* clients, e.g. in a *mORMot* Cloud. Then RESTful (AJAX/mobile) clients, may rely on plain HTTP, with `hcDeflate` compression.

11.7. Thread-safety

We tried to make *mORMot* at the same time fast and safe, and able to scale with the best possible performance on the hardware it runs on. Multi-threading is the key to better usage of modern multi-core CPUs, and also client responsiveness.

As a result, on the Server side, our framework was designed to be thread-safe.

On typical production use, the *mORMot* HTTP server - see *JSON RESTful Client-Server* (page 296) - will run on its own optimized thread pool, then call the `TSQLRestServer.URI` method. This method is therefore expected to be thread-safe, e.g. from the `TSQLHttpClient`. Request method. Thanks to the RESTful approach of our framework, this method is the only one which is expected to be thread-safe, since it is the single entry point of the whole server. This KISS design ensure better test coverage.

On the Client side, all `TSQLRestClientURI` classes are protected by a global mutex (*Critical Sections*), so are thread-safe. As a result, a single `TSQLHttpClient` instance can be shared among several threads, even if you may also use one client per thread, as is done with sample 21 - see below, for better responsiveness.

11.7.1. Thread safe design

We will now focus on the server side, which is the main strategic point (and potential bottleneck or point of failure) of any *Client-Server* architecture.

In order to achieve this thread-safety without sacrificing performance, the following rules were applied in `TSQLRestServer.URI`:

- Most of this method's logic is to process the URI and parameters of the incoming request (in `TSQLRestServerURIContext.URIDecode*` methods), so is thread-safe by design (e.g. `Model` and `RecordProps` access do not change during process);
- At RESTful / CRUD level, `Add/Update/Delete/TransactionBegin/Commit/Rollback` methods are locked by default (with a 2 seconds timeout), and `Retrieve*` methods are not;
- `TSQLRestStorage` main methods (`EngineList`, `EngineRetrieve`, `EngineAdd`, `EngineUpdate`, `EngineDelete`, `EngineRetrieveBlob`, `EngineUpdateBlob`) are thread-safe: e.g. `TSQLRestStorageInMemory` uses a per-Table *Critical Section*;
- `TSQLRestServerCallback` method-based services - i.e. published methods of the inherited `TSQLRestServer` class as stated below (page 374) - must be implemented to be thread-safe by default;
- Interface-based services - see below (page 420) - have several execution modes, including thread safe automated options (see `TServiceMethodOption`) or manual thread safety expectation, for better scaling - see below (page 462);
- A protected `fSessionCriticalSection` is used to protect shared `fSession[]` access between clients;
- The *SQLite3* engine access is protected at SQL/JSON cache level, via `DB.LockJSON()` calls in `TSQLRestServerDB` methods;
- Remote external tables - see *External SQL database access* (page 240) - use thread-safe connections and statements when accessing the databases via SQL;
- Access to `fStats` was not made thread-safe, since this data is indicative only: a *mutex* was not used to protect this resource.

We tried to make the internal *Critical Sections* as short as possible, or relative to a table only (e.g. for

TSQLRestStorageInMemory).

At *SQLite3* engine level, there is some kind of "giant lock", so all TSQLDatabase requests process will be queued. This induces only a slight performance penalty - see *Data access benchmark* (page 199) - since the internal SQL/JSON cache implementation needs such a global lock, and since most of the *SQLite3* resource use will consist in disk access, which gains to be queued. It also allows to use the *SQLite3* engine in *lmExclusive* locking mode if needed - see *ACID and speed* (page 222) - with both benefits of high performance and multi-thread friendliness.

From the Client-side, the REST core of the framework is expected to be Client-safe by design, therefore perfectly thread-safe: it is one benefit of the stateless architecture.

11.7.2. Advanced threading settings

You can use TSQLRestServerURI.AcquireExecutionMode[] property to refine the server-side threading mode. When amLocked is set, you can also set the AcquireExecutionLockedTimeOut[] property to specify a wait time to acquire the lock.

The default threading behavior is the following:

Command	Description	Default
execSOAByMethod	for method-based services	amUnlocked
execSOAByInterface	for interface-based services	amUnlocked
execORMGet	for ORM reads i.e. <i>Retrieve*</i> methods	amUnlocked
execORMWrite	for ORM writes i.e. <i>Add Update Delete TransactionBegin Commit Rollback</i> methods	amLocked + timeout of 2000 ms

On need, you can change those settings, to define a particular execution scheme.

For instance, some external databases (like MS SQL) expect any transaction to be executed within the same connection, so in the same thread context for *SynOleDb.pas*, since it uses a per-thread connection pool. When the server is remotely access via HTTP, the incoming requests will be executed from any thread of the HTTP server thread pool. As a result, you won't be able to manage a transaction over MS SQL from the client-side with the default settings.

To fix it, you can ensure all ORM write operations will be executed in a dedicated background thread, by setting either:

```
aServer.AcquireExecutionMode[execORMWrite] := amBackgroundThread;  
aServer.AcquireWriteMode := amBackgroundThread; // same as previous
```

The same level of thread-safety can be defined for all kind of commands, even if you should better know what you are doing when changing the default settings, since it may create some *giant locks* on the server side, therefore voiding any attempt to performance scaling via multi-threading - which is what *mORMot* excels in.

At ORM level, with external databases, your *mORMot* server may suffer from broken connection to the remote database. To avoid this, you may use *ConnectionTimeoutMinutes* property to specify a maximum period of inactivity after which all connections will be flushed and recreated, to avoid potential broken connections issues.

In this case, you should ensure that all ORM process is blocked so that clearing the connection pool won't break anything in your multi-threaded server. As such, you may set a blocking mode for both *execORMGet* and *execORMWrite*, for instance:

```
aServer.AcquireExecutionMode[execORMGet] := amBackgroundThread;  
aServer.AcquireExecutionMode[execORMWrite] := amBackgroundThread;
```

The above commands will create one thread for all read operations (execORMGet), and another thread for all write operations (execORMWrite). If you want all database access to take place in a *single* thread, for both read and write operations, you could write:

```
aServer.AcquireExecutionMode[execORMGet] := amBackgroundORMSharedThread;  
aServer.AcquireExecutionMode[execORMWrite] := amBackgroundORMSharedThread;
```

For instance, this sounds mandatory when using Jet/MSAccess as external database, since its implementation seems not thread-safe: if you write in one thread, then read immediately in another thread, the Jet engine is not able to find the just written data from the 2nd thread. This is clearly a bug of the Jet engine - but setting amBackgroundORMSharedThread option to circumvent the issue.

During any ORM or SOA process, you can access the current execution context from the ServiceContext threadvar variable, as stated below (page 433). For instance, you can retrieve the current logged user, or its session ID.

In practice, execSOAByMethod may benefit of a per-method locking, execSOAByInterface of using its own execution options - see below (page 462), and execORMGet to be let unlocked to allow concurrent reads of all connected clients.

11.7.3. Proven behavior

When we are talking about thread-safety, nothing compares to a dedicated stress test program. An average human brain (like ours) is not good enough to ensure proper design of such a complex process. So we have to prove the abilities of our little *mORMot*.

In the supplied regression tests, we designed a whole class of multi-thread testing, named TTestMultiThreadProcess. Its methods will run every and each Client-Server protocols available (direct access via TSQLRestServerDB or TSQLRestClientDB, Windows Messages, named pipes, and both HTTP servers - i.e. http.sys based or WinSock-based)- see *Client-Server process* (page 319).

Each protocol will execute in parallel a list of INSERTs - i.e. TSQLRest.Add() - followed by a list of SELECTs - i.e. TSQLRest.Retrieve(). Those requests will be performed in 1 thread, then 2, 5, 10, 30 and 50 concurrent threads. The very same *SQLite3* database (in *lmExclusive* locking mode) is accessed at once by all those clients. Then the IDs generated by each thread are compared together, to ensure no cross-insertion did occur during the process.

Those automated tests did already reveal some issues in the initial implementation of the framework. We fixed any encountered problems, as soon as possible. Feel free to send us any feedback, with code to reproduce the issue: but do not forget that multi-threading is also difficult to test - problems may occur not in the framework, but in the testing code itself!

When setting OperationCount to 1000 instead of the default 200, i.e. running 1000 INSERTions and 1000 SELECTs in concurrent threads, the numbers are the following, on the local machine (compiled with *Delphi* XE4):

```
Multi thread process:  
- Create thread pool: 1 assertion passed 3.11ms  
- TSQLRestServerDB: 24,061 assertions passed 903.31ms  
  1=41986/s 2=24466/s 5=14041/s 10=9212/s 30=10376/s 50=10028/s  
- TSQLRestClientDB: 24,062 assertions passed 374.93ms  
  1=38606/s 2=35823/s 5=30083/s 10=32739/s 30=33454/s 50=30905/s  
- TSQLRestClientURINamedPipe: 12,012 assertions passed 1.68s  
  1=4562/s 2=5002/s 5=3177/s  
- TSQLRestClientURIMessage: 16,022 assertions passed 616.00ms
```

```
1=16129/s 2=24873/s 5=8613/s 10=11857/s
- TSQLHttpClientWinHTTP_HTTPAPI: 24,056 assertions passed 1.63s
1=5352/s 2=7441/s 5=7563/s 10=7903/s 30=8413/s 50=9106/s
- TSQLHttpClientWinSock_WinSock: 24,061 assertions passed 1.10s
1=11528/s 2=10941/s 5=12014/s 10=12039/s 30=9443/s 50=10831/s
Total failed: 0 / 124,275 - Multi thread process PASSED 6.31s
```

For direct in-process access, TSQLRestClientDB sounds the best candidate: its abstraction layer is very thin, and much more multi-thread friendly than straight TSQLRestServerDB calls. It also will feature a cache, on need - see *ORM Cache* (page 174). And it will allow your code to switch between TSQLRestClientURI kind of classes, from its shared abstract methods.

Named pipes and Windows Messages are a bit constrained in highly parallel mode, but HTTP does pretty good. The server based on http.sys (HTTP API) is even impressive: the more clients, the more responsive it is. It is known to scale much better than the WinSock-based class supplied, which shines with one unique local client (i.e. in the context of those in-process regression tests), but sounds less reliable on production.

11.7.4. Highly concurrent clients performance

In addition, you can make yourself an idea, and run the "21 - HTTP Client-Server performance" sample programs, locally or over a network, to check the *mORMot* abilities to scale and serve a lot of clients with as few resources as possible.

Compile both client and server projects, then launch Project21HttpServer.exe. The server side will execute as a console window.

This Server will define the same TSQLRecordPeople as used during our multi-thread regression tests, that is:

```
type
TSQLRecordPeople = class(TSQLRecord)
private
fFirstName: RawUTF8;
fLastName: RawUTF8;
fYearOfBirth: integer;
fYearOfDeath: word;
published
property FirstName: RawUTF8 read fFirstName write fFirstName;
property LastName: RawUTF8 read fLastName write fLastName;
property YearOfBirth: integer read fYearOfBirth write fYearOfBirth;
property YearOfDeath: word read fYearOfDeath write fYearOfDeath;
end;
```

The server main block is just the following:

```
aModel := TSQLModel.Create([TSQLRecordPeople]);
try
aDatabaseFile := ChangeFileExt(paramstr(0), '.db3');
DeleteFile(aDatabaseFile);
aServer := TSQLRestServerDB.Create(aModel, aDatabaseFile);
try
aServer.DB.Synchronous := smOff;
aServer.DB.LockingMode := lmExclusive;
aServer.NoAJAXJSON := true;
aServer.CreateMissingTables;
// Launch the server
aHTTPServer := TSQLHttpServer.Create('888', [aServer]);
try
writeln(#13#10'Background server is running at http://localhost:888'#13#10+
#13#10'Press [Enter] to close the server.');
```

```

    aHTTPServer.Free;
  end;
  finally
    aServer.Free;
  end;
  finally
    aModel.Free;
  end;

```

Following the *Model-View-Controller* (page 86) pattern, aServer will give remote CRUD access to the TSQLRecordPeople table (as defined in aModel), from HTTP. We defined Synchronous := smOff and LockingMode := lmExclusive to have the best performance possible, as stated by *ACID and speed* (page 222). Our purpose here is not to have true ACID behavior, but test concurrent remote access.

The Client is just a RAD form which will execute the very same code than during the regression tests, i.e. a TTestMultiThreadProcess class instance, as shown by the following code:

```

Tests := TSynTestsLogged.Create;
Test := TTestMultiThreadProcess.Create(Tests);
try
  Test.ClientOnlyServerIP := StringToAnsi7(lbledtServerAddress.Text);
  Test.MinThreads := ThreadCount;
  Test.MaxThreads := ThreadCount;
  Test.OperationCount := OperationCount;
  Test.ClientPerThread := ClientPerThread;
  Test.CreateThreadPool;
  txt := Format
    ('%s'#13#10'#13#10'Test started with %d threads, %d client(s) per thread and %d rows to be
inserted...',
    [txt, ThreadCount, ClientPerThread, OperationCount]);
  mmoInfo.Text := txt;
  Timer.Start;
  Test._TSQLHttpClientWinHTTP_HTTPAPI;
  txt := mmoInfo.Text+Format('#13#10'Assertion(s) failed: %d / %d'+
    #13#10'Number of clients connected at once: %d'+
    #13#10'Time to process: %s'#13#10'Operation per second: %d',
    [Test.AssertionsFailed, Test.Assertions,
    ThreadCount*ClientPerThread, Timer.Stop, Timer.PerSec(OperationCount*2)]);
  mmoInfo.Text := txt;
finally
  Test.Free;
  Tests.Free;
end;

```

Each thread of the thread pool will create its own HTTP connection, then loop to insert (Add ORM method) and retrieve (Retrieve ORM method) a fixed number of objects - checking that the retrieved object fields match the inserted values. Then all generated IDs of all threads are checked for consistency, to ensure no race condition did occur.

The input parameters are therefore the following:

- Remote HTTP server IP (port is 888);
- Number of client threads;
- Number of client instances per thread;
- Number of TSQLRecordPeople objects added.

When running over the following hardware configuration:

- Server is a Core i7 Notebook, with SSD, under Windows 7;
- Client is a Core 2 Duo Workstation, with regular hard-drive (not used), under Windows 7;
- Communicating over a somewhat slow 100 Mb network with a low priced Ethernet HUB.

Typical results are the following:

Threads	Clients/thread	Rows inserted	Total Clients	Time (sec)	Op/sec
1	1	10000	1	15.78	1267
50	1	10000	50	2.96	6737
100	1	10000	100	3.09	6462
100	1	20000	100	6.19	6459
50	2	100000	100	34.99	5714
100	2	100000	200	36.56	5469
500	100	100000	50000	92.92	2152

During all tests, no assertion failed, meaning that no concurrency problem did occur, nor any remote command lost. The *SQLite3* core, exposes via the *mORMot* server, outputs data at an amazing pace of 6000 op/sec - i.e. comparable to most high-end databases. It is worth noting that when run several times in a row, the same set of input parameters give the very same speed results: it indicates that the architecture is pretty stable and could be considered as safe. The system is even *able to serve 50000 connected clients at once*, with no data loss - in this case, performance is lower (2152 insert/second in the above table), but we clearly reached the CPU and network limit of our client hardware configuration; in the meanwhile, server CPU resources on the Notebook server did have still some potential, and RAM consumption was pretty slow.

Average performance is pretty good, even more if we consider that we are inserting one object per request, with no transaction. In fact, it sounds like if our little *SQLite3* server is faster than most database servers, even when accessed in highly concurrent mode! In batch mode - see below (page 351) - we may achieve amazing results.

Feel free to send your own benchmark results and feedback, e.g. with concurrent clients on several workstations, or long-running tests, on our forums.

12. Client-Server ORM

Adopt a mORMot

As stated above, all ORM features can be accessible either stand-alone, or remotely via some dedicated *Client-Server process* (page 319).

That is, CRUD operations can be executed either at the database level, or remotely, from the same methods defined in TSQLRest abstract class.

This feature has several benefits, among them:

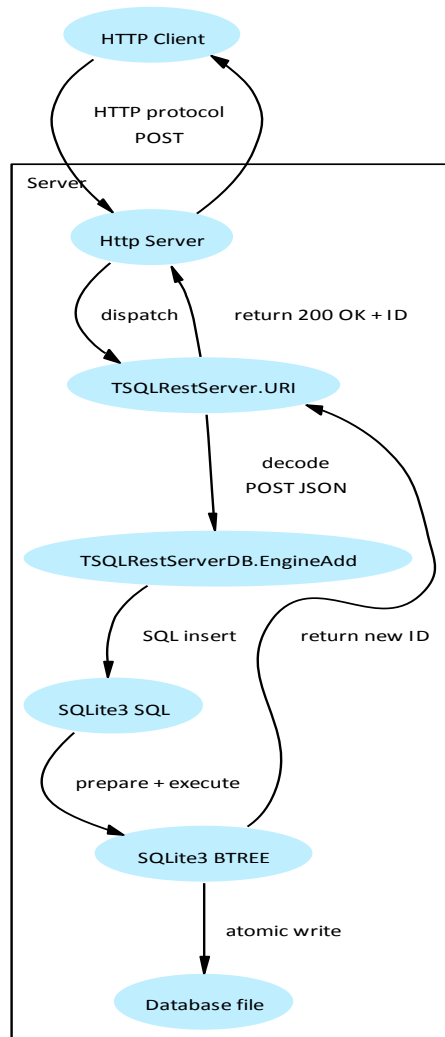

- No need to deploy the database client library for your application clients - a standard IP network connection is enough;
- Therefore the client application can safely remain small, and stand-alone - no installation step is necessary, and you still have the full power of a native rich client;
- Clients access their objects in an abstract way, i.e. without any guess on how persistence is handled: some classes may be stored in one *SQLite3* database, others may exist only in server's memory, others may be stored e.g. in an external *Oracle*, *Firebird*, *PostgreSQL*, *MySQL*, *DB2*, *Informix* or *MS SQL* database;
- You can switch from local to remote access just by changing the class type, even at runtime;
- Optimization is implemented at every level of the n-Tier architecture, e.g. cache or security.

12.1. ORM as local or remote

Typical Client-Server RESTful POST / Add request over HTTP/1.1 will be implemented as such, on both Client and Server side:

Client-Server implementation - Client side

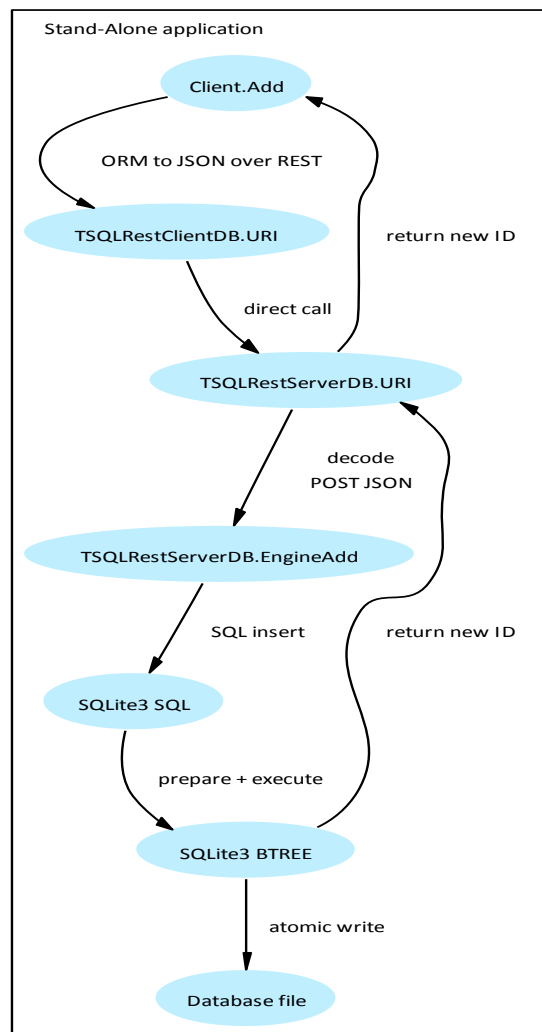

Client-Server implementation - Server side

Of course, several clients can access to the same server.

The same server is also able to publish its RESTful services over several communication protocol at once, e.g. HTTP/1.1 for remote access over a network (either corporate or the Internet), named pipes or Windows Messages for fast local access.

The above diagram describes a direct INSERT into the Server's main *SQLite3* engine, but other database back-ends are available - see *Database layer* (page 196).

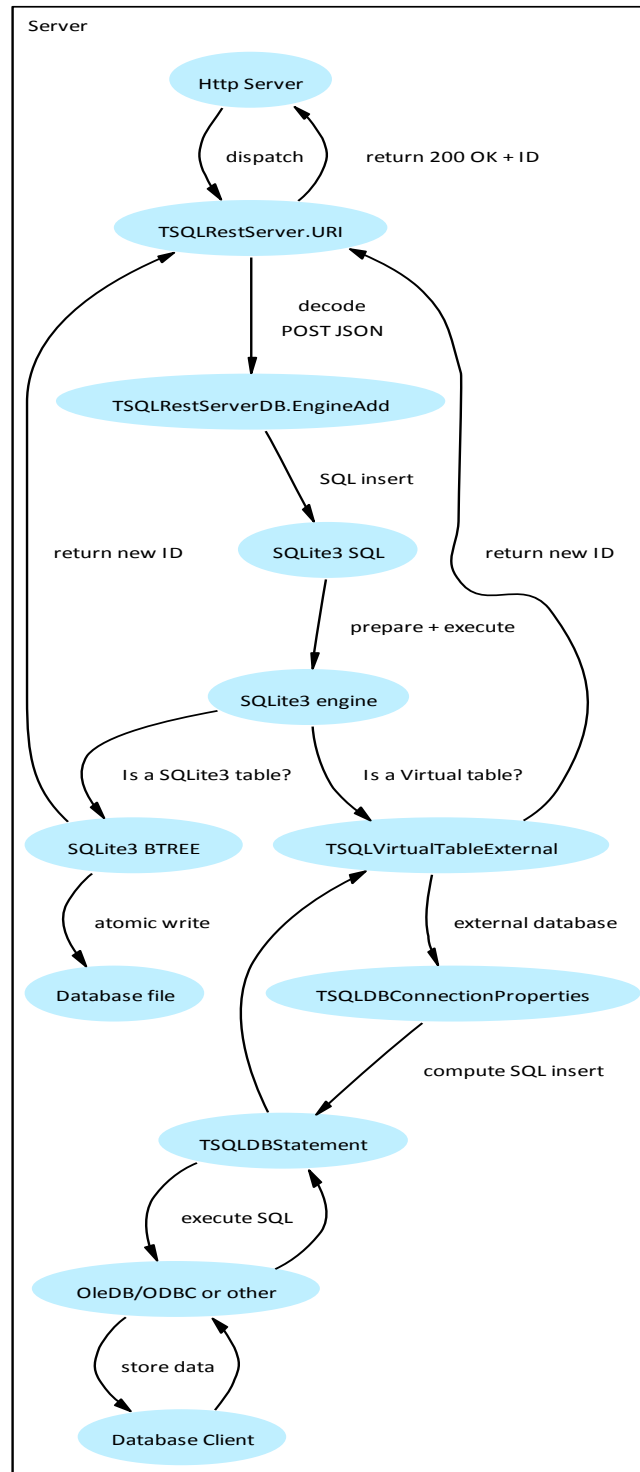

It is possible to by-pass the whole Client-Server architecture, and let the application be stand-alone, by defining a *TSQLRestClientDB* class, which will embed a *TSQLRestServerDB* instance in the same executable:

Client-Server implementation - Stand-Alone application

In fact, the same executable could be launched as server, as stand-alone application, or even client application! It is just a matter of how you initialize your *TSQLRest* classes instances - see *Client-Server process* (page 319). Some *mORMot* users use this feature to ease deployment, support and configuration. It can be also extremely useful at debugging time, since you may run the server and client side of your project at once within the same application, from the IDE.

In case of a Virtual Table use (either in-memory or for accessing an external database), the client side remains identical. Only the server side is modified as was specified by *External database ORM internals* (page 274):

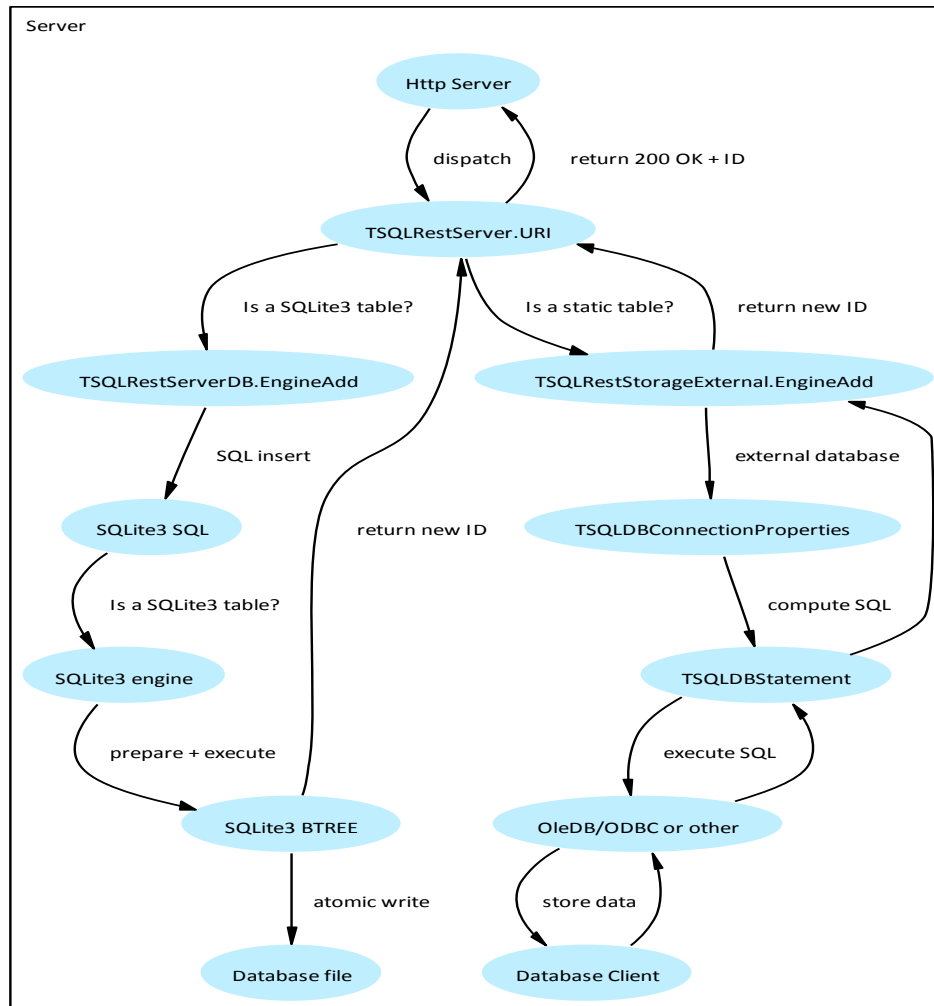

Client-Server implementation - Server side with Virtual Tables

In fact, the above function correspond to a database model with only external virtual tables, and with `StaticVirtualTableDirect=false`, i.e. calling the Virtual Table mechanism of *SQLite3* for each

request.

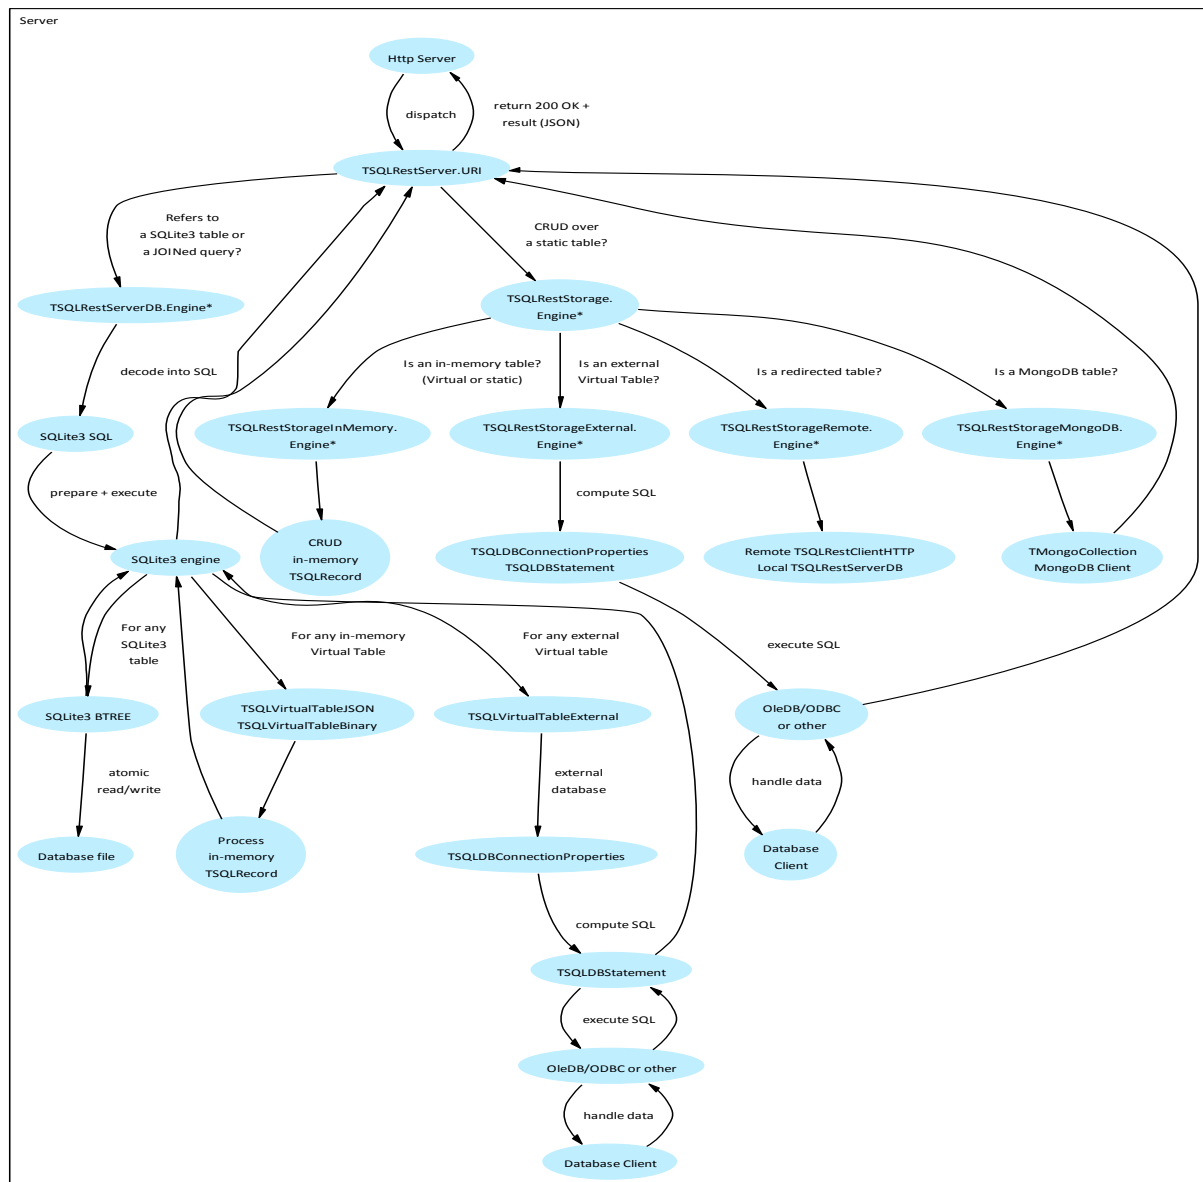

But most of the time, i.e. for RESTful / CRUD commands, the execution is more direct:

Client-Server implementation - Server side with "static" Virtual Tables

As stated in *External SQL database access* (page 240), the static `TSQLRestStorageExternal` instance is called for most RESTful access. In practice, this design will induce no speed penalty, when compared to a direct database access. It could be even faster, if the server is located on the same computer than the database: in this case, use of JSON and REST could be faster - even faster when using below (page 351).

In order to be exhaustive, here is a more complete diagram, showing how native *SQLite3*, in-memory or external tables are handled on the server side. You'll find out how CRUD statements are handled directly for better speed, whereas any SQL JOIN query can also be processed among all kind of tables.

Client-Server implementation - Server side

You will find out some speed numbers resulting from this unique architecture in the supplied *Data access benchmark* (page 199).

12.2. Stateless design

12.2.1. Server side synchronization

Even if *Stateless ORM* (page 315), it's always necessary to have some event triggered on the server side when a record is edited.

On the server side, you can use this method prototype:

```
type
  /// used to define how to trigger Events on record update
  // - see TSQLRestServer.OnUpdateEvent property
  // - returns true on success, false if an error occurred (but action must continue)
  TNotifySQLEvent = function(Sender: TSQLRestServer; Event: TSQLEvent;
    aTable: TSQLRecordClass; aID: TID): boolean of object;

  TSQLRestServer = class(TSQLRest)
  (...)
    /// a method can be specified here to trigger events after any table update
    OnUpdateEvent: TNotifySQLEvent;
```

12.2.2. Client side synchronization

But if you want all clients to be notified from any update, there is no direct way of broadcasting some event from the server to all clients.

It's not even technically possible with pipe-oriented transport layer, like named pipes or the TCP/IP - HTTP protocol.

What you can do easily, and is what should be used in such case, is to have a timer in your client applications which will call `TSQLRestClientURI.UpdateFromServer()` method to refresh the content of any `TSQLRecord` or `TSQLTableJSON` instance:

```
/// check if the data may have changed of the server for this objects, and
/// update it if possible
// - only working types are TSQLTableJSON and TSQLRecord descendants
// - make use of the InternalState function to check the data content revision
// - return true if Data is updated successfully, or false on any error
// during data retrieval from server (e.g. if the TSQLRecord has been deleted)
// - if Data contains only one TSQLTableJSON, PCurrentRow can point to the
// current selected row of this table, in order to refresh its value
function UpdateFromServer(const Data: array of TObject; out Refreshed: boolean;
  PCurrentRow: PInteger = nil): boolean;
```

With a per-second timer, it's quick and reactive, even over a remote network.

The stateless aspect of REST allows this approach to be safe, by design.

This is handled natively by our Client User Interface classes, with the following parameter defining the User interface:

```
/// defines the settings for a Tab
TSQLRibbonTabParameters = object
  (...)
    /// by default, the screens are not refreshed automatically
    // - but you can enable the auto-refresh feature by setting this
    // property to TRUE, and creating a WM_TIMER timer to the form
    AutoRefresh: boolean;
```

This parameter will work only if you handle the `WM_TIMER` message in your main application form, and call `Ribbon.WMRefreshTimer`.

See for example this method in the main demo (FileMain.pas unit):

```
procedure TMainForm.WMRefreshTimer(var Msg: TWMTimer);
begin
  Ribbon.WMRefreshTimer(Msg);
end;
```

In a multi-threaded client application, and even on the server side, a stateless approach makes writing software easier. You do not have to care about forcing data refresh in your client screens. It's up to the screens to get refreshed. In practice, I found it very convenient to rely on a timer instead of calling the somewhat "delicate" TThread. Synchronize method.

12.2.3. Let applications be responsive

All the client communication is executed by default in the current thread, i.e. the main thread for a typical GUI application.

Since all communication is performed in *blocking* mode, if the remote request takes long to process (due to a bad/slow network, or a long server-side action), the application may become unresponsive, from the end-user experience. Even *Windows* may be complaining about a "non responsive application", and may propose to kill the process, which is far away from an expected behavior.

In order to properly interacts with the user, a OnIdle property has been defined in TSQLRestClientURI, and will change the way communication is handled. If a callback event is defined, all client communication will be processed in a background thread, and the current thread (probably the main UI thread) will wait for the request to be performed in the background, running the OnIdle callback in loop in the while.

You can find in the mORMotUILogin unit two methods matching this callback signature:

```
TLoginForm = class(TForm)
(...)
  class procedure OnIdleProcess(Sender: TSynBackgroundThreadAbstract; ElapsedMS: Integer);
  class procedure OnIdleProcessForm(Sender: TSynBackgroundThreadAbstract; ElapsedMS: Integer);
end;
```

The first OnIdleProcess() callback will change the mouse cursor shape to crHourGlass after a defined period of time. The OnIdleProcessForm() callback won't only change the mouse cursor, but also display a pop-up window with a 'Please wait...' message, if the request takes even more time. Both will call Application.ProcessMessages to ensure the application User Interface is still responsive.

Some global variable were also defined to tune the behavior of those two callbacks:

```
var
  /// define when TLoginForm.OnIdleProcess() has to display the crHourGlass cursor
  /// after a given time elapsed, in milliseconds
  /// - default is 100 ms
  OnIdleProcessCursorChangeTimeout: integer = 100;

  /// define when TLoginForm.OnIdleProcessForm() has to display the temporary
  /// form after a given time elapsed, in milliseconds
  /// - default is 2000 ms, i.e. 2 seconds
  OnIdleProcessTemporaryFormTimeout: integer = 2000;

  /// define the message text displayed by TLoginForm.OnIdleProcessForm()
  /// - default is sOnIdleProcessFormMessage resourcestring, i.e. 'Please wait...'
  OnIdleProcessTemporaryFormMessage: string;
```

You can therefore change those settings to customize the user experience. We tested it with a 3 second artificial temporizer for each request, and the applications were running smoothly, even if

slowly - but comparable to most Web Applications, in fact. The *SynFile* main demo (available in the `SQLite3\Samples\MainDemo` folder) defines such a callback.

Note that this `OnIdle` feature is defined at `TSQLRestClientURI` class level, so is available for all communication protocols, not only HTTP but named pipes or in-process, so could be used to enhance user experience in case of some time consuming process.

12.3. BATCH sequences for adding/updating/deleting records

12.3.1. BATCH process

When use the so-called BATCH sequences?

In a standard Client-Server architecture, especially with the common understanding (and most implementations) of a RESTful service, any Add / Update / Delete method call requires a back and forth flow to then from the remote server. A so-called *round-trip* occurs: a message is sent to the client, the a response is sent back to the client.

In case of a remote connection via the Internet (or a slow network), you could have up to 100 ms of latency: it's just the "ping" timing, i.e. the time spent for your IP packet to go to the server, then back to you.

If you are making a number of such calls (e.g. add 1000 records), you'll have $100 \times 1000 \text{ ms} = 100 \text{ s} = 1:40 \text{ min}$ just because of this network latency!

BATCH mode Client-Server latency

The BATCH sequence allows you to regroup those statements into just ONE remote call. Internally, it builds a JSON stream, then post this stream at once to the server. Then the server answers at once, after having performed all the modifications.

Some new `TSQLEstClientURI` methods have been added to implement BATCH sequences to speed up database modifications: after a call to `BatchStart`, database modification statements are added to the sequence via `BatchAdd` / `BatchUpdate` / `BatchDelete`, then all statements are sent as one to the remote server via `BatchSend` - this is MUCH faster than individual calls to Add / Update / Delete in case of a slow remote connection (typically HTTP over Internet).

Since the statements are performed at once, you can't receive the result (e.g. the ID of the added row) on the same time as you append the request to the BATCH sequence. So you'll have to wait for the `BatchSend` method to retrieve all results, *at once*, in a *dynamic* array of `TID`.

As you may guess, it's also a good idea to use a transaction for the whole process. By default, the BATCH sequence is not embedded into a transaction.

You have two possibilities to add a transaction:

- Either let the caller use an explicit TransactionBegin ... try... Commit except RollBack block;
- Or specify a number of rows as AutomaticTransactionPerRow parameter to BatchStart(): in this case, a transaction will be emitted (up to the specified number of rows) on the server side. You can just set maxInt if you want all rows to be modified in a single transaction.

This second method is preferred, since defining transactions from the client side is not a good idea: it may block other clients attempts to create their own transaction.

Here is typical use (extracted from the regression tests in SynSelfTests.pas):

```
// start the BATCH sequence
Check(ClientDist.BatchStart(TSQLRecordPeople,1000));
// now a transaction will be created by chunk of 1000 modifications
// delete some elements
for i := 0 to n-1 do
  Check(ClientDist.BatchDelete(IntArray[i])=i);
// update some elements
nupd := 0;
for i := 0 to aStatic.Count-1 do
  if i and 7<>0 then
    begin // not yet deleted in BATCH mode
      Check(ClientDist.Retrieve(aStatic.ID[i],V));
      V.YearOfBirth := 1800+nupd;
      Check(ClientDist.BatchUpdate(V)=nupd+n);
      inc(nupd);
    end;
// add some elements
V.LastName := 'New';
for i := 0 to 1000 do
  begin
    V.FirstName := RandomUTF8(10);
    V.YearOfBirth := i+1000;
    Check(ClientDist.BatchAdd(V,true)=n+nupd+i);
  end;
// send the BATCH sequences to the server
Check(ClientDist.BatchSend(Results)=200);
// now all data has been committed on the server
// now Results[] contains the results of every BATCH statement...
Check(Length(Results)=n+nupd+1001);
// Results[0] to Results[n-1] should be 200 = deletion OK
// Results[n] to Results[n+nupd-1] should be 200 = update OK
// Results[n+nupd] to Results[high(Results)] are the IDs of each added record
for i := 0 to high(Results) do
  if i<nupd+n then
    Check(Results[i]=200) else
    begin
      Check(Results[i]>0);
      ndx := aStatic.IDToIndex(Results[i]);
      Check(ndx>=0);
      with TSQLRecordPeople(aStatic.Items[ndx]) do
        begin
          Check(LastName='New','BatchAdd');
          Check(YearOfBirth=1000+i-nupd-n);
        end;
    end;
// check ClientDist.BatchDelete(IntArray[i]) did erase the record
for i := 0 to n-1 do
  Check(not ClientDist.Retrieve(IntArray[i],V),'BatchDelete');
```

In the above code, all CRUD operations are performed as usual, using BatchAdd BatchDelete BatchUpdate methods instead of plain Add Delete Update methods. The ORM will take care of all the

resource needed. With the new internal *SynLZ* compression (available by default in our HTTP Client-Server classes), used bandwidth is minimal.

Thanks to this BATCH process, most time is now spent into the database engine itself, and not in the communication layer.

12.3.3. Unit Of Work pattern

12.3.3.1. Several Batches

On the *TSQLRestClientURI* side, all *BatchStart/BatchAdd/BatchUpdate/BatchDelete* methods are using a single temporary storage during the BATCH preparation. This may be safe only if one single thread is accessing the methods - which is usually the case for a REST Client application.

In fact, all BATCH process is using a *TSQLRestBatch* class, which can be created on the fly, and safely coexist as multiple instances for the same *TSQLRest*. As a result, you can create your own local *TSQLRestBatch* instances, for safe batch process. This is in fact mandatory on the *TSQLRestServer* side, which do not have the *Batch*()* methods, since they will not be thread safe.

On the server side, you may write for instance:

```
var Batch: TSQLRestBatch;  
    IDs: TIntegerDynArray;  
...  
Batch := TSQLRestBatch.Create(Server, TSQLRecordTest, 30);  
try  
    for i := 10000 to 10099 do begin  
        R.Int := i;  
        R.Test := Int32ToUTF8(i);  
        Check(Batch.Add(R, true)=i-10000);  
    end;  
    Check(Server.BatchSend(Batch, IDs)=HTTP_SUCCESS);  
finally  
    Batch.Free;  
end;
```

The ability to handle several *TSQLRestBatch* classes in the same time will allow to implement the *Unit Of Work* pattern. It can be used to maintain a list of objects affected by a business transaction and coordinates the writing out of changes and the resolution of concurrency problems, especially in a complex SOA application with a huge number of connected clients.

In a way, you can think of the *Unit of Work* as a place to dump all transaction-handling code.

The responsibilities of the *Unit of Work* are to:

- Manage transactions;
- Order the database inserts, deletes, and updates;
- Prevent concurrency problems;
- Group requests to maximize the database performance.

The value of using a *Unit of Work* pattern is to free the rest of your code from these concerns so that you can otherwise concentrate on business logic.

12.3.3.2. Updating only the mapped fields

In practice, the *BatchUpdate* method will only update the mapped fields if called on a record in which a *FillPrepare* was performed, and not unmapped (i.e. with no call to *FillClose*). This is required for coherency of the retrieval/modification process.

For instance, in the following code, `V.FillPrepare` will retrieve only ID and YearOfBirth fields of the `TSQLRecordPeople` table, so subsequent `BatchUpdate(V)` calls will only update the `YearOfBirth` field:

```
// test BATCH update from partial FillPrepare
V.FillPrepare(ClientDist, 'LastName=:( "New" ):', 'ID, YearOfBirth');
if ClientDist.TransactionBegin(TSQLRecordPeople) then
try
  Check(ClientDist.BatchStart(TSQLRecordPeople));
  n := 0;
  V.LastName := 'NotTransmitted';
  while V.FillOne do begin
    Check(V.LastName='NotTransmitted');
    Check(V.YearOfBirth=n+1000);
    V.YearOfBirth := n;
    ClientDist.BatchUpdate(V); // will update only V.YearOfBirth
    inc(n);
  end;
  (...)
```

The transmitted JSON will be computed as such on the client side:

```
..., "PUT", {"RowID":324, "YearOfBirth":1000},...
```

And the generated SQL on the server side will be:

```
UPDATE People SET YearOfBirth=? WHERE RowID=?
... with bound parameters: [1000,324]
```

As a result, BATCH process could be seen as a good way of implementing *Unit Of Work* for your business layer - see below (page 602).

You will be able to modify all your objects as requested, with high-level OOP methods, then have all data transmitted and processed at once when `BatchSend()` is called. The `BatchStart` - `BatchSend` - `BatchAbort` commands will induce a safe transactional model, relying on the client side for tracking the object modifications, and optimizing the database process on the server side as a simple "save and forget" task, to any SQL or NoSQL engine.

Note that if several `ClientDist.BatchUpdate(V)` commands are executed within the same `FillPrepare()` context, they will contain the same fields (`RowID` and `YearOfBirth`). They will therefore generate the same statement (`UPDATE People SET YearOfBirth=? WHERE RowID=?`), which will benefit of *Array Binding* on the database side - see below (page 357) - if available.

Here is some code, extracted from "web blog" sample "30 - MVC Server", which will update an integer array mapped into a table. All `TSQLTag.Occurrence` integers are stored in a local `TSQLTags.Lookup[]` dynamic array, which will be used to display the occurrence count of each tag of the articles.

The following method will first retrieve ID and Occurrence from the database, and update the `TSQLTag.Occurrence` if the internal dynamic array contains a new value.

```
procedure TSQLTags.SaveOccurrence(aRest: TSQLRest);
var tag: TSQLTag;
    batch: TSQLRestBatch;
begin
  Lock.ProtectMethod;
  TAutoFree.Several([
    @tag, TSQLTag.CreateAndFillPrepare(aRest, '', 'RowID, Occurrence'),
    @batch, TSQLRestBatch.Create(aRest, TSQLTag, 1000)]);
  while tag.FillOne do begin
    if tag.ID <= length(Lookup) then
      if Lookup[tag.ID-1].Occurrence <> tag.Occurrence then begin
        tag.Occurrence := Lookup[tag.ID-1].Occurrence;
        batch.Update(tag); // will update only Occurrence field
      end;
    end;
```

```
end;  
aRest.BatchSend(batch);  
end;
```

In the above code, you can identify:

- CreateAndFillPrepare + FillOne methods are able to retrieve all values of the TSQLTag class, and iterate easily over them;
- A local TSQLRestBatch is prepared, and will store locally - via batch.Update() - any modification; as we already stated, only the retrieved field (i.e. 'Occurrence') will be marked as to be updated;
- aRest.BatchSend(batch) will send all new values (if any) to the server, in a single network round trip, and a single transaction;
- This method is made thread safe by using Lock.ProtectMethod (Lock is a mutex private to the TSQLTags instance);
- Local variables are allocated and automatically released when the method exits, using TAutoFree.Several() - see *Automatic TSQLRecord memory handling* (page 149) - which avoid to write two nested try .. finally Free end loops.

Such a pattern is very common in *mORMot*, and illustrate how high-level ORM methods can be used instead of manual SQL. With the potential benefit of a much better performance, and cleaner code.

12.3.4. Local network as bottleneck

When using a remote database on a physical network, a *round-trip* delay occurs for each request, this time between the ORM server side and the external Database engine.

BATCH mode latency issue on external DB

At first, the 1 ms latency due to the external database round-trip may sound negligible. *BATCH sequences for adding/updating/deleting records* (page 351) did already shortcut the Internet latency, which was much higher.

But in a *Service-Oriented Architecture (SOA)* (page 90), most of the process is done on the server side: the slightest execution delay will induce a noticeable performance penalty. In practice, you won't be able to achieve more than 500-600 requests per second when performing individual INSERT, DELETE or UPDATE statements over any SQL database. Even if run locally on the same server, most SQL databases will suffer from the overhead of inter-process communications, achieving 6,000-7,000 update requests per second at best.

Your customers may not understand why using a *SQLite3* engine will be much faster than a dedicated *Oracle* instance they do pay huge amount of money for, since *SQLite3* runs locally in the ORM server process. One common solution is to use stored procedures, or tune the SQL for your database - but you will loose most of the ORM and SOA benefits - see below (page 367).

Of course, *mORMot* can do better than that. Its ORM will automatically use two ways of diminishing the number of round-trips to the database:

- Using *Array Binding* - see below (page 357);
- Or *multi-INSERT statements* - see below (page 358).

Both methods will group all the transmitted data in chunks, as much as possible. Performance will therefore increase, reaching 50,000-60,000 writes per second, depending on the database abilities.

Those features are enabled by default, and the fastest method will always be selected by the ORM core, as soon as it is available on the database back-end. You do not have to worry about configuring your application. Just enjoy its speed.

12.3.4.1. Array binding

12.3.4.1.1. For faster BATCH mode

When used in conjunction with *External SQL database access* (page 240), BATCH methods can be implemented as *array binding* if the corresponding *TSQldbConnection* class implements the feature. By now, only *SynDBOracle*, *SynDBZeos* and *SynDBFireDAC* units implement it.

Our *SynDB.pas* unit offers some *TSQldbStatement.BindArray()* methods, introducing native *array binding* for faster database batch modifications. It is working in conjunction with our the BATCH methods of the ORM, so that CRUD modification actions will transparently be grouped within one *round-trip* over the network.

Thanks to this enhancement, inserting records within *Oracle* (over a 100 Mb Ethernet network) comes from 400-500 rows per second to more than 70,000 rows per second, according to our *Data access benchmark* (page 199).

The great maintainers of the *ZEOS Open Source* library did especially tune its internals to support *mORMot* at its full speed, directly accessing the *ZDBC* layer - see *ZEOS via direct ZDBC* (page 255). The *ZEOS 7.2* branch did benefit of a huge code refactoring, and also introduced *array binding* abilities. This feature will be recognized and handled by our ORM, if available at the *ZDBC* provider side. Today, only the *ZDBC Oracle* and *Firebird* providers do support this feature. But the list is growing.

The *FireDAC* (formerly *AnyDAC*) library is the only one implementing this feature (known as *Array DML* in the *FireDAC* documentation) around all available *Delphi* commercial libraries. Enabling it gives a similar performance boost, not only for *Oracle*, but also *MS SQL*, *Firebird*, *DB2*, *MySQL*, *Informix* and *PostgreSQL*.

In practice, when accessing *Oracle*, our own direct implementation in *SynDBOracle* still gives better performance results than the *ZDBC / FireDAC* implementation.

In fact, some modern database engine (e.g. *Oracle* or *MS SQL*) are even faster when using *array binding*, not only due to the network latency reduce, but to the fact that in such operations, integrity checking and indexes update is performed at the end of the bulk process. If your table has several indexes and constraints, it will make using this feature even faster than a "naive" stored procedure executing individual statements within a loop.

12.3.4.1.2. For faster IN clause

Sometimes, you want to write *SELECT* statements with a huge *IN* clause. If the number of the items in the *IN* expression is stable, you may benefit for a prepared statement, e.g.

```
SELECT * FROM MyTable WHERE ID IN [?, ?, ?, ?, ?]
```

But if the IDs are not fixed, you should have to create an expression without any parameter, or use a temporary table:

```
SELECT * FROM MyTable WHERE ID IN [1,4,8,12,24,27]
```

As an alternative, *SynDBOracle* provides the ability to bind an array of parameters which may be cast to an *Oracle* Object, so that you could use it as a single parameter.

Current implementation support either *TInt64DynArray* or *TRawUTF8DynArray* values, as such:

```
var
  arr: TInt64DynArray = [1, 2, 3];
Query := TSynDBOracleConnectionProperties.NewThreadSafeStatementPrepared(
  'select * from table where table.id in'+
  '(select column_value from table(cast(? as SYS.ODCINUMBERLIST)))');
Query.BindArray(1, arr);
Query.ExecutePrepared;
```

RawUTF8 arrays are also supported (which can be used as fall back in case *Int64* arrays are not supported by the client, e.g. with *Oracle 10*):

```
var
  arr: TRawUTF8DynArray = ['123123423452345', '3124234454351324', '53567568578867867'];
Query := TSynDBOracleConnectionProperties.NewThreadSafeStatementPrepared(
  'select * from table where table.id in'+
  '(select column_value from table(cast(? as SYS.ODCIVARCHAR2LIST)))');
Query.BindArray(1, arr);
Query.ExecutePrepared;
```

From tests on production, this implementation is 2-100 times faster (depending on array and table size) and also simpler, compared to temporary table solution.

Drawback is that it is supported by *SynDBOracle* only by now.

12.3.4.2. Optimized SQL for bulk insert

Sadly, array binding is not available for all databases or libraries.

In order to maximize speed, during *BATCH* insertion, the *mORMot* ORM kernel is able to generate some optimized SQL statements, depending on the target database, to send several rows of data at once. It induces a noticeable speed increase when saving several objects into an external database.

Automatic multi-INSERT statement generation is available for:

- Our internal *SQLite3* engine (in the *mORMotSQLite3.pas* unit);
- Almost all the supported *External SQL database access* (page 240) (in the *mORMotDB.pas* unit): *SQLite3* (3.7.11 and later), *MySQL*, *PostgreSQL*, *MS SQL Server* (2008 and up), *Oracle*, *Firebird*, *DB2*, *Informix* and *NexusDB* - and since it is implemented at SQL level, it is available for all supported access libraries, e.g. *ODBC*, *OleDB*, *Zeos/ZDBC*, *UniDAC*;
- And, in the *NoSQL* form of "documents array" insertion, for the *MongoDB* database (in the *mORMotMongoDB.pas* unit).

It means that even providers not implementing array binding (like *OleDB*, *ODBC* or *UniDAC*) are able to have a huge boost at data insertion.

SQLite3, *MySQL*, *PostgreSQL*, *MSSQL 2008*, *DB2*, *Informix* and *NexusDB* handle INSERT statements with multiple VALUES, in the following SQL-92 standard syntax, using parameters:

```
INSERT INTO TABLE (column-a, [column-b, ...])
VALUES ('value-1a', ['value-1b', ...]),
      ('value-2a', ['value-2b', ...]),
      ...
```

Oracle implements the weird-but-similar syntax (note the mandatory SELECT at the end):

```
INSERT ALL
  INTO phone_book VALUES ('John Doe', '555-1212')
  INTO phone_book VALUES ('Peter Doe', '555-2323')
SELECT * FROM DUAL;
```

Firebird implements its own syntax:

```
execute block
as
begin
  INSERT INTO phone_book VALUES ('John Doe', '555-1212');
  INSERT INTO phone_book VALUES ('Peter Doe', '555-2323');
end
```

As a result, most engines show a nice speed boost when using the `BatchAdd()` method. See *Data access benchmark* (page 199) for numbers and details.

If you want to use a *map/reduce* algorithm in your application, or the *Unit Of Work pattern* (page 354) - in addition to ORM data access - all those enhancements will speed up a lot your data process. Reading and writing huge amount of data has never been so fast and easy: it is time to replace stored-procedure process by high-level code implemented in your *Domain* service.

12.4. CRUD level cache

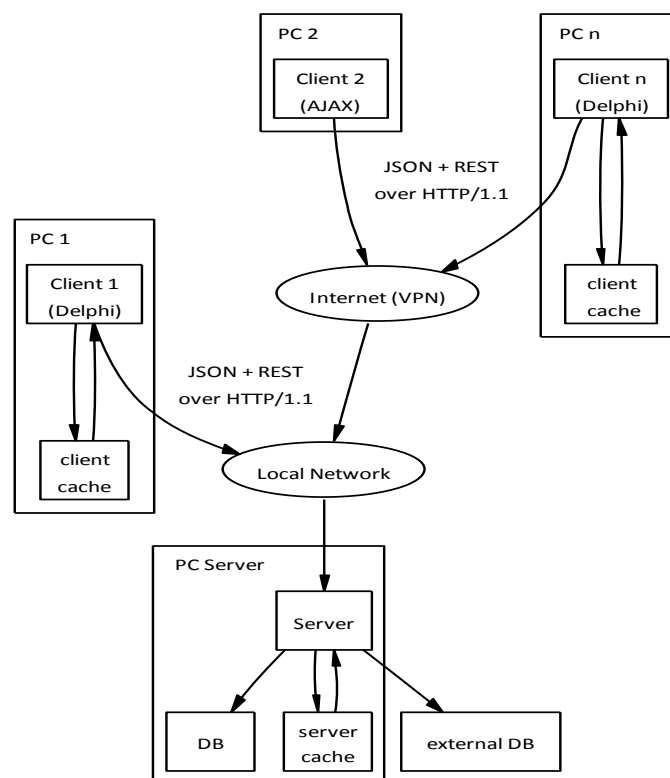

Starting with revision 1.16 of the framework, tuned record cache has been implemented at the CRUD/RESTful level, for specific tables or records, on both the *server* and *client* sides.

See *ORM Cache* (page 174) for the other data cache patterns available in the framework, mainly *JSON global cache* (page 318) at *SQLite3* level, on the server side. All *mORMot*'s data caches are using *JSON* (page 296) as storage format, which was found to be simple and efficient for this purpose.

12.4.1. Where to cache

In fact, a unique caching mechanism is available at the TSQLRest level, for both TSQLRestClient and TSQLRestServer kind of classes. Therefore, *Delphi* clients can have their own cache, and the Server can also have its own cache. A client without any cache (e.g. a rough AJAX client) will take advantage of the server cache, at least.

By default, there is no caching at REST level. Then you can use the TSQLRest.Cache property to tune your cache policy for each TSQLRest instance.

CRUD caching in mORMot

When caching is set *on the server* for a particular record or table, in-memory values could be retrieved from this cache instead of calling the database engine each time. When properly used, this will increase global server responsiveness and allow more clients to be served with the same hardware.

On the client side, a local in-memory cache could be first checked when a record is to be retrieved. If the item is found, the client uses this cached value. If the data item is not in the local cache, the query is then sent to the server, just as usual. Due to the high latency of a remote client-server request,

adding caching on the client side does make sense. Client caching properties can be tuned in order to handle properly remote HTTP access via the Internet, which may be much slower than a local Network.

Our caching implementation is transparent to the CRUD code. The very same usual ORM methods are to be called to access a record (Retrieve Update Add), then either client or server cache will be used, if available. For applications that frequently access the same data - a large category - record-level caching improves both performance and scalability.

12.4.2. When to cache

The main problem with cache is about data that both changes and is accessed simultaneously by multiple clients.

In the current implementation, a "pessimistic" concurrency control is used by our framework, relying on explicit locks, and (ab)use of its *Stateless ORM* (page 315) general design. It is up to the coder to ensure that no major confusion could arise from concurrency issues.

You must tune caching at both Client and Server level - each side will probably require its own set of cache options.

In your project implementation, caching should better not to be used at first, but added on need, when performance and efficiency was found to be required. Adding a cache shall imply having automated regression tests available, since in a Client-Server multi-threaded architecture, *"premature optimization is the root of all evil"* (Donald Knuth).

The main rules may be simply:

- *Not to cache if it may break something relevant* (like a global monetary balance value);
- *Not to cache unless you need to* (see Knuth's wisdom);
- *Ensure that caching is worth it* (if a value is likely to be overridden often, it could be even slower to cache it);
- Test once, test twice, always test and do not forget to test even more.

In practice, caching issues could be difficult to track. So in case of doubt (why was this data not accurate? it sounds like an old revision?), you may immediately disable caching, then ensure that you were not too optimistic about your cache policy.

12.4.3. What to cache

Typical content of these two tuned caches can be any global configuration settings, or any other kind of unchanging data which is not likely to vary often, and is accessed simultaneously by multiple clients, such as catalog information for an on-line retailer.

Another good use of caching is to store data that changes but is accessed by only one client at a time. By setting a cache at the client level for such content, the server won't be called often to retrieve the client-specific data. In such case, the problem of handling concurrent access to the cached data doesn't arise.

Profiling can be necessary to identify which data is to be registered within those caches, either at the client and/or the server side. The logging feature - see below (page 642) - integrated to *mORMot* can be very handy to tune the caching settings, due to its unique customer-side profiling ability.

But most of the time, an human guess at the business logic level is enough to set which data is to be cached on each side, and ensure content coherency.

12.4.4. How to cache

A tuned caching mechanism can be defined, for both `TSQLRestClient` and `TSQLRestServer` classes, at ID level.

By default, REST level cache is disabled, until you call `TSQLRest.Cache`'s `SetCache()` and `SetTimeOut()` methods. Those methods will define the caching policy, able to specify which table(s) or record(s) are to be cached, either at the client or the server level.

Once enabled for a table and a set of IDs on a given table, any further call to `TSQLRest.Retrieve(aClass,aID)` or `TSQLRecord.Create(aRest,aID)` will first attempt to retrieve the `TSQLRecord` of the given `aID` from the internal `TSQLRestCache` instance's in-memory cache, if available.

Note that more complex requests, like queries on other fields than the ID primary key, or JOINed queries, won't be cached at REST level. But such requests may benefit of the *JSON global cache* (page 318), at *SQLite3* level, on the server side.

For instance, here is how the Client-side caching is tested about one individual record:

```
(...)  
Client.Cache.SetCache(TSQLRecordPeople); // cache whole table  
TestOne;  
Client.Cache.Clear; // reset cache settings  
Client.Cache.SetCache(Rec); // cache one record  
// same as Client.Cache.SetCache(TSQLRecordPeople,Rec.ID);  
TestOne;  
(...)  
Database.Cache.SetCache(TSQLRecordPeople); // server-side  
(...)
```

In the above code, `Client.Cache.Clear` is used to reset all cache settings (i.e. not only flush the cache content, but delete all settings previously made with `Cache.SetCache()` or `Cache.SetTimeOut()` calls. So in the above code, a global cache is first enabled for the whole `TSQLRecordPeople` table, then the cache settings are reset, then cache is enabled for only the particular `Rec` record.

To reset the cache content (e.g. if you consider some values may be deprecated), just call the `Cache.Flush` methods (able to flush the in-memory cache for all tables, a given table, or a given record).

It's worth warning once again that it's up to the code responsibility to ensure that these caches are consistent over the network. Server side and client side have their own coherency profile to be ensured. The caching policy has to match your data model, and application use cases.

On the Client side, only local CRUD operations are tracked. According to the stateless design, adding a time out value does definitively make sense, unless the corresponding data is known to be dedicated to this particular client (like a session data). If no time out period is set, it's up to the client to flush its own cache on purpose, by using `TSQLRestClient.Cache.Flush()` methods.

On the Server side, all CRUD operations of the ORM (like `Add / Update / Delete`) will be tracked, and cache will be notified of any data change. But direct SQL statements changing table contents (like a `UPDATE` or a `DELETE` over one or multiple rows with a `WHERE` clause) are not tracked by the current implementation: in such case, you'll have to manually flush the server cache content, to enforce data coherency. If such statements did occur on the server side, `TSQLRestServer.Cache.Flush()` methods are to be called, e.g. in the services which executed the corresponding SQL. If such non-CRUD statements did occur on the client side, it is possible to ensure that the server content is coherent with the client side, via a dedicated `TSQLRestClientURI.ServerCacheFlush()` method, which will call a dedicated standard service on the server to flush its cache content on purpose.

12.4.5. Business logic and API cache

If your implementation follows a good design - see below (page 603) - the high-level logic is encapsulated into business types, and you won't use directly the `TSQLRecord` definitions. Another good practice is to define DTO types - see below (page 601) - probably as *records* or *dynamic arrays*.

The best performance will be achieved if the data is already known by the service, and returned immediately. Even if our ORM is very fast - thanks to its diverse cache levels we just wrote about - it may be hosted in another service, so a network delay may occur. The less communication, the better.

You may consider using *TSynDictionary* (page 111) instances over your business objects, or your DTO objects. You may start with no cache in the business or application layers, but once some bottlenecks are identified - e.g. by carefully looking at the logs generated by the framework below (page 642), defining some *TSynDictionary* instances could help a lot. To release memory, don't forget to setup a proper `TimeOutSeconds` value.

13. Server side SQL/ORM process

Adopt a mORMot

In your developer background and history, you may have been used to write your business code as *stored procedures*, to be executed on the server side.

In short, a *stored procedure* is a way of moving some data-intensive SQL process on the database side. A client will ask for some data to be retrieved or processed on the server, and all actions will be taken on the server: since no data has to be exchanged between the client and the server, such a feature is usually much faster than a pure client-sided solution.

Since *mORMot* is *Client/Server* from the ground up, it features some unique ways of improving data-intensive process on the client or server sides, without necessary relying on proprietary *stored procedures*.

This chapter is worth reading, if you start a new *mORMot* project, and wonder about the architecture of your upcoming applications, or if you are integrating a *mORMot* server in an existing application... in which you or your predecessors may have (ab)used of stored procedures.

It is time to sit down first, and take counsel how your project may be optimized enough to scale and profit.

13.1. Optimize for performance

So, let's do it the *mORMot*'s way.

As we discussed, the main point about *stored procedures* is performance. But they are not magic bullet either: we all have seen slow and endless process in *stored procedures*, almost killing a database server in production. Just as with regular client-side process.

And don't be fooled by performance: *make it right, then make it fast*.

We could make ourself a motto of this Martin Fowler's remark:

One of the first questions people consider with this kind of thing is performance. Personally I don't think performance should be the first question. My philosophy is that most of the time you should focus on writing maintainable code. Then use a profiler to identify hot spots and then replace only those hot spots with faster but less clear code. The main reason I do this is because in most systems only a very small proportion of the code is actually performance critical, and it's much easier to improve the performance of well factored maintainable code.

See <http://www.martinfowler.com/articles/dblogic.html>.. - nice link by the way, if you want to identify some best practice about implementing a persistence layer for our business code.

If you are using a *mORMot* server for the first time, you may be amazed by how most common process will sound just immediate. You can capitalize on the framework optimizations, which are able to unleash the computing power of your hardware, then refine your code only when performance matters.

In order to speed up our data processing, we first have to consider the classic architecture of a *mORMot* application - see *General mORMot architecture - Client Server implementation* (page 82).

A *mORMot* client will have two means of accessing its data:

- Either from CRUD / ORM methods;
- Or via services, most probably *interface-based services* - see below (page 420).

Our optimization goals will therefore be leaded into those two directions.

13.1.1. Profiling your application

If you worry about performance, first reflex may be to enable the framework logging, even on customer sites.

The profiling abilities of the *TSynLog* class, used everywhere in our framework, will allow you to identify the potential bottlenecks of your client applications. See below (page 632) about this feature. From our experiment, we can assure you that the first time you setup *mORMot* advanced logging and profiling on a real application, you may find issues you may never have think of by yourself.

Fight against any duplicated queries, unnecessary returned information (do not forget to specify the fields to be retrieved to your *CreateAndFillPrepare()* request), unattended requests triggered by the User Interface (typically a *TEdit*'s *OnChange* event may benefit of using a *TTimer* before asking for auto-completion)...

Once you have done this cleaning, you may be proud of you, and it may be enough for your customers to enjoy your application. You deserve a coffee or a drink.

13.1.2. Client-side caching

You may have written most of your business logic on the client side, and use CRUD / ORM methods to retrieve the information from your *mORMot* server.

This is perfectly valid, but may be slow, especially if a lot of individual requests are performed over the network, which may be with high latency (e.g. over the Internet).

A new step of optimization, once you did identify your application bottlenecks via profiling, may be to tune your ORM client cache. In fact, there are several layers of caching available in a *mORMot* application. See *CRUD level cache* (page 360) for details about these features.

Marking some tables as potentially cached on the client side may induce a noticeable performance boost, with no need of changing your client code.

13.1.3. Write business logic as Services

A further step of optimization may be to let the business logic be processed on the server side, within a service.

In fact, you will then switch your mind from a classic *Multi-tier architecture* (page 88) to a *Service-Oriented Architecture (SOA)* (page 90).

As a result, your process may take much less time, and you may also be able to benefit from some other optimization tricks, like dedicated caching in your service.

For instance, consider writing your service in *sicShared* mode instead of the default *sicSingle* mode - see below (page 430) - and let some intangible objects be stored as implementation class fields: the next request from a client will not need to load this data from the database, but instead retrieve the information directly from memory, with no latency.

You may also consider using *sicClientDriven* mode, and cache some client-specific information as implementation class fields.

Beside optimization, your code will probably become easier to maintain and scale, when running as services. SOA is indeed a very convenient pattern, and will induce nice side effects, like the ability to switch to multi-platform clients, including mobile or AJAX, since your business logic will stay on the application server.

13.1.4. Using ORM full power

On the server side, your business code, written using CRUD / ORM methods, could be optimized.

First of all, ORM caching may also be used. Any unneeded round-trip to the database - even more with *External SQL database access* (page 240) - could impact your application responsiveness. Then your business logic, written as services, will benefit from it.

Then you may regroup all your database modifications using *BATCH sequences for adding/updating/deleting records* (page 351).

This will offer several benefits:

- Transaction support (nothing is written to the database until *BatchSend* method is executed) similar to the *Unit Of Work pattern* (page 354);
- Faster insertion, update or deletion - via *Array binding* (page 357) and *Optimized SQL for bulk insert* (page 358);
- Perfect integration with the ORM.

In fact, we found out that *Array DML* or *optimized INSERT* could be much faster than a regular *stored procedure*, with individual SQL statements run in a loop.

13.2. Stored procedures

13.2.1. Why to avoid stored procedures

In practice, *stored procedures* have some huge drawbacks:

- Your business logic is tied to the data layout used for storage - and the *Relational Model* is far away from natural language - see below (page 597);
- Debugging is somewhat difficult, since stored procedures will be executed on the database server, far away from your application;
- Each developer will probably need its own database instance to be able to debug its own set of *stored procedures*;
- Project deployment becomes complex, since you have to synchronize your application and database server;
- Cursors and temporary tables, as commonly used in *stored procedures*, may hurt performance;
- They couple you with a particular database engine: you are tied to use *Java*, *C#* or a P/SQL variant to write your business code, then switching from *Oracle* to *PostgreSQL* or *MS SQL* will be error prone, if not impossible;
- They may consume some precious hardware resources on your database server, which may be limited (e.g. proprietary engines like *Oracle* or *MS SQL* will force you to use only one CPU or a limited amount of RAM, unless you need to spend a lot of money to increase your license abilities);
- You will probably have limitations in the virtual environment running in your database engine: deprecated VM or libraries, restricted access to files or network due to security requirements, missing libraries;
- Inefficiency of parameters passing, especially when compared with class OOP programming - you are back to the procedural mode of the 80s;
- Parameters passing will probably result in sub-optimal SQL statements, handling all passed values even if not used;
- Flat design of stored procedures interfaces, far away from the interface segregation principle - see below (page 401);
- Let several versions of your business logic coexist on the same server is a nightmare to maintain;
- Unit testing is made difficult, since you won't be able to mock or stub - see below (page 407) - your *stored procedures* or your data;
- No popular SQL engine does allow *stored procedures* to be written in Delphi, so you won't be able to share code with your other projects;
- If you use an ORM in your main application, you need to manually maintain the table schema used in your stored procedures in synch with your object model - so you are loosing most of ORM benefits;
- What if you want to switch to *NoSQL* storage, or a simple stand-alone version of your application?

We do not want to say, dogmatically, that *stored procedures* are absolute evil. Of course, you are free to use them, even with *mORMot*.

All we wanted to point out is the fact that they are perhaps not the best fit with the design we would like to follow.

13.2.2. Stored procedures, anyway

There may be some cases where this ORM point of view, may be not enough for your project. Do not worry, as usual *mORMot* will allow you to do what you need.

The Server-Side services - see below (page 374) and below (page 420) - appear to be the more RESTful compatible way of implementing a *stored procedure* mechanism in our framework, then consume

them from a *mORMot* client.

According to the current state of our framework, there are several ways of handling such a server-side SQL/ORM process:

- Write your own SQL function to be used in *SQLite3* WHERE statements;
- Low-level dedicated *Delphi* stored procedures;
- External databases stored procedures.

We will discuss those options.

The first two will in fact implement two types of "stored procedure" at SQL level in pure *Delphi* code, making our *SQLite3* kernel as powerful as other Client-Server RDBMS solutions. The latest option may be considered, especially when moving from legacy applications, still relying on stored procedures for their business logic.

13.2.2.1. Custom SQL functions

The *SQLite3* engine defines some standard SQL functions, like `abs()` `min()` `max()` or `upper()`. A complete list is available at http://www.sqlite.org/lang_corefunc.html.

One of the greatest *SQLite3* feature is the ability to define custom SQL functions in high-level language. In fact, its C API allows implementing new functions which may be called within a SQL query. In other database engine, such functions are usually named UDF (for *User Defined Functions*).

Some custom already defined SQL functions are defined by the framework.

You may have to use, on the Server-side:

- Rank used for page ranking in *FTS searches* (page 217);
- Concat to process fast string concatenation;
- Soundex SoundexFR SoundexES for computing the English / French / Spanish soundex value of any text;
- IntegerDynArrayContains, ByteDynArrayContains, WordDynArrayContains, CardinalDynArrayContains, Int64DynArrayContains, CurrencyDynArrayContains, RawUTF8DynArrayContainsCase, RawDynArrayContainsNoCase for direct search inside a BLOB column containing some dynamic array binary content (expecting either an INTEGER or a TEXT search value as 2nd parameter).

Those functions are no part of the *SQLite3* engine, but are available inside our ORM to handle BLOB containing dynamic array properties, as stated in *Dynamic arrays from SQL code* (page 161).

Since you may use such SQL functions in an UPDATE or INSERT SQL statement, you may have an easy way of implementing server-side process of complex data, as such:

```
UPDATE MyTable SET SomeField=0 WHERE IntegerDynArrayContains(IntArrayField,:(10):)
```

13.2.2.1.1. Implementing a function

Let us implement a `CharIndex()` SQL function, defined as such:

```
CharIndex ( SubText, Text [ , StartPos ] )
```

In here, `SubText` is the string of characters to look for in `Text`. `StartPos` indicates the starting index where `charindex()` should start looking for `SubText` in `Text`. Function shall return the position where the match occurred, 0 when no match occurs. Characters are counted from 1, just like in `PosEx()` *Delphi* function.

The SQL function implementation pattern itself is explained in the `sqlite3.create_function_v2()` and `TSQLFunctionFunc`:

- argc is the number of supplied parameters, which are available in argv[] array (you can call ErrorWrongNumberOfArgs(Context) in case of unexpected incoming number of parameters);
- Use sqlite3.value_*(argv[*]) functions to retrieve a parameter value;
- Then set the result value using sqlite3.result_*(Context,*) functions.

Here is typical implementation code of the CharIndex() SQL function, calling the expected low-level *SQLite3* API (note the **cdecl** calling convention, since it is a *SQLite3* / C callback function):

```
procedure InternalSQLFunctionCharIndex(Context: TSQLite3FunctionContext;
  argc: integer; var argv: TSQLite3ValueArray); cdecl;
var StartPos: integer;
begin
  case argc of
    2: StartPos := 1;
    3: begin
        StartPos := sqlite3.value_int64(argv[2]);
        if StartPos <= 0 then
          StartPos := 1;
        end;
      end;
    else begin
        ErrorWrongNumberOfArgs(Context);
        exit;
      end;
  end;
  if (sqlite3.value_type(argv[0])=SQLITE_NULL) or
    (sqlite3.value_type(argv[1])=SQLITE_NULL) then
    sqlite3.result_int64(Context,0) else
    sqlite3.result_int64(Context,SynCommons.PosEx(
      sqlite3.value_text(argv[0]),sqlite3.value_text(argv[1]),StartPos));
  end;
```

This code just get the parameters values using sqlite3.value_*() functions, then call the PosEx() function to return the position of the supplied text, as an INTEGER, using sqlite3.result_int64().

The local StartPos variable is used to check for an optional third parameter to the SQL function, to specify the character index to start searching from.

The special case of a NULL parameter is handled by checking the incoming argument type, calling sqlite3.value_type(argv[]).

13.2.2.1.2. Registering a function

13.2.2.1.2.1. Direct low-level SQLite3 registration

Since we have a InternalSQLFunctionCharIndex() function defined, we may register it with direct *SQLite3* API calls, as such:

```
sqlite3.create_function_v2(Demo.DB,
  'CharIndex',2,SQLITE_ANY,nil,InternalSQLFunctionCharIndex,nil,nil,nil);
sqlite3.create_function_v2(Demo.DB,
  'CharIndex',3,SQLITE_ANY,nil,InternalSQLFunctionCharIndex,nil,nil,nil);
```

The function is registered twice, one time with 2 parameters, then with 3 parameters, to add an overloaded version with the optional StartPos parameter.

13.2.2.1.2.2. Class-driven registration

It is possible to add some custom SQL functions to the *SQLite3* engine itself, by creating a TSQLDataBaseSQLFunction custom class and calling the TSQLDataBase.RegisterSQLFunction method.

The standard way of using this is to override the `TSQLRestServerDB.InitializeEngine` virtual method, calling `DB.RegisterSQLFunction()` with an defined `TSQLDataBaseSQLFunction` custom class.

So instead of calling low-level `sqlite3.create_function_v2()` API, you can declare the `CharIndex` SQL function as such:

```
Demo.RegisterSQLFunction(InternalSQLFunctionCharIndex,2,'CharIndex');
Demo.RegisterSQLFunction(InternalSQLFunctionCharIndex,3,'CharIndex');
```

The two lines above will indeed wrap the following code:

```
Demo.RegisterSQLFunction(TSQLDataBaseSQLFunction.Create(InternalSQLFunctionCharIndex,2,'CharIndex')
));
Demo.RegisterSQLFunction(TSQLDataBaseSQLFunction.Create(InternalSQLFunctionCharIndex,3,'CharIndex')
));
```

The `RegisterSQLFunction()` method is called twice, one time with 2 parameters, then with 3 parameters, to add an overloaded version with the optional `StartPos` parameter, as expected.

13.2.2.1.2.3. Custom class definition

The generic function definition may be completed, in our framework, with a custom class definition, which is handy to have some specific context, not only relative to the current SQL function context, but global and static to the whole application process.

TSQLDataBaseSQLFunction classes hierarchy

For instance, the following method will register a SQL function able to search into a BLOB-stored custom dynamic array type:

```
procedure TSQLDataBase.RegisterSQLFunction(aDynArrayTypeInfo: pointer;
  aCompare: TDynArraySortCompare; const aFunctionName: RawUTF8);
begin
  RegisterSQLFunction(
    TSQLDataBaseSQLFunctionDynArray.Create(aDynArrayTypeInfo,aCompare,aFunctionName));
end;
```

We specify directly the `TSQLDataBaseSQLFunctionDynArray` class instance to work with, which adds two needed protected fields to the `TSQLDataBaseSQLFunction` root class:

- A `fDummyDynArray` `TDynArray` instance which will handle the dynamic array RTTI handling;
- A `fDummyDynArrayValue` pointer, to be used to store the dynamic array reference values to be used during the dynamic array process.

Here is the corresponding class definition:

```
/// to be used to define custom SQL functions for dynamic arrays BLOB search
TSQLDataBaseSQLFunctionDynArray = class(TSQLDataBaseSQLFunction)
```

```
protected
  fDummyDynArray: TDynArray;
  fDummyDynArrayValue: pointer;
public
  /// initialize the corresponding SQL function
  /// - if the function name is not specified, it will be retrieved from the type
  /// information (e.g. TReferenceDynArray will declare 'ReferenceDynArray')
  /// - the SQL function will expect two parameters: the first is the BLOB
  /// field content, and the 2nd is the array element to search (set with
  /// TDynArray.ElemSave() or with BinToBase64WithMagic(aDynArray.ElemSave())
  /// if called via a Client and a JSON prepared parameter)
  /// - you should better use the already existing faster SQL functions
  /// Byte/Word/Integer/Cardinal/Int64/CurrencyDynArrayContains() if possible
  /// (this implementation will allocate each dynamic array into memory before
  /// comparison, and will be therefore slower than those optimized versions)
  constructor Create(aTypeInfo: pointer; aCompare: TDynArraySortCompare;
    const aFunctionName: RawUTF8=''); override;
end;
```

And the constructor implementation:

```
constructor TSQLDataBaseSQLFunctionDynArray.Create(aTypeInfo: pointer;
  aCompare: TDynArraySortCompare; const aFunctionName: RawUTF8);
begin
  fDummyDynArray.Init(aTypeInfo, fDummyDynArrayValue);
  fDummyDynArray.Compare := aCompare;
  inherited Create(InternalSQLFunctionDynArrayBlob, 2, aFunctionName);
end;
```

The InternalSQLFunctionDynArrayBlob function is a low-level *SQLite3* engine SQL function prototype, which will retrieve a BLOB content, then un-serialize it into a dynamic array (using the fDummyDynArrayValue. LoadFrom method), then call the standard ElemLoadFind method to search the supplied element, as such:

```
(...)
with Func.fDummyDynArray do
try
  LoadFrom(DynArray); // temporary allocate all dynamic array content
  try
    if ElemLoadFind(Elem)<0 then
      DynArray := nil;
  finally
    Clear; // release temporary array content in fDummyDynArrayValue
  end;
end;
(...)
```

You can define a similar class in order to implement your own custom SQL function.

Here is how a custom SQL function using this TSQLDataBaseSQLFunctionDynArray class is registered in the supplied unitary tests to an existing database connection:

```
Demo.RegisterSQLFunction(TypeInfo(TIntegerDynArray), SortDynArrayInteger,
  'MyIntegerDynArrayContains');
```

This new SQL function expects two BLOBs arguments, the first being a reference to the BLOB column, and the 2nd the searched value. The function can be called as such (lines extracted from the framework regression tests):

```
aClient.OneFieldValues(TSQLRecordPeopleArray, 'ID',
  FormatUTF8('MyIntegerDynArrayContains(Ints, :("%"))'),
  [BinToBase64WithMagic(@k, sizeof(k))], IDs);
```

Note that since the 2nd parameter is expected to be a BLOB representation of the searched value, the BinToBase64WithMagic function is used to create a BLOB parameter, as expected by the ORM. Here, the element type is an integer, which is a pure binary variable (containing no reference-counted internal fields): so we use direct mapping from its binary in-memory representation; for more complex

element type, you should use the generic `BinToBase64WithMagic(aDynArray.ElemSave())` expression instead, calling `TDynArray.ElemSave` method.

Note that we did not use here the overloaded `OneFieldValues` method expecting '?' bound parameters here, but we may have use it as such:

```
aClient.OneFieldValues(TSQLRecordPeopleArray, 'ID',  
  FormatUTF8('MyIntegerDynArrayContains(Ints,?)',[]),  
  [BinToBase64WithMagic(@k,sizeof(k))],IDs);
```

Since the `MyIntegerDynArrayContains` function will create a temporary dynamic array in memory from each row (stored in `fDummyDynArrayValue`), the dedicated `IntegerDynArrayContains` SQL function is faster.

13.2.2.2. Low-level SQLite3 stored procedure in Delphi

To implement a more complete request, and handle any kind of stored data in a column (for instance, some TEXT format to be parsed), a `TOnSQLStoredProc` event handler can be called for every row of a prepared statement, and is able to access directly to the database request.

This event handler can be specified to the `TSQLRestServerDB.StoredProcExecute()` method.

Be aware that code inside this event handler should not use the ORM methods of the framework, but direct low-level *SQLite3* access (to avoid re-entrance issues).

This will allow direct content modification during the `SELECT` statement. Be aware that, up to now, *Virtual Tables magic* (page 226) `TSQLVirtualTableCursorJSON` cursors are not safe to be used if the *Virtual Table* data is modified.

See the description of the `TOnSQLStoredProc` event handler and associated `StoredProcExecute()` method in the second part of this document.

13.2.2.3. External stored procedure

If the application relies on external databases - see *External SQL database access* (page 240) - the external database may be located on a remote computer.

In such situation, all RESTful Server-sided solutions could produce a lot of network traffic. In fact, custom SQL functions or stored procedures both use the *SQLite3* engine as root component.

In order to speed up the process, you may define some RDMS stored procedures in the external database syntax (P/SQL, .Net, Java or whatever), then define some below (page 373) to launch those functions.

Note that in this case, you'll loose the database independence of the framework, and most of the benefits of using an ORM/ODM - later on, switching to another database engine may become impossible. Such RDBMS stored procedures may be envisaged only during the transition phase of an existing application. *BATCH sequences for adding/updating/deleting records* (page 351) has almost all the speed advantages of stored procedures, with the benefit of a pure object oriented code, easy to debug and maintain.

13.3. Server side Services

Adopt a mORMot

In order to follow a *Service-Oriented Architecture (SOA)* (page 90) design, your application's business logic can be implemented in several ways using *mORMot*:

- Via some *TSQLRecord* inherited classes, inserted into the database *model*, and accessible via some RESTful URI - this is implemented by our ORM architecture - see *Client-Server process* (page 319);
- By some RESTful services, implemented in the Server as *published methods*, and consumed in the Client via native *Delphi* methods;
- Defining some RESTful *service contracts* as standard *Delphi* interface, and then run it seamlessly on both client and client sides.

The first is similar to *RemObject's DataAbstract* product, which allows remote access to database, over several protocols. There are some similarities with *mORMot* (like on-the-fly SQL translation for external databases), but also a whole diverse use case (RAD/components and wizards versus ORM/MVC) and implementation (*mORMot* takes advantages of the *SQLite3* SQL core and is much more optimized for speed and scaling).

If you paid for a *Delphi Architect* edition, the first two items can be compared to the *DataSnap* Client-Server features. Since *Delphi 2010*, you can in fact define JSON-based RESTful services, in addition to the original *DCOM/DBExpress* remote data broker. It makes uses of the new RTTI available since *Delphi 2010*, but it has some known stability and performance issues, and lack of strong security. It is also RAD/Wizard based, whereas *mORMot* uses a code approach.

The last item is purely interface-based, so matches the "designed by contract" principle - see below (page 390) - as implemented by Microsoft's WCF technology - see below (page 479). We included most of the nice features made available in WCF in *mORMot*, in a *KISS convention over configuration* manner.

So *mORMot* is quite unique, in the fact that it features, in one unique code base, all three ways of implementing a SOA application. And it is an Open Source project, existing since years - you won't be stucked with proprietary code nor licenses. You can move your existing code base into a *Domain-Driven Design*, on your management pace (and money), without the need of upgrading to the latest version of the IDE.

14. Client-Server services via methods

Adopt a mORMot

To implement a service in the *Synapse mORMot framework*, the first method is to define published method Server-side, then use easy functions about JSON or URL-parameters to get the request encoded and decoded as expected, on Client-side.

We'll implement the same example as in the official Embarcadero docwiki page above. Add two numbers. Very useful service, isn't it?

14.1. Publishing a service on the server

On the server side, we need to customize the standard `TSQLRestServer` class definition (more precisely a `TSQLRestServerDB` class which includes a *SQLite3* engine, or a lighter `TSQLRestServerFullMemory` kind of server, which is enough for our purpose), by adding a new published method:

```
type
  TSQLRestServerTest = class(TSQLRestServerFullMemory)
    (...)
    published
      procedure Sum(Ctxt: TSQLRestServerURIContext);
    end;
```

The method name ("Sum") will be used for the URI encoding, and will be called remotely from *ModelRoot/Sum* URL. The *ModelRoot* is the one defined in the Root parameter of the *model* used by the application.

This method, like all Server-side methods, MUST have the same exact parameter definition as in the `TSQLRestServerCallback` prototype, i.e. only one `Ctxt` parameter, which refers to the whole

execution context:

```
type
  TSQLRestServerCallBack = procedure(Ctxt: TSQLRestServerURIContext) of object;
```

Then we implement this method:

```
procedure TSQLRestServerTest.Sum(Ctxt: TSQLRestServerURIContext);
begin
  Ctxt.Results([Ctxt['a']+Ctxt['b']]);
end;
```

The Ctxt variable publish some properties named InputInt[] InputDouble[] InputUTF8[] and Input[] able to retrieve directly a parameter value from its name, respectively as Integer/Int64, double, RawUTF8 or variant. The Ctxt.Input[] array property, returning variant values, has been defined as default array property for the TSQLRestServerURIContext class, so writing Ctxt['a'] is the same as writing Ctxt.Input['a'].

Therefore, the code above using Ctxt[] or Ctxt.Input[] will introduce a conversion via a variant, which may be a bit slower, and in case of string content, may loose some content for older non Unicode versions of *Delphi*. So it is a good idea to use the exact expected Input*[] property corresponding to your value type. It does make sense even more when handling text, i.e. InputUTF8[] is to be used in such case. For our floating-point computation method, we may have coded it as such:

Those methods will raise an EParsingException exception if the parameter is not available at the URI. So you may want to use InputExists[] or even InputIntOrVoid[] InputDoubleOrVoid[] InputUTF8OrVoid[] InputOrVoid[] methods, which won't raise any exception but return a void value (i.e. either 0, "" or Unassigned).

```
procedure TSQLRestServerTest.Sum(Ctxt: TSQLRestServerURIContext);
begin
  with Ctxt do
    Results([InputDouble['a']+InputDouble['b']]);
end;
```

The Ctxt.Results([]) method is used to return the service value as one JSON object with one "Result" member, with default MIME-type JSON_CONTENT_TYPE.

For instance, the following request URI:

```
GET /root/Sum?a=3.12&b=4.2
```

will let our server method return the following JSON object:

```
{"Result":7.32}
```

That is, a perfectly AJAX-friendly request.

Note that all parameters are expected to be plain case-insensitive 'A'..'Z', '0'..'9' characters.

An *important point* is to remember that the implementation of the callback method **must be thread-safe** - as stated by *Thread-safety* (page 336) and *Safe locks for multi-thread applications* (page 123). In fact, the TSQLRestServer.URI method expects such callbacks to handle the thread-safety on their side. It's perhaps some more work to handle a *critical section* in the implementation, but, in practice, it's the best way to achieve performance and scalability: the resource locking can be made at the tiniest code level.

14.2. Defining the client

The client-side is implemented by calling some dedicated methods, and providing the service name ('sum') and its associated parameters:

```
function Sum(aClient: TSQLRestClientURI; a, b: double): double;
var err: integer;
begin
  val(aClient.CallBackGetResult('sum', ['a', a, 'b', b]), Result, err);
end;
```

You could even implement this method in a dedicated client method - which make sense:

```
type
  TMyClient = class(TSQLHttpClient) // could be TSQLRestClientURINamedPipe
  (...)
  function Sum(a, b: double): double;
  (...)
end;

function TMyClient.Sum(a, b: double): double;
var err: integer;
begin
  val(CallBackGetResult('sum', ['a', a, 'b', b]), Result, err);
end;
```

This later implementation is to be preferred on real applications.

You have to create the server instance, and the corresponding TSQLRestClientURI (or TMyClient), with the same database model, just as usual...

On the Client side, you can use the CallBackGetResult method to call the service from its name and its expected parameters, or create your own caller using the UriEncode() function. Note that you can specify most class instance into its JSON representation by using some TObject into the method arguments:

```
function TMyClient.SumMyObject(a, b: TObject): double;
var err: integer;
begin
  val(CallBackGetResult('summyobject', ['a', a, 'b', b]), Result, err);
end;
```

This Client-Server protocol uses JSON here, as encoded server-side via Ctxt.Results() method, but you can serve any kind of data, binary, HTML, whatever... just by overriding the content type on the server with Ctxt>Returns().

14.3. Direct parameter marshalling on server side

We have used above the `Ctxt[]` and `Ctxt.Input*[]` properties to retrieve the input parameters. This is pretty easy to use and powerful, but the supplied `Ctxt` gives full access to the input and output context.

Here is how we may implement the fastest possible parameters parsing - see sample `Project06Server.dpr`:

```
procedure TSQLRestServerTest.Sum(Ctxt: TSQLRestServerURIContext);
var a,b: double;
begin
  if UrlDecodeNeedParameters(Ctxt.Parameters, 'A,B') then begin
    while Ctxt.Parameters<>nil do begin
      UrlDecodeDouble(Ctxt.Parameters, 'A=', a);
      UrlDecodeDouble(Ctxt.Parameters, 'B=', b, @Ctxt.Parameters);
    end;
    Ctxt.Results([a+b]);
  end else
    Ctxt.Error('Missing Parameter');
end;
```

The only not obvious part of this code is the parameters marshalling, i.e. how the values are retrieved from the incoming `Ctxt.Parameters` text buffer, then converted into native local variables.

On the Server side, typical implementation steps are therefore:

- Use the `UrlDecodeNeedParameters` function to check that all expected parameters were supplied by the caller in `Ctxt.Parameters`;
- Call `UrlDecodeInteger` / `UrlDecodeInt64` / `UrlDecodeDouble` / `UrlDecodeExtended` / `UrlDecodeValue` / `UrlDecodeObject` functions (all defined in `SynCommons.pas`) to retrieve each individual parameter from standard JSON content;
- Implement the service (here it is just the `a+b` expression);
- Then return the result calling `Ctxt.Results()` method or `Ctxt.Error()` in case of any error.

The powerful `UrlDecodeObject` function (defined in `mORMot.pas`) can be used to un-serialize most class instance from its textual JSON representation (`TPersistent`, `TSQLRecord`, `TStringList`...).

Using `Ctxt.Results()` will encode the specified values as a JSON object with one "Result" member, with default mime-type `JSON_CONTENT_TYPE`:

```
{"Result": "OneValue"}
```

or a JSON object containing an array:

```
{"Result": ["One", "two"]}
```

14.4. Returns non-JSON content

Using `Ctxt.Returns()` will let the method return the content in any format, e.g. as a JSON object (via the overloaded `Ctxt.Returns([])` method expecting field name/value pairs), or any content, since the returned MIME-type can be defined as a parameter to `Ctxt.Returns()` - it may be useful to specify another mime-type than the default constant `JSON_CONTENT_TYPE`, i.e. 'application/json; charset=UTF-8', and returns plain text, HTML or binary.

For instance, you can return directly a value as plain text:

```
procedure TSQLRestServer.Timestamp(Ctxt: TSQLRestServerURIContext);
begin
  Ctxt.Returns(Int64ToUtf8(ServerTimestamp),HTTP_SUCCESS,TEXT_CONTENT_TYPE_HEADER);
end;
```

Or you can return some binary file, retrieving the corresponding MIME type from its binary content:

```
procedure TSQLRestServer.GetFile(Ctxt: TSQLRestServerURIContext);
var fileName: TFileName;
    content: RawByteString;
    contentType: RawUTF8;
begin
  fileName := 'c:\data\' + ExtractFileName(Ctxt['filename']); // or Ctxt.Input['filename']
  content := StringFromFile(fileName);
  if content='' then
    Ctxt.Error('',HTTP_NOTFOUND) else
    Ctxt.Returns(content,HTTP_SUCCESS,HEADER_CONTENT_TYPE+
      GetMimeContentType(pointer(content),Length(content),fileName));
end;
```

The corresponding client method may be defined as such:

```
function TMyClient.GetFile(const aFileName: RawUTF8): RawByteString;
begin
  if CallbackGet('GetFile',['filename',aFileName],RawUTF8(result))<>HTTP_SUCCESS then
    raise Exception.CreateFmt('Impossible to get file: %s',[result]);
end;
```

Note that the `Ctxt.ReturnFile()` method - see below (page 380) - is preferred than manual file retrieval as implemented in this `TSQLRestServer.GetFile()` method. It is shown here for demonstration purposes only.

If you use HTTP as communication protocol, you can consume these services, implemented Server-Side in fast *Delphi* code, with any AJAX application on the client side.

Using `GetMimeContentType()` when sending non JSON content (e.g. picture, pdf file, binary...) will be interpreted as expected by any standard Internet browser: it could be used to serve some good old HTML content within a page, not necessary consume the service via *JavaScript*.

14.5. Advanced process on server side

On server side, method definition has only one `Ctxt` parameter, which has several members at calling time, and publish all service calling features and context, including *RESTful* URI routing, session handling or low-level HTTP headers (if any).

At first, `Ctxt` may indicate the expected `TSQLRecord` ID and `TSQLRecord` class, as decoded from *RESTful* URI. It means that a service can be related to any table/class of our ORM framework, so you will be able to create easily any *RESTful* compatible requests on URI like `ModelRoot/TableName/TableID/MethodName`. The ID of the corresponding record is decoded from its *RESTful* scheme into `Ctxt.TableID`, and the table is available in `Ctxt.Table` or `Ctxt.TableIndex` (if you need its index in the associated server `Model`).

For example, here we return a BLOB field content as hexadecimal, according to its `TableName/TableID`:

```
procedure TSQLRestServerTest.DataAsHex(Ctxt: TSQLRestServerURIContext);
var aData: TSQLRawBlob;
begin
  if (self=nil) or (Ctxt.Table<>TSQLRecordPeople) or (Ctxt.TableID<=0) then
    Ctxt.Error('Need a valid record and its ID') else
    if RetrieveBlob(TSQLRecordPeople,Ctxt.TableID,'Data',aData) then
      Ctxt.Results([SynCommons.BinToHex(aData)]) else
      Ctxt.Error('Impossible to retrieve the Data BLOB field');
end;
```

A corresponding client method may be:

```
function TSQLRecordPeople.DataAsHex(aClient: TSQLRestClientURI): RawUTF8;
begin
  Result := aClient.CallBackGetResult('DataAsHex',[],RecordClass,fID);
end;
```

If authentication - see below (page 547) - is used, the current session, user and group IDs are available in `Session / SessionUser / SessionGroup` fields. If authentication is not available, those fields are meaningless: in fact, `Ctxt.Context.Session` will contain either 0 (`CONST_AUTHENTICATION_SESSION_NOT_STARTED`) if any session is not yet started, or 1 (`CONST_AUTHENTICATION_NOT_USED`) if authentication mode is not active. Server-side implementation can use the `TSQLRestServer.SessionGetUser` method to retrieve the corresponding user details (note that when using this method, the returned `TSQLAuthUser` instance is a local thread-safe copy which shall be freed when done).

In `Ctxt.Call^` member, you can access low-level communication content, i.e. all incoming and outgoing values, including headers and message body. Depending on the transmission protocol used, you can retrieve e.g. HTTP header information. For instance, here is how you may access the client remote IP address and application User-Agent, at lowest level:

```
aRemoteIP := FindIniNameValue(pointer(Ctxt.Call.InHead), 'REMOTEIP: ');
aUserAgent := FindIniNameValue(pointer(Ctxt.Call.InHead), 'USER-AGENT: ');
```

Of course, for those fields, it is much preferred to use the `Ctxt.RemoteIP` or `Ctxt.UserAgent` properties, which use an efficient cache.

14.6. Browser speed-up for unmodified requests

When used over a slow network (e.g. over the Internet), you can set the optional `Handle304NotModified` parameter of both `Ctxt>Returns()` and `Ctxt.Results()` methods to return the response body only if it has changed since last time.

In practice, result content will be hashed (using `crc32c` algorithm, and fast SSE4.2 hardware instruction, if available) and in case of no modification will return "*304 Not Modified*" status to the browser, without the actual result content. Therefore, the response will be transmitted and received much faster, and will save a lot of bandwidth, especially in case of periodic server pooling (e.g. for client screen refresh).

Note that in case of hash collision of the `crc32c` algorithm (we never did see it happen, but such a mathematical possibility exists), a false positive "not modified" status may be returned; this option is therefore unset by default, and should be enabled only if your client does not handle any sensitive accounting process, for instance.

Be aware that you should *disable authentication* for the methods using this `Handle304NotModified` parameter, via a `TSQLRestServer.ServiceMethodByPassAuthentication()` call. In fact, our RESTful authentication - see below (page 547) - uses a per-URI signature, which change very often (to avoid men-in-the-middle attacks). Therefore, any browser-side caching benefit will be voided if authentication is used: browser internal cache will tend to grow for nothing since the previous URIs are deprecated, and it will be a cache-miss most of the time. But when serving some static content (e.g. HTML content, fixed JSON values or even UI binaries), this browser-side caching can be very useful.

This stateless *REST* (page 312) model will enable several levels of caching, even using an external *Content Delivery Network* (CDN) service. See below (page 543) for some potential hosting architectures, which may let your *mORMot* server scale to thousands of concurrent users, served around the world with the best responsiveness.

14.7. Returning file content

Framework's HTTP server is able to handle returning a file as response to a method-based service. The *High-performance http.sys server* (page 327) is even able to serve the file content asynchronously from kernel mode, with outstanding performance.

You can use the `Ctxt.ReturnFile()` method to return a file directly.

This method is also able to guess the MIME type from the file extension, and handle `HTTP_NOTMODIFIED = 304` process, if `Handle304NotModified` parameter is true, using the file time stamp.

Another possibility may be to use the `Ctxt.ReturnFileFromFolder()` method, which is able to efficiently return any file specified by its URI, from a local folder. It may be very handy to

return some static web content from a *mORMot* HTTP server.

14.8. JSON Web Tokens (JWT)

JSON Web Token (JWT) is an open standard (*RFC 7519*) that defines a compact and self-contained way for securely transmitting information between parties as a JSON object. This information can be verified and trusted because it is digitally signed. JWTs can be signed using a secret (with the HMAC

algorithm) or a public/private key pair using RSA or ECDSA.

They can be used for:

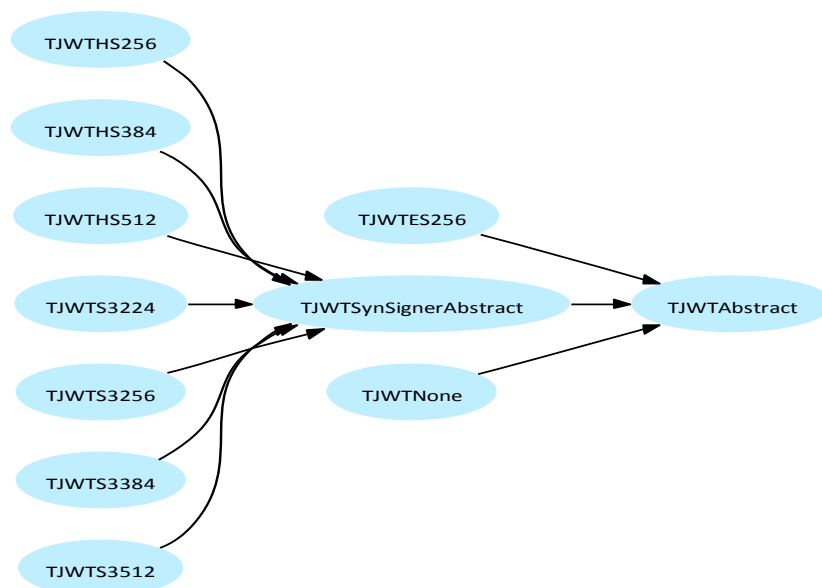

- Authentication: including a JWT to any HTTP request allows *Single Sign On* user validation across different domains;
- Secure Information Exchange: a small amount of data can be stored in the JWT payload, and is digitally signed to ensure its provenance and integrity.

See <http://jwt.io..> for an introduction to *JSON Web Tokens*.

Our framework implements JWT:

- "HS256/384/512" (HMAC-SHA2-256/384/512), "ES256" (256-bit ECDSA) standard algorithms, and "S3256/384/512" (for non-yet-standard SHA3-256/384/512) - with the addition of the "none" weak algo, to be used with caution;
- Computes and validates all JWT *claims*: dates, audiences, JWT ID;
- Thread-safe and high performance (2 us for a HS256 verification under x64), with optional in-memory cache if needed (e.g. for slower ES256);
- Stand-alone and cross-platform code: no external dll, works with Delphi or FPC;
- Enhanced security - it is by design immune from <https://auth0.com/blog/2015/03/31/critical-vulnerabilities-in-json-web-token-libraries..>
- Full integration with the framework.

It is architected around a set of classes, one per algorithm, following the least astonishment principle, and enhancing security:

TJWTAbstract classes hierarchy

In SynCrypto.pas and SynEcc.pas, you will find:

- TJWTAbstract as abstract parent class for implementing JSON Web Tokens;
- TJWTNone implementing the "none" algorithm;
- TJWTHS256 TJWTHS384 TJWTHS512 implementing the "HS256 HS384 HS512" algorithms, i.e. HMAC-SHA2 over 256, 384 or 512 bits;
- TJWTS3256 TJWTS3384 TJWTS3512 implementing the "S3256 S3384 S3512" algorithms, i.e. SHA3 over 256, 384 or 512 bits;
- TJWTES256 implementing the "ES256" algorithm, i.e. ECDSA using the P-256 curve and the SHA-256

hash algorithm.

To work with JWT, you may write for instance:

```
var j: TJWTAbstract;
    jwt: TJWTContent;
...
j := TJWTHS256.Create('secret',0,[jrcSubject],[]);
try
  j.Verify('eyJhbGciOiJIUzI1NiIsInR5cCI6IkpXVCJ9.eyJzdWIiOiIxMjM0NTY3ODkwIiwibm' +
    'FtZSI6IkpvaG4gRG9lIiwiaWVhYXRtaW4iOiOnRydWV9.TjVA95OrM7E2cBab30RMHrHDcEfxjoYZgeF' +
    'ONFh7HgQ',jwt); // reference from jwt.io
  check(jwt.result=jwtValid);
  check(jwt.reg[jrcSubject]='1234567890');
  check(jwt.data.U['name']='John Doe');
  check(jwt.data.B['admin']);
finally
  j.Free;
end;
```

The 'eyJhbGciOiJIUzI1NiIsInR5cCI6IkpXVCJ9.eyJzdWIiOiIxMjM0NTY3ODkwIiwibm' token contains in fact the following, once *base-64* decoded:

- header: {"alg":"HS256","typ":"JWT"}
- payload: {"sub":"1234567890","name":"John Doe","admin":true}
- signature: HMACSHA256(base64UrlEncode(header) + "." + base64UrlEncode(payload), "secret")

The TJWTAbstract classes implement the logic from supplied security parameters about a given set of JWT, then you can use TJWTAbstract.Verify to decode and check the payload and signature of a JWT into a TJWTContent local variable. As you can see, TJWTContent.result contains the decoding status, TJWTContent.reg[] the decoded claims, and TJWTContent.data is a *TDocVariant custom variant type* (page 112) giving access to any stored private information.

It has a built-in support of JWT *claims* when tokens are generated, so you can write:

```
j := TJWTHS256.Create('sec',10,[jrcIssuer,jrcExpirationTime,jrcIssuedAt,jrcJWTID],[],60);
token := j.Compute(['http://example.com/is_root',true], 'joe');
```

Now, the token variable contains e.g. as signed payload:

```
{"http://example.com/is_root":true,"iss":"joe","iat":1482177879,"exp":1482181479,"jti":"1496DCE0676925DD33BB5A81"}
```

The issuer has been encoded as an expected "iss": field, "iat" and "exp" fields contain the issuing and expiration timestamps, and "jti" has been filled with an obfuscated TSynUniqueIdentifier as JWT ID. Since we use a TJWTHS256 class, HMAC-SHA256 digital signature of the header and payload has then been appended - with a secret safely derived from 'sec' passphrase using 10 rounds of a PBKDF2_HMAC_SHA256 derivation (in practice, you may use a much higher number like 20,000).

Then you can decode such a token, and access its payload in a single method:

```
j.Verify(token,jwt);
assert(jwt.result=jwtValid);
assert(jwt.reg[jrcIssuer]='joe');
```

Integration with method-based services is easy, using TSQLRestServerURIContext.AuthenticationCheck method:

```
TMyDaemon = class(...)
protected
  fJWT: TJWTAbstract;
  ....
procedure TMyDaemon.Files(Ctxt: TSQLRestServerURIContext);
begin
  if Ctxt.AuthenticationCheck(fJWT)=jwtValid then
```

```
Ctxt.ReturnFileFromFolder('c:\datafolder');  
end;
```

The above method will define a method-based service returning the content of a local folder, only if a valid JWT is supplied within the HTTP headers of the incoming request. If `AuthenticationCheck` fails to validate the token supplied in the associated `Ctxt`, it will return 401 `HTTP_UNAUTHORIZED` to the client, as expected.

An alternative to use JWT for authentication may be to assign a `TJWTAbstract` inherited instance to `TSQLRestServer.JWTForUnauthenticatedRequest` - see below (page 558).

14.9. Handling errors

When using `Ctxt.Input*[]` properties, any missing parameter will raise an `EParsingException`. It will therefore be intercepted by the server process (as any other exception), and returned to the client with an error message containing the Exception class name and its associated message.

But you can have full access to the error workflow, if needed. In fact, calling either `Ctxt.Results()`, `Ctxt.Returns()`, `Ctxt.Success()` or `Ctxt.Error()` will specify the HTTP status code (e.g. 200 / "OK" for `Results()` and `Success()` methods by default, or 400 / "Bad Request" for `Error()`) as an integer value. For instance, here is how a service not returning any content can handle those status/error codes:

```
procedure TSQLRestServer.Batch(Ctxt: TSQLRestServerURIContext);
begin
  if (Ctxt.Method=mPUT) and RunBatch(nil,nil,Ctxt) then
    Ctxt.Success else
    Ctxt.Error;
end;
```

In case of an error on the server side, you may call `Ctxt.Error()` method (only the two valid status codes are 200 and 201).

The `Ctxt.Error()` method has an optional parameter to specify a custom error message in plain English, which will be returned to the client in case of an invalid status code. If no custom text is specified, the framework will return the corresponding generic HTTP status text (e.g. "Bad Request" for default status code `HTTP_BADREQUEST = 400`).

In this case, the client will receive a corresponding serialized JSON error object, e.g. for `Ctxt.Error('Missing Parameter',HTTP_NOTFOUND)`:

```
{
  "ErrorCode":404,
  "ErrorText":"Missing Parameter"
}
```

If called from an AJAX client, or a browser, this content should be easy to interpret.

Note that the framework core will catch any exception during the method execution, and will return a "Internal Server Error" / `HTTP_SERVERERROR = 500` error code with the associated textual exception details.

14.10. Benefits and limitations of this implementation

Method-based services allow fast and direct access to all mORMot Client-Server RESTful features, over all usual protocols of our framework: HTTP/1.1, Named Pipe, Windows Messages, direct in-memory/in-process access.

The *mORMot* implementation of method-based services gives full access to the lowest-level of the framework core, so it has some advantages:

- It can be tuned to fit any purpose (such as retrieving or returning some HTML or binary data, or modifying the HTTP headers on the fly);
- It is integrated into the RESTful URI model, so it can be related to any table/class of our ORM framework (like DataAsHex service above), or it can handle any remote query (e.g. any AJAX or SOAP requests);
- It has a very low performance overhead, so can be used to reduce server workload for some common tasks.

Note that due to this implementation pattern, the *mORMot* service implementation is very fast, and not sensitive to the "Hash collision attack" security issue, as reported with *Apache* - see <http://blog.synapse.info/post/2011/12/30/Hash-collision-attack..> for details.

But with this implementation, a lot of process (e.g. parameter marshalling) is to be done by hand on both client and server side code. In addition, building and maintaining a huge SOA system with a "method by method" approach could be difficult, since it publishes one big "flat" set of services. This is where interfaces enter the scene.

15. Interfaces

Adopt a mORMot

15.1. Delphi and interfaces

15.1.1. Declaring an interface

No, interface(-book) is not another social network, sorry.

In *Delphi* OOP model, an interface defines a type that comprises abstract virtual methods. The short, easy definition is that an interface is a declaration of functionality without an implementation of that functionality. It defines "what" is available, not "how" it is made available. This is the so called "abstraction" benefit of interfaces (there are another benefits, like orthogonality of interfaces to classes, but we'll see it later).

In *Delphi*, we can declare an interface like so:

```
type
  ICalculator = interface(IInvokable)
    ['{9A60C8ED-CEB2-4E09-87D4-4A16F496E5FE}']
    /// add two signed 32-bit integers
    function Add(n1,n2: integer): integer;
  end;
```

It just sounds like a class definition, but, as you can see:

- It is named *ICalculator*, and not *TCalculator*: it is a common convention to start an interface name with a *I*, to make a difference with a *T* for a class or other implementation-level type definition;
- There is no visibility attribute (no *private* / *protected* / *public* / *published* keywords): in fact, it is just as if all methods were published;
- There is no fields, just methods (fields are part of the implementation, not of the interface): in fact, you can have properties in your interface definition, but those properties shall redirect to existing

- getter and setter methods, via read and write keywords;
- There is a strange number below the interface name, called a GUID: this is an unique identifier of the interface - you can create such a genuine constant on the editor cursor position by pressing Ctrl + Shift + G in the *Delphi* IDE;
 - But the methods are just defined as usual.

15.1.2. Implementing an interface with a class

Now that we have an interface, we need to create an implementation.

Our interface is very basic, so we may implement it like this:

```
type
  TServiceCalculator = class(TInterfacedObject, ICalculator)
  protected
    fBulk: string;
  public
    function Add(n1,n2: integer): integer;
    procedure SetBulk(const aValue: string);
  end;

function TServiceCalculator.Add(n1, n2: integer): integer;
begin
  result := n1+n2;
end;

procedure TServiceCalculator.SetBulk(const aValue: string);
begin
  fBulk := aValue;
end;
```

You can note the following:

- We added ICalculator name to the class() definition: this class inherits from TInterfacedObject, and implements the ICalculator interface;
- Here we have protected and public keywords - but the Add method can have any visibility, from the interface point of view: it will be used as implementation of an interface, even if the method is declared as private in the implementation class;
- There is a SetBulk method which is not part of the ICalculator definition - so we can add other methods to the implementation class, and we can even implement several interfaces within the same method (just add other interface names after like class(TInterfacedObject, ICalculator, IAnotherInterface);
- There a fBulk protected field member within this class definition, which is not used either, but could be used for the class implementation.
- Here we have to code an implementation for the TServiceCalculator.Add() method (otherwise the compiler will complain for a missing method), whereas there is no implementation expected for the ICalculator.Add method - it is perfectly "abstract".

15.1.3. Using an interface

Now we have two ways of using our TServiceCalculator class:

- The classic way;
- The abstract way (using an interface).

The "classic" way, using an explicit class instance:

```
function MyAdd(a,b: integer): integer;
var Calculator: TServiceCalculator;
```

```
begin
  Calculator := TServiceCalculator.Create;
  try
    result := Calculator.Add(a,b);
  finally
    Calculator.Free;
  end;
end;
```

Note that we used a try..finally block to protect the instance memory resource.

Then we can use an interface:

```
function MyAdd(a,b: integer): integer;
var Calculator: ICalculator;
begin
  Calculator := TServiceCalculator.Create;
  result := Calculator.Add(a,b);
end;
```

What's up over there?

- We defined the local variable as ICalculator: so it will be an interface, not a regular class instance;
- We assigned a TServiceCalculator instance to this interface variable: the variable will now handle the instance life time;
- We called the method just as usual - in fact, the computation is performed with the same exact expression: result := Calculator.Add(a,b);
- We do not need any try...finally block here: in *Delphi*, interface variables are *reference-counted*: that is, the use of the interface is tracked by the compiler and the implementing instance, once created, is automatically freed when the compiler realizes that the number of references to a given interface variable is zero;
- And the performance cost is negligible: this is more or less the same as calling a virtual method (just one more redirection level).

In fact, the compiler creates an hidden try...finally block in the MyAdd function, and the instance will be released as soon as the Calculator variable is out of scope. The generated code could look like this:

```
function MyAdd(a,b: integer): integer;
var Calculator: TServiceCalculator;
begin
  Calculator := TServiceCalculator.Create;
  try
    Calculator.FRefCount := 1;
    result := Calculator.Add(a,b);
  finally
    dec(Calculator.FRefCount);
    if Calculator.FRefCount=0 then
      Calculator.Free;
    end;
  end;
end;
```

Of course, this is a bit more optimized than this (and thread-safe), but you have got the idea.

15.1.4. There is more than one way to do it

One benefit of interfaces we have already told about, is that it is "orthogonal" to the implementation.

In fact, we can create another implementation class, and use the same interface:

```
type
  TOtherServiceCalculator = class(TInterfacedObject, ICalculator)
```

```
protected
function Add(n1,n2: integer): integer;
end;

function TOtherServiceCalculator.Add(n1, n2: integer): integer;
begin
  result := n2+n1;
end;
```

Here the computation is not the same: we use $n2+n1$ instead of $n1+n2$... of course, this will result into the same value, but we can use this another method for our very same interface, by using its `TOtherServiceCalculator` class name:

```
function MyOtherAdd(a,b: integer): integer;
var Calculator: ICalculator;
begin
  Calculator := TOtherServiceCalculator.Create;
  result := Calculator.Add(a,b);
end;
```

15.1.5. Here comes the magic

Now you may begin to see the point of using interfaces in a client-server framework like ours.

Our *mORMot* is able to use the same interface definition on both client and server side, calling all expected methods on both sides, but having all the implementation logic on the server side. The client application will transmit method calls (using JSON instead of much more complicated XML/SOAP) to the server (using a "fake" implementation class created on the fly by the framework), then the execution will take place on the server (with obvious benefits), and the result will be sent back to the client, as JSON. The same interface can be used on the server side, and in this case, execution will be in-place, so very fast.

By creating a whole bunch of interfaces for implementing the business logic of your project, you will benefit of an open and powerful implementation pattern.

More on this later on... first we'll take a look at good principles of playing with interfaces.

15.2. SOLID design principles

The acronym SOLID is derived from the following OOP principles (quoted from the corresponding *Wikipedia* article):

- *Single responsibility principle*: the notion that an object should have only a single responsibility;
- *Open/closed principle*: the notion that "software entities ... should be open for extension, but closed for modification";
- *Liskov substitution principle*: the notion that "objects in a program should be replaceable with instances of their subtypes without altering the correctness of that program" - also named as "design by contract";
- *Interface segregation principle*: the notion that "many client specific interfaces are better than one general purpose interface.";
- *Dependency inversion principle*: the notion that one should "Depend upon Abstractions. Do not depend upon concretions.". *Dependency injection* is one method of following this principle, which is also called *Inversion Of Control* (aka IoC).

If you have some programming skills, those principles are general statements you may already found out by yourself. If you start doing serious object-oriented coding, those principles are best-practice guidelines you will definitively gain following.

They certainly help to fight the three main code weaknesses:

- *Rigidity*: Hard to change something because every change affects too many other parts of the system;
- *Fragility*: When you make a change, unexpected parts of the system break;
- *Immobility*: Hard to reuse in another application because it cannot be disentangled from the current application.

15.2.1. Single Responsibility Principle

When you define a class, it shall be designed to implement only one feature. The so-called feature can be seen as an "*axis of change*" or a "*a reason for change*".

Therefore:

- One class shall have only one reason that justifies changing its implementation;
- Classes shall have few dependencies on other classes;
- Classes shall be abstract from the particular layer they are running - see *Multi-tier architecture* (page 88).

For instance, a `TRectangle` object should not have both `ComputeArea` and `Draw` methods defined at once - they will define two responsibilities or axis of change: the first responsibility is to provide a mathematical model of a rectangle, and the second is to render it on GUI.

15.2.1.1. Splitting classes

To take an example from real coding, imagine you define a communication component. You want to communicate, say, with a bar-code scanner peripheral. You may define a single class, e.g. `TBarcodeScanner`, supporting such device connected over a serial port. Later on, the manufacturer deprecates the serial port support, since no computer still have it, and offer only USB models in its catalog. You may inherit from `TBarcodeScanner`, and add USB support.

SOLID Principles - Single Responsibility: Single-to-rule-them-all class

But in practice, this new TUsbBarCodeScanner class is difficult to maintain, since it will inherit from serial-related communication.

So you start splitting the class hierarchy, using an *abstract* parent class:

SOLID Principles - Single Responsibility: Abstract parent class

We may define some `virtual` abstract methods, which will be overridden in inherited classes:

```

type
  TAbstractBarcodeScanner = class(TComponent)
  protected
    function ReadChar: byte; virtual; abstract;
    function ReadFrame: TProtocolFrame; virtual; abstract;
    procedure WriteChar(aChar: byte); virtual; abstract;
    procedure WriteFrame(const aFrame: TProtocolFrame); virtual; abstract;
  ...
  
```

Then, TSerialBarCodeScanner and TUsbBarCodeScanner classes will override those classes, according to the final implementation.

In fact, this approach is cleaner. But it is not perfect either, since it may be hard to maintain and extend. Imagine the manufacturer is using a standard protocol for communication, whatever USB or Serial connection is used. You will put this communication protocol (e.g. its state machine, its stream computation, its delaying settings) in the TAbstractBarcodeScanner class. But perhaps they will be diverse flavors, in TSerialBarCodeScanner or TUsbBarCodeScanner, or even due to diverse models and features (e.g. if it supports 2D or 3D bar-codes).

It appears that putting everything in a single class is not a good idea. Splitting protocol and communication appears to be preferred. Each "*axis of change*" - i.e. every aspect which may need modifications - requires its own class. Then the T*BarcodeScanner classes will *compose* protocols and communication classes within a single component.

Imagine we have two identified protocols (named BCP1 and BCP2), and two means of communication (serial and USB). So we will define the following classes:

SOLID Principles - Single Responsibility: Splitting protocol and communication

Then, we may define our final classes and components as such:

```
type
  TAbstractBarcodeConnection = class
  protected
    function ReadChar: byte; override;
    procedure WriteChar(aChar: byte); override;
    ...
  TAbstractBarcodeProtocol = class
  protected
    fConnection: TAbstractBarcodeConnection;
    function ReadFrame: TProtocolFrame; override;
    procedure WriteFrame(const aFrame: TProtocolFrame); override;
    ...
  TAbstractBarcodeScanner = class(TComponent)
  protected
    fProtocol: TAbstractBarcodeProtocol;
    fConnection: TAbstractBarcodeConnection;
    ...
```

And each actual inherited class will initialize the protocol and connection according to the expected model:

```
constructor TSerialBarCodeScanner.Create(const aComPort: string; aBitRate: integer);
begin
  fConnection := TSerialBarcodeConnection(aComPort, aBitRate);
  fProtocol := TBCP1BarcodeProtocol.Create(fConnection);
end;
```

Here, we inject the connection instance to the protocol, since the later may need to read or write some bytes on the wire, when needed.

Another example is how our database classes are defined in SynDB.pas - see *External SQL database access* (page 240):

- The *connection properties* feature is handled by TSQLDBConnectionProperties classes;
- The actual *living connection* feature is handled by TSQLDBConnection classes;
- And *database requests* feature is handled by TSQLDBStatement instances using dedicated NewConnection / ThreadSafeConnection / NewStatement methods.

Therefore, you may change how a database connection is defined (e.g. add a property to a TSQLDBConnectionProperties child), and you won't have to change the statement implementation itself.

15.2.1.2. Do not mix UI and logic

Another practical "*Single Responsibility Principle*" smell may appear in your uses clause.

If your data-only or peripheral-only unit starts like this:

```
unit MyDataModel;

uses
  Winapi.Windows,
  mORMot,
  ...
```

It will induce a dependency about the *Windows* Operating System, whereas your data will certainly benefit from being OS-agnostic. Our today's compiler (Delphi or FPC) targets several OS, so coupling our data to the actual *Windows* unit does show a bad design.

Similarly, you may add a dependency to the VCL, via a reference to the Forms unit.

If your data-only or peripheral-only unit starts like the following, beware!

```
unit MyDataModel;  
  
uses  
  Winapi.Messages,  
  Vcl.Forms,  
  mORMot,  
  ...
```

If you later want to use FMX, or LCL (from Lazarus) in your application, or want to use your MyDataModel unit on a pure server application without any GUI, hosted on Windows - or even better on Linux/BSD - you are stuck.

Note that if you are used to developed in RAD mode, the units generated by the IDE wizards come with some default references in the uses clause of the generated .pas file. So take care of not introducing any coupling to your own business code!

As a general rule, our ORM/SOA framework source code tries to avoid such dependencies. All OS-specificities are centralized in our SynCommons.pas unit, and there is no dependency to the VCL when it is not mandatory, e.g. in mORMot.pas.

Following the RAD approach, you may start from your UI, i.e. defining the needed classes in the unit where you visual form (may be VCL or FMX) is defined. Don't follow this tempting, but dangerous path!

Code like the following may be accepted for a small example (e.g. the one supplied in the SQLite3\Samples sub-folder of our repository source code tree), but is to be absolutely avoided for any production ready *mORMot*-based application:

```
interface  
  
uses  
  Winapi.Windows, Winapi.Messages, System.SysUtils, System.Variants, System.Classes, Vcl.Graphics,  
  Vcl.Controls, Vcl.Forms, Vcl.Dialogs, mORMot, mORMotSQLite3;  
  
type  
  TForm1 = class(TForm)  
    procedure FormCreate(Sender: TObject);  
  private  
    fModel: TSQLModel;  
    fDatabase: TSQLRestServerDB;  
  public  
  end;  
  
implementation  
  
procedure TForm1.FormCreate(Sender: TObject);  
begin  
  fModel := TSQLModel.Create([TSQLMyOwnRecord], 'root');  
  fDatabase := TSQLRestServerDB.Create(fModel, ChangeFileExt(paramstr(0), '.db'));  
end;
```

In your actual project units, when you define an ORM or SOA class, never include GUI methods within. In fact, the fact that our TSQLRecord class definitions are common to both Client and Server sides makes this principle mandatory. You should not have any GUI related method on the Server side, and the Client side could use the objects instances with several GUI implementations (*Delphi* Client, *AJAX* Client...).

Therefore, if you want to change the GUI, you won't have to recompile the TSQLRecord class and the

associated database model. If you want to deploy your server on a *Linux* box (using e.g. *CrossKylix* or *FPC* as compiler), you could reuse your very same code, since you do not have reference to the VCL in your business code.

This *Single responsibility principle* may sound simple and easy to follow (even obvious), but in fact, it is one of the hardest principles to get right. Naturally, we tend to join responsibilities in our class definitions. Our framework architecture will enforce you, by its Client-Server nature and all its high-level methods involving *interface*, to follow this principle, but it is always up to the end coder to design properly his/her types.

15.2.2. Open/Closed Principle

When you define a class or a unit, at the same time:

- They shall be *open for extension*;
- But *closed for modification*.

It means that you may be able to extend your existing code, without breaking its initial behavior. Some other guidelines may be added, but you got the main idea.

Conformance to this open/closed principle is what yields the greatest benefit of OOP, i.e.:

- Code re-usability;
- Code maintainability;
- Code extendibility.

Following this principle will make your code far away from a regular RAD style. But benefits will be huge.

15.2.2.1. Applied to our framework units

When designing our ORM/SOA set of units, we tried to follow this principle. In fact, you should not have to modify its implementation. You should define your own units and classes, without the need to *hack* the framework source code.

Even if *Open Source* paradigm allows you to modify the supplied code, this shall not be done unless you are either fixing a bug or adding a new common feature. This is in fact the purpose of our <https://synopse.info..> web site, and most of the framework enhancements have come from user requests.

The framework Open Source license - see below (page 644) - may encourage user contributions in order to fulfill the Open/closed design principle:

- Your application code extends the *Synopse mORMot Framework* by defining your own classes or event handlers - this is how it is *open for extension*;
- The main framework units shall remain inviolate, and common to all users - this illustrates the *closed for modification* design.

As a beneficial side effect, this principle will ensure that your code will be ready to follow the framework updates (which are quite regular). When a new version of *mORMot* is available, you should be able to retrieve it for free from our web site, replace your files locally, then build a new enhanced version of your application, with the benefit of all included fixes and optimizations. Even the source code repository is available - at <https://synopse.info/fossil..> or from <https://github.com/synopse/mORMot..> - and allows you to follow the current step of evolution of the framework.

In short, abstraction is the key to peace of mind. All your code shall not depend on a particular implementation.

15.2.2.2. Open/Closed in practice

In order to implement this principle, several conventions could be envisaged:

- You shall better define some abstract classes, then use specific overridden classes for each and every implementation: this is for instance how Client-Server classes were implemented - see *Client-Server process* (page 319);
- All object members shall be declared private or protected - this is a good idea to use *Service-Oriented Architecture (SOA)* (page 90) for defining server-side process, and/or make the TSQLRecord published properties read-only and using some client-side constructor with parameters;
- No singleton nor global variable - *ever*;
- RTTI is dangerous - that is, let our framework use RTTI functions for its own cooking, but do not use it in your code.

In our previous bar-code scanner class hierarchy, we will therefore define the

```
type
TAbstractBarcodeScanner = class(TComponent)
protected
  fProtocol: TAbstractBarcodeProtocol;
  fConnection: AbstractBarcodeConnection;
...
public
  property Protocol: TAbstractBarcodeProtocol read fProtocol;
  property Connection: AbstractBarcodeConnection read fConnection;
...
```

In this code, the actual variables are stored as protected fields, with only getters (i.e. **read**) in the public section. There is no setter (i.e. **write**) attribute, which may allow to change the fProtocol/fConnection instances in user code. You can still access those fields (it is mandatory in your inherited constructors), but user code should not use it.

As stated above - see *SOLID Principles - Single Responsibility: Splitting protocol and communication* (page 391) - having dedicated classes for defining protocol and connection will also help implementing the *open/closed* principle. You will be able to define a new class, combining its own protocol and connection class instances, so it will be *Open for extension*. But you will not change the behavior of a class, by inheriting it: since protocol and connection are uncoupled, and used via *composition* in a dedicated class, it will be *Closed for modification*.

Using the newest sealed directive for a class may ensure that your class definition will follow this principle. If the class method or property is sealed, you will not be able to change its behavior in its inherited types, even if you are tempted to.

15.2.2.3. No Singleton nor global variables

About the singleton pattern, you should better always avoid it in your code. In fact, a singleton was a C++ (and Java) hack invented to implement some kind of global variables, hidden behind a static class definition. They were historically introduced to support mixed mode of application-wide initialization (mainly allocate the stdio objects needed to manage the console), and were abused in business logic.

Once you use a singleton, or a global variable, you will miss most of the benefit of OOP. A typical use of singleton is to register some class instances globally for the application. You may see some framework - or some part of the RTL - which will allow such global registration. But it will eventually

void most benefits of proper dependency injection - see below (page 401) - since you will not be able to have diverse resolution of the same class.

For instance, if your database properties, or your application configuration are stored within a singleton, or a global variable, you will certainly not be able to use several database at once, or convert your single-user application with its GUI into a modern multi-user AJAX application:

```
var
  DBServer: string = 'localhost';
  DBPort: integer = 1426;

  UITextColor: TColor = clNavy;
  UITextSize: integer = 12;
```

Such global variables are a smell of a broken *Open/Closed Principle*, since your project will definitely won't be open for extension. Using a static class variable (as allowed in newer version of Delphi), is just another way of defining a global variable, just adding the named scope of the class type.

Even if you do not define some global variable in your code, you may couple your code from an existing global variable. For instance, defining some variables with your `TMainForm = class(TForm)` class defined in the IDE, then using its global `MainForm: TMainForm` variable, or the `Application.MainForm` property, in your code. You will start to feel not right, when the unit where your `TMainForm` is defined will start to appear in your business code uses clause... just another global variable in disguise!

In our framework, we tried to never use global registration, but for the cases where it has been found safe to be implemented, e.g. when RTTI is cached, or JSON serialization is customized for a given type. All those informations will be orthogonal to the proper classes using them, so you may find some global variables in the framework units, only when it is worth it. For instance, we split `TSQLRecord`'s information into a `TSQLRecordProperties` for the shared intangible RTTI values, and `TSQLModelRecordProperties` instances, one per `TSQLModel`, for all the `TSQLModel/TSQLRest` specific settings - see *Several Models* (page 171).

15.2.3. Liskov Substitution Principle

Even if her name is barely unmemorable, *Barbara Liskov* is a great computer scientist, we should better learn from. It is worth taking a look at her presentation at <https://www.youtube.com/watch?v=GDVAHA0oyJU..>

The "*Liskov substitution principle*" states that, if `TChild` is a subtype of `TParent`, then objects of type `TParent` may be replaced with objects of type `TChild` (i.e., objects of type `TChild` may be substitutes for objects of type `TParent`) without altering any of the desirable properties of that program (correctness, task performed, etc.).

The example given by *Barbara Liskov* was about stacks and queues: even if both do share `Push` and `Pop` methods, they should not inherit from a single parent type, since the storage behavior of a stack is quite the contrary of a queue. In your program, if you start to replace a stack by a queue, you will meet strange behaviors, for sure. According to proper *top-bottom* design flow, both types should be uncoupled. You may implement a `TFastStack` class using an in-memory list for storage, or another `TPersistedStack` class using a remote SQL engine, but both will have to behave like a `TStack`, i.e. according to the last-in first-out (LIFO) principle. On the other hand, any class implementing a *queue* type should follow the the first-in first-out (FIFO) order, whatever kind of storage is used.

In practical *Delphi* code, relying on abstractions may be implemented by two means:

- Using only abstract parent class variables when consuming objects;

- Using interface variable instead of class implementations.

Here, we do not use inheritance for sharing implementation code, but for defining an expected behavior. Sometimes, you may break the *Liskov Substitution* principle in implementation methods which will be coded just to gather some reusable pieces of code (the *inheritance for implementation* pattern), preparing some behavior which may be used only by some of the subtypes. Such "internal" virtual methods of a subtype may change the behavior of its inherited method, for the sake of efficiency and maintainability. But with this kind of implementation inheritance, which is closer to plumbing than designing, methods should be declared as protected, and not published as part of the type definition.

By the way, this is exactly what interface type definitions have to offer. You can inherit from another interface, and this kind of polymorphism should strictly follow the *Liskov Substitution* principle. Whereas the class types, implementing the interfaces, may use some protected methods which may break the principle, for the sake of code efficiency.

In order to fulfill this principle, you should:

- Properly name (and comment) your class or interface definition: having Push and Pop methods may be not enough to define a contract, so in this case type inheritance will define the expected expectation - as a consequence, you should better stay away from "duck typing" patterns, and dynamic languages, but rely on strong typing;
- Use the "behavior" design pattern, when defining your objects hierarchy - for instance, if a square may be a rectangle, a TSquare object is definitively *not* a TRectangle object, since the behavior of a TSquare object is not consistent with the behavior of a TRectangle object (square width always equals its height, whereas it is not the case for most rectangles);
- Write your tests using abstract local variables (and this will allow test code reuse for all children classes);
- Follow the concept of *Design by Contract*, i.e. the Meyer's rule defined as "*when redefining a routine [in a derivative], you may only replace its precondition by a weaker one, and its postcondition by a stronger one*" - use of preconditions and postconditions also enforce testing model;
- Separate your classes hierarchy: typically, you may consider using separated object types for implementing persistence and object creation (this is the common separation between *Factory* and *Repository* patterns).

15.2.3.1. Use parent classes

Within our framework, it will signify that TSQLRestServer or TSQLRestClient instances can be substituted to a TSQLRest object. Most ORM methods, especially at TSQLRecord level, expect an abstract TSQLRest parameter to be supplied - see *Working with Objects* (page 144).

For instance, you may write:

```
var anyRest: TSQLRest;  
    ID: TID;  
    rec1, rec2: TSQLMyRecord;  
...  
ID := anyRest.Add(rec1, true);  
rec2 := TSQLMyRecord.Create(anyRest, ID);  
...
```

And you may set any kind of actual class instance to anyRest, either a local stored database engine, or a HTTP remote access:

```
anyRest := TSQLRestServerDB.Create(aModel, 'mydatabase.db');  
anyRest := TSQLHttpClient.Create('1.2.3.4', '8888', aModel, false);
```

You may even find in the `dddInfraSettings.pas` unit a powerful `TRestSettings.NewRestInstance()` method which is able to instantiate the needed `TSQLRest` inherited class from a set of JSON settings, i.e. either a `TSQLHttpClient`, or a local `TSQLRestServerFullMemory`, or a `TSQLRestServerDB` - the later either with a local *SQLite3* database, an external SQL engine, or an external NoSQL/MongoDB database.

Your code shall refer to abstractions, not to implementations. By using only methods and properties available at classes parent level, your code won't need to change because of a specific implementation.

15.2.3.2. I'm your father, Luke

You should note that, in the *Liskov substitution principle* definition, "parent" and "child" are no absolute. Which actual class is considered as "parent" may depend on the context use.

Most of the time, the parent may be the highest class in the hierarchy. For instance, in the context of a GUI application, you may use the most abstract class to access the application data, may it be stored locally, or remotely accessed over HTTP.

But when you initialize the class instance of a local stored server, you may need to setup the actual data storage, e.g. the file name or the remote SQL/NoSQL settings. In this context, you will need to access the "child" properties, regardless of the "parent" abstract use which will take care later on in the GUI part of the application.

Furthermore, in the context of data replication, server side or client side will have diverse behavior. In fact, they may be used as master or slave database, so in this case, you may explicitly define server or client class in your code. This is what our ORM does for its master/slave replication - see *Master/slave replication* (page 180).

If we come back to our bar-code scanner sample, most of your GUI code may rely on `TAbstractBarcodeScanner` components. But in the context of the application options, you may define the internal properties of each "child" class - e.g. the serial or USB port name, so in this case, your new "parent" class may be either `TSerialBarcodeScanner` or `TUsbBarcodeScanner`, or even better the `TSerialBarcodeConnection` or `TUsbBarcodeConnection` properties, to fulfill *Single Responsibility principle*.

15.2.3.3. Don't check the type at runtime

Some patterns shall never appear in your code. Otherwise, code refactoring should be done as soon as possible, to let your project be maintainable in the future.

Statements like the following are to be avoided, in either the parents' or the childs' methods:

```
procedure TAbstractBarcodeScanner.SomeMethod;
begin
  if self is TSerialBarcodeScanner then
  begin
    ....
  end
  else
  if self is TUsbBarcodeScanner then
  ...
end
```

Or, in its disguised variation, using an enumerated item:

```
case fProtocol.MeanOfCommunication of
meanSerial: begin
  ...
end
```

```
end;
meantUsb:
...
```

This later piece of code does not check `self`, but the `fProtocol` protected field. So even if you try to implement the *Single Responsibility principle*, you may still be able to break *Liskov Substitution*!

Note that both patterns will eventually break the *Single Responsibility principle*: each behavior shall be defined in its own child class methods. As the *Open/Closed principle* will also be broken, since the class won't be open for extension, without touching the parent class, and modify the nested `if self is T* then ... or case fProtocol.* of ...` expressions.

15.2.3.4. Partially abstract classes

Another code smell may appear when you define a method which will stay abstract for some children, instantiated in the project. It will imply that some of the parent class behavior is not implemented at this particular hierarchy level. So you will not be able to use all the parent's methods, as will be expected by the *Liskov Substitution principle*.

Note that the compiler will complain for it, hinting that you are creating a class with abstract methods. Never ignore such hints - which may benefit for being handled as errors at compilation time. The (in)famous "Abstract Error" error dialog, which may appear at runtime, will reflect this bad code implementation. When it occurs on a server application without GUI... you got a picture of the terror, I guess...

A more subtle violation of *Liskov* may appear if you break the expectation of the parent class. The following code, which emulates a bar-code reader peripheral by sending the frame by email for debugging purpose (why not?), clearly fails the *Design by Contract* approach:

```
TEMailEmulatedBarcodeProtocol = class(TAbstractBarcodeProtocol)
protected
  function ReadFrame: TProtocolFrame; override;
  procedure WriteFrame(const aFrame: TProtocolFrame); override;
  ...

function TEmailEmulatedBarcodeProtocol.ReadFrame: TProtocolFrame;
begin
  raise EBarcodeException.CreateUTF8('%.ReadFrame is not implemented!',[self]);
end;

procedure TEmailEmulatedBarcodeProtocol.WriteFrame(const aFrame: TProtocolFrame);
begin
  SendEmail(fEmailNotificationAddress,aFrame.AsString);
end;
```

We expected this class to fully implement the `TAbstractBarcodeProtocol` contract, whereas calling `TEMailEmulatedBarcodeProtocol.ReadFrame` will not be able to read any data frame, but will raise an exception. So we can not use this `TEMailEmulatedBarcodeProtocol` class as replacement to any other `TAbstractBarcodeProtocol` class, otherwise it will fail at runtime.

A correct implementation may perhaps to define a `TFakeBarcodeProtocol` class, implementing all the parent methods via a set of events or some text-based scenario, so that it will behave just like a correct `TAbstractBarcodeProtocol` class, in the full extend of its expectations.

15.2.3.5. Messing units dependencies

Last but not least, if you need to explicitly add child classes units to the parent class unit uses clause, it looks like if you just broke the *Liskov Substitution principle*.

```
unit AbstractBarcodeScanner;
```

```
uses
  SysUtils,
  Classes,
  SerialBarcodeScanner; // Barbara complains: "it smells"!
  UsbBarcodeScanner;    // Barbara complains: "it smells"!
...
```

If your code is like this, you will have to remove the reference to the inherited classes, for sure.

Even a dependency to one of the low-level implementation detail is to be avoided:

```
unit AbstractBarcodeScanner;

uses
  Windows,
  SysUtils,
  Classes,
  ComPort;
...
```

Your abstract parent class should **not** be coupled to a particular *Operating System*, or a mean of communication, which may not be needed. Why will you add a dependency to raw RS-232 communication protocol, which is very likely to be deprecated?

One way of getting rid of this dependency is to define some abstract types (e.g. enumerations or simple structures like record), which will then be translated into the final types as expected by the ComPort.pas or Windows.pas units. Consider putting all the child classes dependencies at constructor level, and/or use class composition via the *Single Responsibility principle* so that the parent class definition will not be polluted by implementation details of its children.

You may also use a *registration list*, maintained by the parent unit, which may be able to register the classes implementing a particular behavior at runtime. Thanks to *Liskov*, you will be able to *substitute* any parent class by any of its inherited implementation, so defining the types at runtime only should not be an issue.

15.2.3.6. Practical advantages

The main advantages of this coding pattern are the following:

- Thanks to this principle, you will be able to *stub* or *mock* an interface or a class - see below (page 407) - e.g. uncouple your object persistence to the actual database it runs on: this principle is therefore mandatory for implementing unitary testing to your project;
- Furthermore, testing will be available not only at isolation level (testing each child class), but also at abstracted level, i.e. from the client point of view - you can have implementation which behave correctly when tested individually, but which failed when tested at higher level if the *Liskov* principle was broken;
- As we have seen, if this principle is violated, the other principles are very likely to be also broken - e.g. the parent class will need to be modified whenever a new derivative of the base class is defined (violation of the *Open/Closed* principle), or your class types may implement more than one behavior at a time (violation of the *Single Responsibility* principle);
- Code re-usability is enhanced by method re-usability: a method defined at a parent level does not require to be implemented for each child.

The SOA and ORM concepts, as implemented by our framework, try to be compliant with the *Liskov substitution principle*. It is true at class level for the ORM, but a more direct *Design by Contract* implementation pattern is also available, since the whole SOA stack involves a wider usage of interfaces in your projects.

15.2.4. Interface Segregation Principle

This principle states that once an interface has become too 'fat' it shall be split into smaller and more specific interfaces so that any clients of the interface will only know about the methods that pertain to them. In a nutshell, no client should be forced to depend on methods it does not use.

As a result, it will help a system stay decoupled and thus easier to re-factor, change, and redeploy.

15.2.4.1. Consequence of the other principles

Interface segregation should first appear at class level. Following the *Single Responsibility* principle, you are very likely to define several smaller classes, with a small extent of methods. Then use dedicated types of class, relying on composition to expose its own higher level set of methods.

The bar-code class hierarchy illustrates this concept. Each `T*BarcodeProtocol` and `T*BarcodeConnection` class will have its own set of methods, dedicated either to protocol handling, or data transmission. Then the `T*BarcodeScanner` classes will *compose* those smaller classes into a new class, with a single event handler:

```
type
  TOnBarcodeScanned = procedure(Sender: TAbstractBarcodeScanner; const Barcode: string) of object;

  TAbstractBarcodeScanner = class(TComponent)
  ...
  property OnBarcodeScanned: TOnBarcodeScanned read fOnBarcodeScanned write fOnBarcodeScanned;
  ...
```

This single `OnBarcodeScanned` event will be the published property of the component. Both protocol and connection details will be hidden within the internal classes. The final application will use this event, and react as expected, without actually knowing anything about the implementation details.

15.2.4.2. Using interfaces

The SOA part of the framework allows direct use of interface types to implement services. This great Client-Server SOA implementation pattern - see *Server side Services* (page 373) - helps decoupling all services to individual small methods. In this case also, the stateless used design will also reduce the use of 'fat' session-related processes: an object life time can be safely driven by the interface scope.

By defining *Delphi* interface instead of plain class, it helps creating small and business-specific contracts, which can be executed on both client and server side, with the same exact code.

Since the framework makes interface consumption and publication very easy, you won't be afraid of exposing your implementation classes as small pertinent interface.

For instance, if you want to publish a third-party API, you may consider publishing dedicated interfaces, each depending on every API consumer expectations. So your main implementation logic won't be polluted by how the API is consumed, and, as correlative, the published API may be closer to each particular client needs, without been polluted by the other client needs. DDD will definitively benefit for *Interface Segregation*, since this principle is the golden path to avoid *domain leaking* - see below (page 601).

15.2.5. Dependency Inversion Principle

Another form of decoupling is to invert the dependency between high and low level of a software design:

- High-level modules should not depend on low-level modules. Both should depend on abstractions;
- Abstractions should not depend upon details. Details should depend upon abstractions.

The goal of the *dependency inversion principle* is to decouple high-level components from low-level components such that reuse with different low-level component implementations becomes possible. A simple implementation pattern could be to use only interfaces owned by, and existing only with the high-level component package.

This principle results in *Inversion Of Control* (aka IoC): since you rely on the abstractions, and try not to depend upon concretions (i.e. on implementation details), you should first concern by defining your interfaces.

15.2.5.1. Upside Down Development

In conventional application architecture, lower-level components are designed to be consumed by higher-level components which enable increasingly complex systems to be built. This design limits the reuse opportunities of the higher-level components, and certainly breaks the *Liskov substitution principle*.

For our bar-code reader sample, we may be tempted to start from the final `TSerialBarcodeScanner` we need in our application. We were asked by our project leader to allow bar-code scanning in our flagship application, and the extend of the development has been reduced to support a single model of device, in RS-232 mode - this may be the device already owned by our end customer.

This particular customer may have found some RS-232 bar-code relics from the 90s in its closets, but, as an experience programmer, you know that the next step will be to support USB, in a very close future. All this bar-code reading stuff will be marketized by your company, so it is very likely that another customer will very soon ask for using its own brand new bar-code scanners... which will support only USB.

So you will modelize your classes as with *SOLID Principles - Single Responsibility: Abstract parent class* (page 391) and *SOLID Principles - Single Responsibility: Splitting protocol and communication* (page 391). Even if the `TUsbBarCodeScanner` - and its correlative `TUsbBarCodeConnection` class - is not written, nor tested (you do not even have an actual USB bar-code scanner to do proper testing yet!), you are prepared for it.

When you will eventually add USB support, the UI part of the application won't have to be touched. Just implementing your new inherited class, leveraging all previous coding. Following *Dependency Inversion* from the beginning will definitively save your time. Even in an *Agile* kind of process - where "*Responding to change*" is most valuable - the small amount of work on implementing first from the abstraction with the initial implementation will be very beneficial.

In fact, this *Dependency Inversion* principle is a prerequisite for proper *Test-Driven Design*. Following this TDD pattern, you first write your test, then fail your test, then write the implementation. In order to write the test, you need the abstracted interface of the feature to be available. So you will start from the abstraction, then write the concretion.

15.2.5.2. Injection patterns

In other languages (like Java or .Net), various patterns such as *Plug-in*, *Service Locator*, or *Dependency Injection* are then employed to facilitate the run-time provisioning of the chosen low-level component implementation to the high-level component.

Our Client-Server architecture facilitates this decoupling pattern for its ORM part, and allows the use of native *Delphi* interface to call services from an abstract factory, for its SOA part.

A set of dedicated classes, defined in `mORMot.pas`, allows to leverage IoC: see e.g.

`TInjectableObject`, `TInterfaceResolver`, `TInterfaceResolverForSingleInterface` and `TInterfaceResolverInjected`, which may be used in conjunction with `TInterfaceStub` or `TServiceContainer` high-level mocking and SOA features of the framework - see below (page 407) and below (page 420).

15.3. Circular reference and (zeroing) weak pointers

15.3.1. Weak pointers

The memory allocation model of the *Delphi* interface type uses some kind of *Automatic Reference Counting* (ARC). In order to avoid memory and resource leaks and potential random errors in the applications (aka the terrible `EAccessViolation` exception on customer side) when using *Interfaces* (page 386), a SOA framework like *mORMot* has to offer so-called *Weak pointers* and *Zeroing Weak pointers* features.

By default in *Delphi*, all references are defined:

- as *weak references* for pointer and class instances;
- with *explicit copy* for low-level value types like integer, `Int64`, currency, double or record (and old deprecated object or shortstring);
- via *copy-on-write* with *reference counting* for high-level value types (e.g. string, widestring, variant or a *dynamic array* - with the exception of tuned memory handling for *TDocVariant custom variant type* (page 112));
- as *strong reference* with *reference counting* for interface instances.

The main issue with *strong reference counting* is the potential *circular reference* problem.

This occurs when an interface has a strong pointer to another, but the target interface has a strong pointer back to the original. Even when all other references are removed, they still will hold on to one another and won't be released. This can also happen indirectly, by a chain of objects that might have the last one in the chain referring back to an earlier object.

See the following interface definition for instance:

```
IParent = interface
  procedure SetChild(const Value: IChild);
  function GetChild: IChild;
  function HasChild: boolean;
  property Child: IChild read GetChild write SetChild;
end;

IChild = interface
  procedure SetParent(const Value: IParent);
  function GetParent: IParent;
  property Parent: IParent read GetParent write SetParent;
end;
```

The following implementation will definitively leak memory:

```
procedure TParent.SetChild(const Value: IChild);
begin
  FChild := Value;
end;

procedure TChild.SetParent(const Value: IParent);
begin
  FParent := Value;
end;
```

In *Delphi*, most common kind of reference-copy variables (i.e. variant, *dynamic array* or string)

solve this issue by implementing *copy-on-write*. Unfortunately, this pattern is not applicable to interface, which are not *value* objects, but *reference* objects, tied to an implementation class, which can't be copied.

One common solution is to use *Weak pointers*, by which the interface is assigned to a property without incrementing the reference count.

Note that garbage collector based languages (like Java or C#) do not suffer from this problem, since the circular references are handled by their memory model: objects lifetime are maintained globally by the memory manager. Of course, it will increase memory use, slowdown the process due to additional actions during allocation and assignments (all objects and their references have to be maintained in internal lists), and may slow down the application when garbage collector enters in action. In order to avoid such issues when performance matters, experts tend to pre-allocate and re-use objects: this is one common limitation of this memory model, and why *Delphi* is still a good candidate (like unmanaged C or C++ - and also *Objective C*) when it deals with performance and stability. In some cases (e.g. when using an object cache), such languages have to introduce some kind of "weak pointers", to allow some referenced objects to be reclaimed by garbage collection: but it is a diverse mechanism, under the same naming.

15.3.2. Handling weak pointers

In order to easily create a weak pointer, the following function was added to `mORMot.pas`:

```
procedure SetWeak(aInterfaceField: PInterface; const aValue: IInterface);
begin
  PPointer(aInterfaceField)^ := Pointer(aValue);
end;
```

It will assign the interface reference to a field by assigning the pointer of this instance to the internal field. It will by-pass the reference counting, so memory won't be leaked any more.

Therefore, it could be used as such:

```
procedure TParent.SetChild(const Value: IChild);
begin
  SetWeak(@FChild, Value);
end;

procedure TChild.SetParent(const Value: IParent);
begin
  SetWeak(@FParent, Value);
end;
```

15.3.3. Zeroing weak pointers

But there are still some cases where it is not enough. Under normal circumstances, a class instance should not be deallocated if there are still outstanding references to it. But since weak references don't contribute to an interface reference count, a class instance can be released when there are outstanding weak references to it. Some memory leak or even random access violations could occur. A debugging nightmare...

In order to solve this issue, ARC's *Zeroing Weak pointers* come to mind.

It means that weak references will be set to `nil` when the object they reference is released. When this happens, the automatic zeroing of the outstanding weak references prevents them from becoming dangling pointers. And *voilà*! No access violation any more!

Such a *Zeroing* ARC model has been implemented in *Objective C* by Apple, starting with Mac OS X 10.7

Lion, in replacement (and/or addition) to the previous manual memory handling implementation pattern: in its Apple's flavor, ARC is available not only for interfaces, but for objects, and is certainly more sophisticated than the basic implementation available in the *Delphi* compiler: it is told (at least from the marketing paper point of view) to use some deep knowledge of the software architecture to provide an accurate access to all instances - whereas the *Delphi* compiler just relies on a *out-of-scope* pattern. In regard to classic *garbage collector* memory model, ARC is told to be much more efficient, due to its deterministic nature: Apple's experts ensure that it does make a difference, in term of memory use and program latency - which both are very sensitive on "modest" mobile devices. In short, thanks to ARC, your phone UI won't glitch during background garbage recycling. So mORMot will try to offer a similar feature, even if the *Delphi* compiler does not implement it (yet).

In order to easily create a so-called zeroing weak pointer, the following function was defined in mORMot.pas:

```
procedure SetWeakZero(aObject: TObject; aObjectInterfaceField: PIInterface;  
  const aValue: IInterface);
```

A potential use case could be:

```
procedure TParent.SetChild(const Value: IChild);  
begin  
  SetWeakZero(self,@FChild,Value);  
end;
```

```
procedure TChild.SetParent(const Value: IParent);  
begin  
  SetWeakZero(self,@FParent,Value);  
end;
```

We also defined a class helper around the TObject class, to avoid the need of supplying the self parameter, but unfortunately, the class helper implementation is so buggy it won't be even able to compile before *Delphi* XE version of the compiler. But it will allow to write code as such:

```
procedure TParent.SetChild(const Value: IChild);  
begin  
  SetWeak0(@FChild,Value);  
end;
```

For instance, the following code is supplied in the regression tests, and will ensure that weak pointers are effectively zeroed when SetWeakZero() is used:

```
function TParent.HasChild: boolean;  
begin  
  result := FChild<>nil;  
end;  
  
Child := nil; // here Child is destroyed  
Check(Parent.HasChild=(aWeakRef=weakref), 'ZEROed Weak');
```

Here, aWeakRef=weakref is true when SetWeak() has been called, and equals false when SetWeakZero() has been used to assign the Child element to its Parent interface.

15.3.4. Weak pointers functions implementation details

The SetWeak() function itself is very simple. The *Delphi* RTL/VCL itself use similar code when necessary.

But the SetWeakZero() function has a much more complex implementation, due to the fact that a list of all weak references has to be maintained per class instance, and set to nil when this referring instance is released.

The *mORMot* implementation tries to implement:

- Best performance possible when processing the *Zeroing* feature;
- No performance penalty for other classes not involved within weak references;
- Low memory use, and good scalability when references begin to define huge graphs;
- Thread safety - which is mandatory at least on the server side of our framework;
- Compatible with *Delphi* 6 and later (avoid syntax tricks like *generic*).

Some good existing implementations can be found on the Internet:

- *Andreas Hausladen* provided a classical and complete implementation at <http://andy.jgknet.de/blog/2009/06/weak-interface-references..> using some nice tricks (like per-instance optional speed up using a void *IWeakInterface* interface whose VMT slot will refer to the references list), is thread-safe and is compatible with most *Delphi* versions - but it will slow down all *TObject.FreeInstance* calls (i.e. within *Free* / *Destroy*) and won't allow any overridden *FreeInstance* method implementation;
- *Vincent Parrett* proposed at <http://www.finalbuilder.com/Resources/Blogs/PostId/410/WeakRefence-in-Delphi-solving-circular-interfac.aspx..> a *generic*-based solution (not thread-safe nor optimized for speed), but requiring to inherit from a base class for any *class* that can have a weak reference pointing to it;
- More recently, *Stefan Glienke* published at <http://delphisorcery.blogspot.fr/2012/06/weak-interface-references.html..> another *generic*-based solution, not requiring to inherit from a base class, but not thread-safe and suffering from the same limitations related to *TObject.FreeInstance*.

The implementation included within *mORMot* uses several genuine patterns, when compared to existing solutions:

- It will hack the *TObject.FreeInstance* at the *class* VMT level, so will only slow down the exact *class* which is used as a weak reference, and not others (also its inherited *classes* won't be overridden) - and it will allow custom override of the *virtual FreeInstance* method;
- It makes use of our *TDynArrayHashed* wrapper to provide a very fast lookup of instances and references, without using *generic* definitions - hashing will start when it will be worth it, i.e. for any list storing more than 32 items;
- The unused *vmtAutoTable* VMT slot is used to handle the class-specific orientation of this feature (similar to *TSQLRecordProperties* lookup as implemented for *DI # 2.1.3*), for best speed and memory use.

See the *TSetWeakZeroClass* and *TSetWeakZeroInstance* implementation in *mORMot.pas* for the details.

15.4. Interfaces in practice: dependency injection, stubs and mocks

In order to fulfill the *SOLID design principles* (page 390), two features are to be available when handling interfaces:

- *Dependency injection* or *Inversion of Control* (aka IoC) - see *Dependency Inversion Principle* (page 401);
- *Stubbing* and *mocking* of interfaces for proper testing.

We will show now how *mORMot* provides all needed features for such patterns, testing a simple "forgot my password" scenario: a password shall be computed for a given user name, then transmitted via SMS, and its record shall be updated in the database.

15.4.1. Dependency Injection at constructors

A direct implementation of dependency injection at a class level can be implemented in *Delphi* as such:

- All external dependencies shall be defined as abstract interface;
- An external factory could be used to retrieve an interface instance, **or** class constructor shall receive the dependencies as parameters.

Using an external factory can be made within *mORMot* via *TServiceFactory* - see below (page 420). Automated dependency injection is also available via a set of classes, uncoupled from the SOA features of the framework, mainly *TInjectableObject* and *TInterfaceResolver* types, and their inherited classes - see below (page 418).

Here, we will use the more direct constructor-based pattern for a simple "forgot my password" scenario.

This is the class we want to test:

```
TLoginController = class(TInterfacedObject, ILoginController)
protected
  fUserRepository: IUserRepository;
  fSmsSender: ISmsSender;
public
  constructor Create(const aUserRepository: IUserRepository;
    const aSmsSender: ISmsSender);
  procedure ForgotMyPassword(const UserName: RawUTF8);
end;
```

The constructor will indeed *inject* its dependencies into its own instance:

```
constructor TLoginController.Create(const aUserRepository: IUserRepository;
  const aSmsSender: ISmsSender);
begin
  fUserRepository := aUserRepository;
  fSmsSender := aSmsSender;
end;
```

The dependencies are defined with the following two interfaces (only the needed methods are listed here, but a real interface may have much more members, but not too much, to follow the *interface segregation* SOLID principle):

```
IUserRepository = interface(IInvokable)
  ['{B21E5B21-28F4-4874-8446-BD0B06DAA07F}']
  function GetUserByName(const Name: RawUTF8): TUser;
  procedure Save(const User: TUser);
end;
ISmsSender = interface(IInvokable)
```

```
[ '{8F87CB56-5E2F-437E-B2E6-B3020835DC61}' ]  
function Send(const Text, Number: RawUTF8): boolean;  
end;
```

Note also that all those code will use a plain record as *Data Transfer Object* (DTO):

```
TUser = record  
  Name: RawUTF8;  
  Password: RawUTF8;  
  MobilePhoneNumber: RawUTF8;  
  ID: TID;  
end;
```

Here, we won't use TSQLRecord nor any other classes, just plain records, which will be used as neutral means of transmission. The difference between *Data Transfer Objects* and *business objects* or *Data Access Objects* (DAO) like our TSQLRecord is that a DTO does not have any behavior except for storage and retrieval of its own data. It can also be independent to the persistence layer, as implemented underneath our business domain. Using a record in *Delphi* ensure it won't be part of a complex business logic, but will remain used as value objects.

Now, let's come back to our TLoginController class.

Here is the method we want to test:

```
procedure TLoginController.ForgotMyPassword(const UserName: RawUTF8);  
var U: TUser;  
begin  
  U := fUserRepository.GetUserByName(UserName);  
  U.Password := Int32ToUtf8(Random(MaxInt));  
  if fSmsSender.Send('Your new password is '+U.Password,U.MobilePhoneNumber) then  
    fUserRepository.Save(U);  
end;
```

It will retrieve a TUser instance from its repository, then compute a new password, and send it via SMS to the user's mobile phone. On success, it is supposed to persist (save) the new user information to the database.

15.4.2. Why use fake / emulated interfaces?

Using the real implementation of IUserRepository will expect a true database to be available, with some potential issues on existing data. Similarly, the class implementing ISmsSender in the final project should better not to be called during the test phase, since sending a SMS does cost money, and we will need a true mobile phone or Internet gateway to send the password.

For our testing purpose, we only want to ensure that when the "forgot my password" scenario is executed, the user record modification is persisted to the database.

One possibility could be to define two new dedicated classes, implementing both IUserRepository and ISmsSender interfaces. But it will be obviously time consuming and error-prone. This may be typical case when writing the test could be more complex than writing the method to be tested.

In order to maximize your ROI, and allow you to focus on your business logic, the *mORMot* framework proposes a simple and efficient way of creating "fake" implementations of any interface, just by defining the minimum behavior needed to run the test.

15.4.2.1. Stubs and mocks

In the book "*The Art of Unit Testing*" (Osherove, Roy - 2009), a distinction is drawn between *stub* and *mock* objects:

- *Stubs* are the simpler of the two families of fake objects, simply implementing the same interface as

the object that they represent and returning pre-arranged responses. Thus a fake object merely provides a set of method stubs. Therefore the name. In *mORMot*, it is created via the `TInterfaceStub` generator;

- *Mocks* are described as a fake object that helps decide if a test failed or passed, by verifying if an interaction on an object occurred or not. Everything else is defined as a stub. In *mORMot*, it is created via the `TInterfaceMock` generator, which will link the fake object to an existing `TSynTestCase` instance - see below (page 627).

In practice, there should be only **one** mock per test, with as many stubs as necessary to let the test pass. Using a mocking/stubbing framework allows quick on-the-fly generation of interface with unique behavior dedicated to a particular test. In short, you define the stubs needed to let your test pass, and define one mock which will pass or fail the test depending on the feature you want to test.

Our *mORMot* framework follows this distinction, by defining two dedicated classes, named `TInterfaceStub` and `TInterfaceMock`, able to define easily the behavior of such classes.

15.4.2.2. Defining stubs

Let's implement our "forgot my password" scenario test.

The `TSynTestCase` child method could start as such:

```
procedure TMyTest.ForgetThePassword;  
var SmsSender: ISmsSender;  
    UserRepository: IUserRepository;
```

This is all we need: one dedicated test case method, and our two local variables, ready to be set with our stubbed / mocked implementation classes.

First of all, we will need to implement `ISmsSender.Send` method. We should ensure that it returns `true`, to indicate a successful sending.

With *mORMot*, it is as simple as:

```
TInterfaceStub.Create(TypeInfo(ISmsSender),SmsSender).  
Returns('Send',[true]);
```

It will create a fake class (here called a "stub") emulating the whole `ISmsSender` interface, store it in the local `SmsSender` variable, and let its `Send` method return `true`.

What is nice with this stubbing / mocking implementation is that:

- The "fluent" style of coding makes it easy to write and read the class behavior, without any actual coding in *Delphi*, nor class definition;
- Even if `ISmsSender` has a lot of methods, only `Send` matters for us: `TInterfaceStub` will create all those methods, and let them return default values, with additional line of code needed;
- Memory allocation will be handled by the framework: when `SmsSender` instance will be released, the associated `TInterfaceStub` data will also be freed (and in case a mock, any expectations will be verified).

15.4.2.3. Defining a mock

Now we will define another fake class, which may fail the test, so it is called a "mock", and the *mORMot* generator class will be `TInterfaceMock`:

```
TInterfaceMock.Create(TypeInfo(IUserRepository),UserRepository,self).  
ExpectsCount('Save',qoEqualTo,1);
```

We provide the `TMyTest` instance as `self` to the `TInterfaceMock` constructor, to associate the

mocking aspects with this test case. That is, any registered `Expect*`() rule will let `TMyTest.Check()` be called with a boolean condition reflecting the test validation status of every rule.

The `ExpectCount()` method is indeed where mocking is defined. When the `UserRepository` generated instance is released, `TInterfaceMock` will check all the `Expect*`() rules, and, in this case, check that the `Save` method has been called exactly one time (`qoEqualTo, 1`).

15.4.2.4. Running the test

Since we have all the expected stub and mock at hand, let's run the test itself:

```
with TLoginController.Create(UserRepository, SmsSender) do
try
  ForgotMyPassword('toto');
finally
  Free;
end;
```

That is, we run the actual implementation method, which will call our fake methods:

```
procedure TLoginController.ForgotMyPassword(const UserName: RawUTF8);
var U: TUser;
begin
  U := fUserRepository.GetUserByName(UserName);
  U.Password := Int32ToUtf8(Random(MaxInt));
  if fSmsSender.Send('Your new password is '+U.Password, U.MobilePhoneNumber) then
    fUserRepository.Save(U);
end;
```

Let's put all this together.

15.5. Stubs and Mocks in mORMot

Our *mORMot* framework is therefore able to stub or mock any *Delphi* interface.

We will now detail how it is expected to work.

15.5.1. Direct use of interface types without TypeInfo()

First of all, it is a good practice to always register your service interfaces in the unit which define their type, as such:

```
unit MyServiceInterfaces;
...
type
  ISmsSender = interface(IInvokable)
  ...
  IUserRepository = interface(IInvokable)
  ...

initialization
  TInterfaceFactory.RegisterInterfaces(
    [TypeInfo(ISmsSender), TypeInfo(IUserRepository)]);
end.
```

Then creating a stub or a mock could be done directly from the interface name, which will be transmitted as its TGUID, without the need of using the TypeInfo() pseudo-function:

```
TInterfaceStub.Create(ISmsSender, SmsSender);
TInterfaceMock.Create(IUserRepository, UserRepository, self);
```

In the code below, we will assume that the interface type information has been registered, so that we may be able to use directly I* without the TypeInfo(I*) syntax

15.5.2. Manual dependency injection

As usual, the best way to explain what a library does is to look at the code using it.

Here is an example (similar to the one shipped with *RhinoMocks*) of verifying that when we execute the "forgot my password" scenario as implemented by the TLoginController class, we actually called the Save() method:

```
procedure TMyTest.ForgotMyPassword;
var SmsSender: ISmsSender;
    UserRepository: IUserRepository;
begin
  TInterfaceStub.Create(ISmsSender, SmsSender).
    Returns('Send', [true]);
  TInterfaceMock.Create(IUserRepository, UserRepository, self).
    ExpectsCount('Save', qoEqualTo, 1);
  with TLoginController.Create(UserRepository, SmsSender) do
  try
    ForgotMyPassword('toto');
  finally
    Free;
  end;
end;
```

And... that's all, since the verification will take place when IUserRepository instance will be released.

If you want to follow the "test spy" pattern (i.e. no expectation defined *a priori*, but manual check after the execution), you can use:

```
procedure TMyTest.ForgotMyPassword;
var SmsSender: ISmsSender;
    UserRepository: IUserRepository;
    Spy: TInterfaceMockSpy;
begin
  TInterfaceStub.Create(ISmsSender, SmsSender).
    Returns('Send', [true]);
  Spy := TInterfaceMockSpy.Create(IUserRepository, UserRepository, self);
  with TLoginController.Create(UserRepository, SmsSender) do
    try
      ForgotMyPassword('toto');
    finally
      Free;
    end;
  Spy.Verify('Save');
end;
```

This is something unique with our library: you can decide if you want to use the classic "expect-run-verify" pattern, or the somewhat more direct "run-verify" / "test spy" pattern. With *mORMot*, you pick up your mocking class (either *TInterfaceMock* or *TInterfaceMockSpy*), then use it as intended. You can even mix the two aspects in the same instance! It is just a matter of taste and opportunity for you to use the right pattern.

For another easier pattern, like the one in the *Mockito* home page:

```
TInterfaceMock.Create(ICalculator, ICalc, self).
  ExpectsCount('Multiply', qoEqualTo, 1).
  ExpectsCount('Add', [10, 20], qoEqualTo, 1);
ICalc.Add(10, 20);
ICalc.Multiply(10, 30)
```

If you want to follow the "test spy" pattern, you can use:

```
Mock := TInterfaceMockSpy.Create(ICalculator, ICalc, self);
ICalc.Add(10, 20);
ICalc.Multiply(10, 30)
Mock.Verify('Add');
Mock.Verify('Multiply', [10, 30]);
```

If you compare with existing mocking frameworks, even in other languages / platforms like the two above, you will find out that the features included in *mORMot* are quite complete:

- Stubbing of any method, returning default values for results;
- Definition of the stubbed behavior via a simple fluent interface, with *TInterfaceStub.Returns()*, including easy definition of returned results values, for the whole method or following parameters/arguments matchers;
- Handle methods with *var*, *out* or function result returned values - i.e. not only the function result (as other *Delphi* implementations does, due to a limitation of the *TVirtualInterface* standard implementation, on which *mORMot* does not rely), but all outgoing values, as an array of values;
- Stubbed methods can use delegates or event callbacks with *TInterfaceStub.Executes()* rule definitions, for the whole method or following parameters/arguments matchers, to run a more complex process;
- Stubbed methods can also raise exceptions with *TInterfaceStub.Raises()* rule definitions, for the whole method or following parameters/arguments matchers, if this is the behavior to be tested;
- Clear distinction between *mocks* and *stubs*, with two dedicated classes, named *TInterfaceStub* and *TInterfaceMock*;
- Mocks are directly linked to *mORMot*'s unitary tests / test-driven classes - see below (page 627);
- Mocked methods can trigger test case failure with *TInterfaceMock.Fails()* definitions, for the whole method or following parameters/arguments matchers;
- Mocking via "expect-run-verify" or "run-verify" (aka "test spy") patterns, on choice, depending on

- your testing expectations;
- Mocking validation against number of execution of a method, or a method with arguments/parameters matchers, or the global execution trace - in this case, pass count can be compared with operators like `<` `<=` `=` `<>` `>` `>=` and not only the classic exact-number-of-times and at-least-once verifications;
- Most common parameters and results can be defined as simple array of `const` in the *Delphi* code, or by supplying JSON arrays (needed e.g. for more complex structures like record values);
- Execution trace retrieval in easy to read or write text format (and not via complex "fluent" interface e.g. with `When` clauses);
- Auto-release of the `TInterfaceStub` `TInterfaceMock` `TInterfaceMockSpy` generator instance, when the interface is no longer required, to minimize the code to type, and avoid potential memory leaks;
- Works from *Delphi* 6 up to the latest available *Delphi* version - since no use of syntax sugar like generics, nor the `RTTI.pas` features;
- Very good performance (the faster *Delphi* mocking framework, for sure), due to very low overhead and its reuse of *mORMot*'s low-level interface-based services kernel using JSON serialization, which does not rely on the slow and limited `TVirtualInterface`.

15.5.3. Stubbing complex return values

Just imagine that the `ForgotMyPassword` method does perform an internal test:

```
procedure TLoginController.ForgotMyPassword(const UserName: RawUTF8);
var U: TUser;
begin
  U := fUserRepository.GetUserByName(UserName);
  Assert(U.Name=UserName);
  U.Password := Int32ToUtf8(Random(MaxInt));
  if fSmsSender.Send('Your new password is '+U.Password,U.MobilePhoneNumber) then
    fUserRepository.Save(U);
end;
```

This will fail the test for sure, since by default, `GetUserByName` stubbed method will return a valid but void record. It means that `U.Name` will equal `''`, so the highlighted line will raise an `EAssertionFailed` exception.

Here is how we may enhance our stub, to ensure it will return a `TUser` value matching `U.Name='toto'`:

```
var UserRepository: IUserRepository;
    U: TUser;
    (...)
    U.Name := 'toto';
    TInterfaceMock.Create(IUserRepository,UserRepository,self).
      Returns('GetUserByName','toto',RecordSaveJSON(U,TypeInfo(TUser))).
      ExpectsCount('Save',qeEqualTo,1);
```

The only trick in the above code is that we use `RecordSaveJSON()` function to compute the internal JSON representation of the record, as expected by *mORMot*'s data marshalling.

15.5.4. Stubbing via a custom delegate or callback

In some cases, it could be very handy to define a complex process for a given method, without the need of writing a whole implementation class.

A delegate or event callback can be specified to implement this process, with three parameters marshalling modes:

- Via some `Named[]` variant properties (which are the default for the `Ctxt` callback parameter) - the easiest and safest to work with;
- Via some `Input[]` and `Output[]` variant properties;
- Directly as a JSON array text (the fastest, since native to the *mORMot* core).

Let's emulate the following behavior:

```
function TServiceCalculator.Subtract(n1, n2: double): double;  
begin  
  result := n1-n2;  
end;
```

15.5.4.1. Delegate with named variant parameters

You can stub a method using a the `Named[]` variant arrays as such:

```
TInterfaceStub.Create(ICalculator, ICalc).  
  Executes('Subtract', IntSubtractVariant);  
(...)  
Check(ICalc.Subtract(10.5, 1.5)=9);
```

The callback function can be defined as such:

```
procedure TTestServiceOrientedArchitecture.IntSubtractVariant(  
  Ctxt: TOnInterfaceStubExecuteParamsVariant);  
begin  
  Ctxt['result'] := Ctxt['n1']-Ctxt['n2'];  
end;
```

That is, callback shall use `Ctxt[' ']` property to access the parameters and result as variant values.

In fact, we use the `Ctxt.Named[]` default property, so it is exactly as the following line:

```
Ctxt.Named['result'] := Ctxt.Named['n1']-Ctxt.Named['n2'];
```

If the execution fails, it shall execute `Ctxt.Error()` method with an associated error message to notify the stubbing process of such a failure.

Using named parameters has the advantage of being more explicit in case of change of the method signature (e.g. if you add or rename a parameter). It should be the preferred way of implementing such a callback, in most cases.

15.5.4.2. Delegate with indexed variant parameters

There is another way of implementing such a callback method, directly by using the `Input[]` and `Output[]` indexed properties. It should be (a bit) faster to execute:

```
procedure TTestServiceOrientedArchitecture.IntSubtractVariant(  
  Ctxt: TOnInterfaceStubExecuteParamsVariant);  
begin  
  with Ctxt do  
    Output[0] := Input[0]-Input[1]; // result := n1-n2  
end;
```

Just as with `TOnInterfaceStubExecuteParamsJSON` implementation, `Input[]` index follows the exact order of const and var parameters at method call, and `Output[]` index follows the exact order of var and out parameters plus any function result.

That is, if you call:

```
function Subtract(n1,n2: double): double;  
...  
MyStub.Subtract(100,20);
```

you have in `TOnInterfaceStubExecuteParamsJSON`:

```
Ctxt.Params = '100,20.5'; // at method call
Ctxt.Result = '[79.5]';  // after Ctxt.Returns([..])
```

and in the variant arrays:

```
Ctxt.Input[0] = 100;      // =n1 at method call
Ctxt.Input[1] = 20.5;     // =n2 at method call
Ctxt.Output[0] = 79.5;    // =result after method call
```

In case of additional var or out parameters, those should be added to the `Output[]` array before the last one, which is always the function result.

If the method is defined as a procedure and not as a function, of course there is no last `Output[]` item, but only var or out parameters.

15.5.4.3. Delegate with JSON parameters

You can stub a method using a JSON array as such:

```
TInterfaceStub.Create(ICalculator, ICalc).
  Executes('Subtract', IntSubtractJSON);
(...)
Check(ICalc.Subtract(10.5, 1.5)=9);
```

The callback shall be defined as such:

```
procedure TTestServiceOrientedArchitecture.IntSubtractJSON(
  Ctxt: TOnInterfaceStubExecuteParamsJSON);
var P: PUTF8Char;
begin // result := n1-n2
  P := pointer(Ctxt.Params);
  Ctxt.Returns([GetNextItemDouble(P)-GetNextItemDouble(P)]);
end;
```

That is, it shall parse incoming parameters from `Ctxt.Params`, and store the result values as a JSON array in `Ctxt.Result`.

Input parameter order in `Ctxt.Params` follows the exact order of const and var parameters at method call, and output parameter order in `Ctxt.Returns([])` or `Ctxt.Result` follows the exact order of var and out parameters plus any function result.

This method could have been written as such, if you prefer to return directly the JSON array:

```
procedure TTestServiceOrientedArchitecture.IntSubtractJSON(
  Ctxt: TOnInterfaceStubExecuteParamsJSON);
var P: PUTF8Char;
begin // result := n1-n2
  P := pointer(Ctxt.Params);
  Ctxt.Result := '['+DoubleToStr(GetNextItemDouble(P)-GetNextItemDouble(P))+']';
end;
```

This may sound somewhat convenient here in case of double values, but it will be error prone if types are more complex. In all cases, using `Ctxt.Returns([])` is the preferred method.

15.5.4.4. Accessing the test case when mocking

In case of mocking, you may add additional verifications within the implementation callback, as such:

```
TInterfaceMock.Create(ICalculator, ICalc, self).
  Executes('Subtract', IntSubtractVariant, 'toto');
(...)
procedure TTestServiceOrientedArchitecture.IntSubtractVariant(
  Ctxt: TOnInterfaceStubExecuteParamsVariant);
```

```
begin
  Ctxt.TestCase.Check(Ctxt.EventParams='toto');
  Ctxt['result'] := Ctxt['n1']-Ctxt['n2'];
end;
```

Here, an additional callback-private parameter containing 'toto' has been specified at TInterfaceMock definition. Then its content is checked on the associated test case via Ctxt.Sender instance. If the caller is not a TInterfaceMock, it will raise an exception when accessing the Ctxt.TestCase property.

15.5.5. Calls tracing

As stated above, *mORMot* is able to log all interface calls into its internal TInterfaceStub's structures. This is indeed the root feature of its "test spy" TInterfaceMockSpy.Verify() methods.

```
Stub := TInterfaceStub.Create(ICalculator,I).
  SetOptions([imoLogMethodCallsAndResults]);
  Check(I.Add(10,20)=0,'Default result');
  Check(Stub.LogAsText='Add(10,20)=[0]');
```

Here above, we retrieved the whole call stack, including input parameters and returned results, as an easy-to-read JSON content. We found out that JSON is a very convenient way of tracing the method calls, both efficient for the computer and the human being hardly testing the code.

A more complex trace verification could be defined for instance, in the context of an interface *mock*:

```
TInterfaceMock.Create(ICalculator,I,self).
  Returns('Add','30').
  Returns('Multiply',[60]).
  Returns('Multiply',[2,35],[70]).
  ExpectsCount('Multiply',qoEqualTo,2).
  ExpectsCount('Subtract',qoGreaterThan,0).
  ExpectsCount('ToTextFunc',qoLessThan,2).
  // check trace for a whole method execution
  ExpectsTrace('Add','Add(10,30)=[30]').
  ExpectsTrace('Multiply','Multiply(10,30)=[60],Multiply(2,35)=[70]').
  // check trace for a whole method execution, filtering with given parameters
  ExpectsTrace('Multiply',[10,30], 'Multiply(10,30)=[60]').
  // check trace for the whole interface execution
  ExpectsTrace('Add(10,30)=[30],Multiply(10,30)=[60],'+
    'Multiply(2,35)=[70],Subtract(2.3,1.2)=[0],ToTextFunc(2.3)=[\"default\"]').
  Returns('ToTextFunc',['default']);
  Check(I.Add(10,30)=30);
  Check(I.Multiply(10,30)=60);
  Check(I.Multiply(2,35)=70);
  Check(I.Subtract(2.3,1.2)=0,'Default result');
  Check(I.ToTextFunc(2.3)='default');
```

The overloaded ExpectsTrace() methods are able to add some checks not only about the number of calls of a given method, but the exact order of the executed commands, with associated parameters and all retrieved result values. They can validate the trace of one specific method (optionally with a filter against the incoming parameters), or globally for the whole mocked interface.

Note that internally, those methods will compute a Hash32() hash value of the expected trace, which is a good way of minimizing data in memory or re-use a value retrieved at execution time for further regression testing. Some *overloaded* signatures are indeed available to directly specify the expected Hash32() value, in case of huge regression scenarios: run the test once, debugging all expected behavior by hand, then store the hash value to ensure that no expected step will be broken in the future.

You have even a full access to the internal execution trace, via the two TInterfaceStub.Log and LogCount properties. This will allow any validation of mocked interface calls logic, beyond

ExpectsTrace() possibilities.

You can take a look at `TTestServiceOrientedArchitecture.MocksAndStubs` regression tests, for a whole coverage of all the internal features.

15.6. Dependency Injection and Interface Resolution

In our example, we *injected* the dependencies explicitly as parameters to the class constructor - see *Dependency Injection at constructors* (page 407). We will present below (page 420), in a dedicated chapter, how the framework SOA features do resolve services as interfaces.

But real-world application may be much complex, and a generic way of resolving dependencies, and *Inversion Of Control* (aka IoC) has been implemented.

First of all, if you inherit from `TInjectableObject`, you will be able to resolve dependencies in two ways:

- Explicitly via its `Resolve()` overloaded methods, for lazy initialization of any registered interface;
- Automatically at instance creation, for all its published properties declared with an interface type.

A dedicated set of overloaded constructors is also available at `TInjectableObject` class level, so that you may be able to easily stub/mock or inject any instance, e.g. for testing purposes:

```
procedure TMyTestCase.OneTestCaseMethod;
var Test: IServiceToBeTested;
begin
  Test := TServiceToBeTested.CreateInjected(
    [ICalculator],
    [TInterfaceMock.Create(IPersistence,self).
      ExpectsCount('SaveItem',qoEqualTo,1),
      RestInstance.Services],
    [AnyInterfacedObject]);
  ...
end;
```

In this code, we have *Direct use of interface types without TypeInfo()* (page 411). So we could write directly `ICalculator` or `IPersistence` to refer to an explicit interface type.

This test case (`TMyTestCase` inherits from `TSynTestCase`) will create a `TServiceToBeTested` instance, create a `TInterfaceStub` for its `ICalculator` dependency, then a `TInterfaceMock` expecting the `IPersistence.SaveItem` method to be called exactly one time, allowing resolution from a `TSQLRest.Services` SOA resolver, and injecting a pre-existing `AnyInterfacedObject` `TInterfacedObject` instance.

Then, dependency resolution may take place as published properties:

```
type
  TServiceToBeTested = class(TInjectableObject)
  protected
    fCalculator: ICalculator;
  ...
  published
    property Calculator: ICalculator read fCalculator;
  ...
  end;
...

function TServiceToBeTested.DoCalculation(a,b: integer): integer;
begin
  result := Calculator.Add(a,b);
end;
```

This `fCalculator` instance will be resolved and instantiated by `TInjectableObject.Create`, then released as any regular interface field in the class destructor. You do not have to overload the `TServiceToBeTested` constructor, nor manage this `fCalculator` life time. Its auto-created instance

will be shared by the whole TServiceToBeTested context, so it should be either stateless (like adding two numbers), or expected to evolve at each use.

Sometimes, there may be an over-cost to initialize such properties each time a TServiceToBeTested class instance is created. Or maybe the interface implementation is not stateless, and a new instance should be retrieved before each use. As an alternative, any interface may be resolved on need, in a *lazy* way:

```
procedure TServiceToBeTested.DoSomething;  
var persist: IPersistence;  
begin  
  Resolve(IPersistence,persist);  
  persist.SaveItem('John','Doe');  
end;
```

The TInjectableObject.Resolve() overloaded methods will retrieve one instance of the asked interface. The above code will raise an exception if the supplied IPersistence was not previously registered to the TInjectableObject class.

When such an TInjectableObject instance is created within mORMot's SOA methods (i.e. TSQLRest.Services property), the injection will transparently involve all registered classes. Also take a look at the TInterfaceResolverInjected.RegisterGlobal() overloaded methods, which are able to register some class types or instances globally for the whole executable context. Just make sure that you won't break the *Open/Closed Principle* (page 394), by defining such a global registration, which should occur only for specific needs, truly orthogonal to the whole application, or specific to a test case.

16. Client-Server services via interfaces

Adopt a mORMot

In real world, especially when your application relies heavily on services, the *Client-Server services via methods* (page 374) implementation pattern has some drawbacks:

- Most content marshalling is to be done by hand, so may introduce implementation issues;
- Client and server side code does not have the same implementation pattern, so you will have to code explicitly data marshalling twice, for both client and server (*DataSnap* and WCF both suffer from a similar issue, by which client classes shall be coded separately, most time generated by a Wizard);
- You can not easily *test* your services, unless you write a lot of code to emulate a "fake" service implementation;
- The services do not have any hierarchy, and are listed as a plain list, which is not very convenient;
- It is difficult to synchronize several service calls within a single context, e.g. when a workflow is to be handled during the application process (you have to code some kind of state machine on both sides, and define all session handling by hand);
- Security is handled globally for the user, or should be checked by hand in the implementation method (using the `Ctxt.Session*` members);
- There is no way of implementing service *callbacks*, using e.g. *WebSockets*.

You can get rid of those limitations with the interface-based service implementation of *mORMot*. For a detailed introduction and best practice guide to SOA, see *Service-Oriented Architecture (SOA)* (page 90). All commonly expected SOA features are now available in the current implementation of the *mORMot* framework (including service catalog aka "broker", via the optional publication of interface signatures).

16.1. Implemented features

Here are the key features of the current implementation of services using interfaces in the *Synapse mORMot framework*, as implemented in `mORMot.pas` unit:

Feature	Remarks
Service Orientation	Allow loosely-coupled relationship
Design by contract	Service Contracts are defined in <i>Delphi</i> code as standard interface custom types
Factory driven	Get an implementation instance from a given interface
Server factory	You can get an implementation on the server side
Client factory	You can get a "fake" implementation on the client side, remotely calling the server to execute the process
Cross-platform clients	A <i>mORMot</i> server is able to generate cross-platform client code via a set of templates - see below (page 482)
Auto marshalling	The contract is transparently implemented: no additional code is needed e.g. on the client side, and will handle simple types (strings, numbers, dates, sets and enumerations) and high-level types (objects, collections, records, dynamic arrays, variants) from <i>Delphi</i> 6 up to the latest available <i>Delphi</i> version
Flexible	Methods accept per-value or per-reference parameters
Instance lifetime	An implementation class can be: <ul style="list-style-type: none"> - Created on every call, - Shared among all calls, - Shared for a particular user or group, - Dedicated to the thread it runs on, - Alive as long as the client-side interface is not released, - Or as long as an authentication session exists
Stateless	Following a standard request/reply pattern
Statefull	Server side implementation may be synchronized with client-side interface, e.g. over <i>WebSockets</i>
Dual way	You can define callbacks, using e.g. <i>WebSockets</i> for immediate notification
Signed	The contract is checked to be consistent before any remote execution
Secure	Every service and/or methods can be enabled or disabled on need
Safe	Using extended RESTful authentication - see below (page 547)
Multi-hosted (with DMZ)	Services are hosted by default within the main ORM server, but can have their own process, with a dedicated connection to the ORM core
Broker ready	Service meta-data can be optionally revealed by the server

Multiple transports	All Client-Server protocols of <i>mORMot</i> are available, i.e. direct in-process connection, Windows Messages, named pipes, TCP/IP-HTTP
JSON based	Transmitted data uses <i>JavaScript Object Notation</i>
Routing choice	Services are identified either at the URI level (the RESTful way), or in a JSON-RPC model (the AJAX way), or via any custom format (using <code>class</code> inheritance)
AJAX and RESTful	JSON and HTTP combination allows services to be consumed from AJAX rich clients
Light & fast	Performance and memory consumption are very optimized, in order to ensure scalability and ROI

16.2. How to make services

The typical basic tasks to perform are the following:

- Define the service contract;
- Implement the contract;
- Configure and host the service;
- Build a client application.

We will describe those items.

16.3. Defining a service contract

In a SOA, services tend to create a huge list of operations. In order to facilitate implementation and maintenance, operations shall be grouped within common services.

Before defining how such services are defined within *mORMot*, it is worth applying the *Service-Oriented Architecture (SOA)* (page 90) main principles, i.e. loosely-coupled relationship. When you define *mORMot* contracts, ensure that this contract will stay un-coupled with other contracts. It will help writing SOLID code, enhance maintainability, and allow introducing other service providers on demand (some day or later, you'll certainly be asked to replace one of your service with a third-party existing implementation of the corresponding feature: you shall at least ensure that your own implementation will be easily re-coded with external code, using e.g. a SOAP/WSDL gateway).

16.3.1. Define an interface

The service contract is to be defined as a plain *Delphi* interface type. In fact, the sample type as stated above - see *Interfaces* (page 386) - can be used directly:

```
type
  ICalculator = interface(IInvokable)
    ['{9A60C8ED-CEB2-4E09-87D4-4A16F496E5FE}']
    /// add two signed 32-bit integers
    function Add(n1,n2: integer): integer;
  end;
```

This *ICalculator.Add* method will define one "Add" operation, under the "*ICalculator*" service (which will be named internally 'Calculator' by convention). This operation will expect two numbers as input, and then return the sum of those numbers.

The current implementation of service has the following expectations:

- Any interface inheriting from *IInvokable*, with a GUID, can be used - we expect the RTTI to be available, so *IInvokable* is a good parent type;
- You can inherit an interface from an existing one: in this case, the inherited methods will be part of the child interface, and will be expected to be implemented (just as with standard *Delphi* code);
- Only plain ASCII names are allowed for the type definition (as it is conventional to use English spelling for service and operation naming);
- Calling convention shall be *register* (the *Delphi*'s default) - nor *stdcall* nor *cdecl* is available yet, but this won't be a restriction since the interface definition is dedicated to *Delphi* code scope;
- Methods can have a result, and accept per-value or per-reference parameters.

In fact, parameters expectations are the following:

- Simple types (strings, numbers, dates, sets and enumerations) and high-level types (objects, collections, records and dynamic arrays) are handled - see below for the details;
- They can be defined as *const*, *var* or *out* - in fact, *const* and *var* parameters values will be sent from the client to the server as JSON, and *var* and *out* parameters values will be returned as JSON from the server;
- procedure or function kind of method definition are allowed;
- Only exception is that you can't have a function returning a class instance (how will know when to release the instance in this case?), but such instances can be passed as *const*, *var* or *out* parameters (and published properties will be serialized within the JSON message);
- In fact, the *TCollection* kind of parameter is not directly handled by the framework: you shall define a *TInterfacedCollection* class, overriding its *GetClass* abstract virtual method (otherwise the server side won't be able to create the kind of collection as expected);

- Special `TServiceCustomAnswer` kind of record can be used as function result to specify a custom content (with specified encoding, to be used e.g. for AJAX or HTML consumers) - in this case, no var nor out parameters values shall be defined in the method (only the BLOB value is returned).

16.3.2. Service Methods Parameters

Handled types of parameters are:

Delphi type	Remarks
boolean	Transmitted as JSON true/false
integer cardinal Int64 double currency	Transmitted as JSON numbers
enumerations	Transmitted as JSON number
set	Transmitted as JSON number - one bit per element (up to 32 elements)
TDateTime TDateTimeMS	Transmitted as ISO 8601 JSON text
RawUTF8 WideString SynUnicode	Transmitted as JSON text (UTF-8 encoded)
string	Transmitted as UTF-8 JSON text, but prior to <i>Delphi</i> 2009, the framework will ensure that both client and server sides use the same ANSI code page - so you should better use RawUTF8 everywhere
RawJSON	UTF-8 buffer transmitted with no serialization (whereas a RawUTF8 will be escaped as a JSON string) - expects to contain valid JSON content, e.g. for TSQLTableJSON requests
RawByteString	Transmitted as Base64 encoded JSON text - see below (page 470) for optional binary transmission
TPersistent	Published properties will be transmitted as JSON object
TSQLRecord	All published fields (including ID) will be transmitted as JSON object
TCollection	Not allowed directly: inherit from TInterfacedCollection or call TJSONSerializer.RegisterCollectionForJSON()
TInterfacedCollection	Transmitted as a JSON array of JSON objects - see below (page 427)
TObjectList	Transmitted as a JSON array of JSON objects, with a "ClassName": "TMyClass" field to identify the type - see <i>TObjectList serialization</i> (page 310)
any TObject	See <i>TObject serialization</i> (page 307)
dynamic arrays	Transmitted as JSON arrays - see <i>TDynArray dynamic array wrapper</i> (page 107)

record	Need to have RTTI (so a string or dynamic array field within), just like with regular <i>Delphi</i> interface expectations - transmitted as binary with Base64 encoding before <i>Delphi</i> 2010, or as JSON object thanks to the enhanced RTTI available since, or via an custom JSON serialization - see <i>Record serialization</i> (page 298)
variant	Transmitted as JSON, with support of <i>TDocVariant custom variant type</i> (page 112) for objects and arrays; OLE variant arrays are not handled: use <code>_Arr([])</code> <code>_ArrFast([])</code> instead
TServiceCustomAnswer	If used as a function result (not as parameter), the supplied content will be transmitted directly to the client (with no JSON serialization); in this case, no var nor out parameters are allowed in the method - it will be compatible with both our TServiceFactoryClient implementation, and any other service consumers (e.g. AJAX)
interface	A callback instance could be specified, to allow asynchronous notification, using e.g. <i>WebSockets</i> - see below (page 445)

You can therefore define complex interface types, as such:

```
type
  ICalculator = interface(IInvokable)
    ['{9A60C8ED-CEB2-4E09-87D4-4A16F496E5FE}']
    /// add two signed 32-bit integers
    function Add(n1,n2: integer): integer;
    /// multiply two signed 64-bit integers
    function Multiply(n1,n2: Int64): Int64;
    /// subtract two floating-point values
    function Subtract(n1,n2: double): double;
    /// convert a currency value into text
    procedure ToText(Value: Currency; var Result: RawUTF8);
    /// convert a floating-point value into text
    function ToTextFunc(Value: double): string;
    /// do some work with strings, sets and enumerates parameters,
    /// testing also var (in/out) parameters and set as a function result
    function SpecialCall(Txt: RawUTF8; var Int: integer; var Card: cardinal; field:
TSynTableFieldTypes;
    fields: TSynTableFieldTypes; var options: TSynTableFieldOptions): TSynTableFieldTypes;
    /// test integer, strings and wide strings dynamic arrays, together with records
    function ComplexCall(const Ints: TIntegerDynArray; Strs1: TRawUTF8DynArray;
    var Str2: TWideStringDynArray; const Rec1: TVirtualTableModuleProperties;
    var Rec2: TSQLRestCacheEntryValue): TSQLRestCacheEntryValue;
    /// test variant kind of parameters
    function TestVariants(const Text: RawUTF8; V1: variant; var V2: variant): variant;
    /// validates ArgsInputIsOctetStream raw binary upload
    function DirectCall(const Data: TSQLRawBlob): integer;
  end;
```

Note how `SpecialCall` and `ComplexCall` methods have quite complex parameters definitions, including dynamic arrays, sets and records. `DirectCall` will use binary POST, by-passing Base64 JSON encoding - see below (page 470). The framework will handle `const` and `var` parameters as expected, i.e. as input/output parameters, also on the client side. Any simple types of dynamic arrays (like `TIntegerDynArray`, `TRawUTF8DynArray`, or `TWideStringDynArray`) will be serialized as plain JSON arrays - the framework is able to handle any dynamic array definition, but will serialize those simple types in a more AJAX compatible way, thanks to the enhanced RTTI available since to *Delphi* 2010.

16.3.3. TPersistent / TSQLRecord parameters

As stated above, *mORMot* does not allow a method function to return a class instance.

That is, you can't define such a method:

```
ICustomerFactory = interface(IInvokable)
  ['{770D009F-15F4-4307-B2AD-BBAE42FE70C0}']
  function NewCustomer: TCustomer;
end;
```

Who will be in charge of freeing the instance, in client-server mode? There is no standard allocation scheme, in *Delphi*, for such parameters. So every TObject parameter instance shall be managed by the caller, i.e. allocated before the call and released after it. The method will just read or write the instance published properties, and serialize them as JSON.

What you can define is such a method:

```
ICustomerFactory = interface(IInvokable)
  ['{770D009F-15F4-4307-B2AD-BBAE42FE70C0}']
  procedure NewCustomer(out aCustomer: TCustomer);
end;
```

Note that here the `out` keyword does not indicate how the memory is allocated, but shows the communication direction of the remote service, i.e. it will serialize the object at method return. The caller shall instantiate an instance before call - whereas for "normal" *Delphi* code, it may be up to the method to instantiate the instance, and return it.

Then your client code can use it as such:

```
var Factory: ICustomerFactory;
    Repository: ICustomerRepository;
    Customer: TCustomer;
...
Customer := TCustomer.Create; // client side manage object instance
try
  Customer.FirstName := StringToUTF8(EditFirstName.Text);
  Customer.LastName := StringToUTF8(EditLastName.Text);
  NewCutomerID := Repository.Save(Customer); // persist the object
finally
  Customer.Free; // properly manage memory
end;
```

Or, using both *Factory* and *Repository* patterns, as proposed by below (page 596):

```
var Factory: ICustomerFactory;
    Repository: ICustomerRepository;
    Customer: TCustomer;
...
Factory.NewCustomer(Customer); // get a new object instance
try
  Customer.FirstName := StringToUTF8(EditFirstName.Text);
  Customer.LastName := StringToUTF8(EditLastName.Text);
  NewCutomerID := Repository.Save(Customer); // persist the object
finally
  Customer.Free; // properly manage memory
end;
```

In real live, it may be very easy to wrongly write a server method returning an existing instance, which will be released by the server SOA caller, and will trigger unexpected A/V randomly - very difficult to track - on the server side. Which is what we want to avoid... Whereas a pointer to nil gives always a clear access violation on the client side, which doesn't affect the server.

So this requirement/limitation was designed as such to make the server side more resilient to errors, even if the client side is a bit more complex to work with. Usually, on the client side, you can safely pre-allocate your object instances, and reuse them.

16.3.4. Record parameters

By default, any record parameter or function result will be serialized with a proprietary binary (and optimized) layout, then transmitted as a JSON string, after Base64 encoding.

Even if older versions of *Delphi* are not able to generate the needed RTTI information for such serialization, allowing us only to use an efficient but proprietary binary layout, the *mORMot* framework offers a common way of implementing any custom serialization of records. See *Record serialization* (page 298).

Note that the callback signature used for *records* matches the one used for *dynamic arrays* serializations - see *Dynamic array serialization* (page 304) - as it will be shared between the two of them.

When records are used as *Data Transfer Objects* within services (which is a good idea in common SOA implementation patterns), such a custom serialization format can be handy, and makes more natural service consumption with AJAX clients.

16.3.5. TCollection parameters

16.3.5.1. Use of TCollection

With *mORMot* services, you are able to define such a contract, e.g. for a *TCollTests* collection of *TCollTest* items:

```
procedure Collections(Item: TCollTest; var List: TCollTests; out Copy: TCollTests);
```

Typical implementation of this contract may be:

```
procedure TServiceComplexCalculator.Collections(Item: TCollTest;  
  var List: TCollTests; out Copy: TCollTests);  
begin  
  CopyObject(Item, List.Add);  
  CopyObject(List, Copy);  
end;
```

That is, it will append the supplied *Item* object to the provided *List* content, then return a copy in the *Copy* content:

- Setting *Item* without *var* or *out* specification is doing the same as *const*: it will be serialized from client to server (and not back from server to client);
- Setting *List* as *var* parameter will let this collection to be serialized from client to server, and back from server to the client;
- Setting *Copy* as *out* parameter will let this collection to be serialized only from server to client.

Note that *const* / *var* / *out* kind of parameters are used at the contract level in order to specify the direction of serialization, and not as usual (i.e. to define if it is passed *by value* or *by reference*). All class parameters shall be instantiated before method call: you can not pass any object parameter as *nil* (nor use it in a function result): it will raise an error.

Due to the current implementation pattern of the *TCollection* type in *Delphi*, it was not possible to implement directly this kind of parameter.

In fact, the *TCollection* constructor is defined as such:

```
constructor Create(ItemClass: TCollectionItemClass);
```

And, on the server side, we do not know which kind of *TCollectionItemClass* is to be passed. Therefore, the *TServiceFactoryServer* is unable to properly instantiate the object instances,

supplying the expected item class.

The framework propose two potential solutions:

- You can let your collection class inherit from the new `TInterfacedCollection` type;
- You can call the `TJSONSerializer.RegisterCollectionForJSON()` method to register the collection type and its associated item class.

We will now describe both ways.

16.3.5.2. Inherit from `TInterfacedCollection`

A dedicated `TInterfacedCollection` abstract type has been defined:

```
TInterfacedCollection = class(TCollection)
protected
  class function GetClass: TCollectionItemClass; virtual; abstract;
public
  constructor Create; reintroduce; virtual;
end;
```

In order to use a collection of objects, you will have to define at least the abstract method, for instance:

```
TCollTests = class(TInterfacedCollection)
protected
  class function GetClass: TCollectionItemClass; override;
end;

class function TCollTests.GetClass: TCollectionItemClass;
begin
  result := TCollTest;
end;
```

Or, if you want a more complete / convenient implementation:

```
TCollTests = class(TInterfacedCollection)
private
  function GetCollItem(Index: Integer): TCollTest;
protected
  class function GetClass: TCollectionItemClass; override;
public
  function Add: TCollTest;
  property Item[Index: Integer]: TCollTest read GetCollItem; default;
end;
```

All other methods and properties (like `GetCollItem` / `Add` / `Items[]`) are to be defined as usual.

16.3.5.3. Register a `TCollection` type

The other way of using `TCollection` kind of parameters is to declare it explicitly to the framework. You should call `TJSONSerializer.RegisterCollectionForJSON()` with the corresponding `TCollection` / `TCollectionItem` class type pair.

Consider a dedicated class:

```
TMyCollection = type(TCollection)
```

Note that a dedicated type is needed here. You just can't use this registration over a plain `TCollection`.

Then, for instance, after calling:

```
TJSONSerializer.RegisterCollectionForJSON(TMyCollection, TMyCollectionItem);
```

The following lines of code are the same:

```
MyColl := TMyCollection.Create(TMyCollectionItem);  
MyColl := ClassInstanceCreate(TMyCollection) as TMyCollection;  
MyColl := ClassInstanceCreate('TMyCollection') as TMyCollection;
```

The last two will retrieve the associated TMyCollectionItem class type from the previous registration.

Thanks to this internal registration table, *mORMot* will be able to serialize and unserialize plain TCollection type.

16.4. Server side

16.4.1. Implementing the service contract

In order to have an operating service, you'll need to implement a *Delphi* class which matches the expected interface.

In fact, the sample type as stated above - see *Interfaces* (page 386) - can be used directly:

```
type
  TServiceCalculator = class(TInterfacedObject, ICalculator)
  public
    function Add(n1,n2: integer): integer;
  end;

function TServiceCalculator.Add(n1, n2: integer): integer;
begin
  result := n1+n2;
end;
```

And... That is all we need. The *Delphi* IDE will check at compile time that the class really implements the specified interface definition, so you'll be sure that your code meets the service contract expectations. Exact match (like handling type of parameters) will be checked by the framework when the service factory will be initialized, so you won't face any runtime exception due to a wrong definition.

Here the class inherits from *TInterfacedObject*, but you could use any plain *Delphi* class: the only condition is that it implements the *ICalculator* interface.

16.4.2. Set up the Server factory

In order to have a working service, you'll need to initialize a server-side factory, as such:

```
Server.ServiceRegister(TServiceCalculator,[TypeInfo(ICalculator)],sicShared);
```

You may prefer *Direct use of interface types without TypeInfo()* (page 411), if the type has previously been registered:

```
Server.ServiceDefine(TServiceCalculator,[ICalculator],sicShared);
```

The *Server* instance can be any *TSQLRestServer* inherited class, implementing any of the supported protocol of *mORMot's Client-Server process* (page 319), embedding a full *SQLite3* engine (i.e. a *TSQLRestServerDB* class) or a lighter in-memory engine (i.e. a *TSQLRestServerFullMemory* class - which is enough for hosting services with authentication).

The code line above will register the *TServiceCalculator* class to implement the *ICalculator* service, with a single shared instance life time (specified via the *sicShared* parameter). An optional time out value can be specified, in order to automatically release a deprecated instance after some inactivity.

Whenever a service is executed, an implementation class is to be available. The life time of this implementation class is defined on both client and server side, by specifying a *TServiceInstanceImplementation* value. This setting must be the same on both client and server sides (it will be checked by the framework).

16.4.3. Instances life time implementation

The available instance management options are the following:

Lifetime	Description
<code>sicSingle</code>	One class instance is created per call: - This is the most expensive way of implementing the service, but is safe for simple workflows (like a one-type call); - This is the default setting for <code>TSQLRestServer.ServiceRegister/ServiceDefine</code> methods.
<code>sicShared</code>	One object instance is used for all incoming calls and is not recycled subsequent to the calls
<code>sicClientDriven</code>	One object instance will be created in synchronization with the client-side lifetime of the corresponding interface: when the interface will be released on client (either when it comes out of scope or set to nil), it will be released on the server side - a numerical identifier will be transmitted with all JSON requests
<code>sicPerSession</code>	One object instance will be maintained during the whole running session
<code>sicPerUser</code>	One object instance will be maintained and associated with the running user
<code>sicPerGroup</code>	One object instance will be maintained and associated with the running user's authorization group
<code>sicPerThread</code>	One object instance will be maintained and associated with the running thread

Of course, `sicPerSession`, `sicPerUser` and `sicPerGroup` modes will expect a specific user to be authenticated. Those implementation patterns will therefore only be available if the RESTful authentication is enabled between client and server.

Typical use of each mode may be the following:

Lifetime	Use case
<code>sicSingle</code>	An asynchronous process (may be resource consuming)
<code>sicShared</code>	Either a very simple process, or requiring some global data
<code>sicClientDriven</code>	The best candidate to implement a Business Logic workflow
<code>sicPerSession</code>	To maintain some data specific to the client application
<code>sicPerUser</code>	Access to some data specific to one user
<code>sicPerGroup</code>	Access to some data shared by a user category (e.g. administrators, or guests)
<code>sicPerThread</code>	Thread-oriented process (e.g. for proper library initialization)

In the current implementation of the framework, the class instance is allocated in memory.

This has two consequences:

- In client-server architecture, it is very likely that a lot of such instances will be created. It is therefore mandatory that it won't consume a lot of resource, especially with long-term life time: e.g. you should not store any BLOB within these instances, but try to restrict the memory use to the minimum. For a more consuming operation (a process which may need memory and CPU power), the `sicSingle` mode is preferred.
- There is no built-in data durability yet: service implementation shall ensure that data remaining in memory between calls (i.e. when not defined in `sicSingle` mode) won't be missing in case of server shutdown. It is up to the class to persist the needed data - using e.g. *Object-Relational Mapping* (page 130).

Note also that all those life-time modes expect the method implementation code to be *thread-safe* and reentrant on the server side - only exceptions are `sicSingle` mode, which will have its own running instance, and `sicPerThread`, which will have its methods always run in the same thread context. In practice, the same user can open more than one connection, therefore it is recommended to protect all implementation class method process, or set the execution options as expected - see below (page 462).

In order to illustrate `sicClientDriven` implementation mode, let's introduce the following interface and its implementation (extracted from the supplied regression tests of the framework):

```
type
  IComplexNumber = interface(IInvokable)
    ['{29D753B2-E7EF-41B3-B7C3-827FEB082DC1}']
    procedure Assign(aReal, aImaginary: double);
    function GetImaginary: double;
    function GetReal: double;
    procedure SetImaginary(const Value: double);
    procedure SetReal(const Value: double);
    procedure Add(aReal, aImaginary: double);
    property Real: double read GetReal write SetReal;
    property Imaginary: double read GetImaginary write SetImaginary;
  end;
```

Purpose of this interface is to store a complex number within its internal fields, then retrieve their values, and define a "Add" method, to perform an addition operation. We used properties, with associated getter and setter methods, to provide object-like behavior on Real and Imaginary fields, in the code.

This interface is implemented on the server side by the following class:

```
type
  TServiceComplexNumber = class(TInterfacedObject, IComplexNumber)
  private
    fReal: double;
    fImaginary: double;
    function GetImaginary: double;
    function GetReal: double;
    procedure SetImaginary(const Value: double);
    procedure SetReal(const Value: double);
  public
    procedure Assign(aReal, aImaginary: double);
    procedure Add(aReal, aImaginary: double);
    property Real: double read GetReal write SetReal;
    property Imaginary: double read GetImaginary write SetImaginary;
  end;

{ TServiceComplexNumber }

procedure TServiceComplexNumber.Add(aReal, aImaginary: double);
begin
  fReal := fReal+aReal;
```

```
fImaginary := fImaginary+aImaginary;
end;

procedure TServiceComplexNumber.Assign(aReal, aImaginary: double);
begin
  fReal := aReal;
  fImaginary := aImaginary;
end;

function TServiceComplexNumber.GetImaginary: double;
begin
  result := fImaginary;
end;

function TServiceComplexNumber.GetReal: double;
begin
  result := fReal;
end;

procedure TServiceComplexNumber.SetImaginary(const Value: double);
begin
  fImaginary := Value;
end;

procedure TServiceComplexNumber.SetReal(const Value: double);
begin
  fReal := Value;
end;
```

This interface is registered on the server side as such:

```
Server.ServiceDefine(TServiceComplexNumber,[IComplexNumber],sicClientDriven);
```

Using the sicClientDriven mode, also the client side will be able to have its own life time handled as expected. That is, both fReal and fImaginary field will remain allocated on the server side as long as needed. A time-out driven garbage collector will delete any un-closed pending session, therefore release resources allocated in sicClientDriven mode, even in case of a broken connection.

16.4.4. Accessing low-level execution context

16.4.4.1. Retrieve information from the global ServiceContext

When any inter-face-based service is executed, a global threadvar named ServiceContext can be accessed to retrieve the currently running context on the server side.

You will have access to the following information, which could be useful for sicPerSession, sicPerUser and sicPerGroup instance life time modes:

```
TServiceRunningContext = record
  /// the currently running service factory
  // - it can be used within server-side implementation to retrieve the
  // associated TSQLRestServer instance
  // - note that TServiceFactoryServer.Get() won't override this value, when
  // called within another service (i.e. if Factory is not nil)
  Factory: TServiceFactoryServer;
  /// the currently running context which launched the method
  // - Low-level RESTful context is also available in its Call member
  // - Request.Server is the safe access point to the underlying TSQLRestServer,
  // unless the service is implemented via TInjectableObjectRest, so the
  // TInjectableObjectRest.Server property is preferred
  // - make available e.g. current session or authentication parameters
  // (including e.g. user details via Request.Server.SessionGetUser)
  Request: TSQLRestServerURIContext;
```

```
/// the thread which launched the request
// - is set by TSQLRestServer.BeginCurrentThread from multi-thread server
// handlers - e.g. TSQLite3HttpServer or TSQLRestServerNamedPipeResponse
RunningThread: TThread;
end;
```

When used, a local copy or a `PSERVICERunningContext` pointer should better be created, since accessing a threadvar has a non negligible performance cost.

If your code is compiled within some packages, threadvar read won't work, due to a *Delphi* compiler/RTL restriction (bug?). In such case, you have to call the following function instead of directly access the threadvar:

```
function CurrentServiceContext: TServiceRunningContext;
```

Note that this global threadvar is reset to 0 outside an interface-based service method call. It will therefore be useless to read it from a method-based service, for instance.

16.4.4.2. Implement your service from `TInjectableObjectRest`

An issue with the `ServiceContext` threadvar is that the execution context won't be filled when a SOA method is executed outside a client/server context, e.g. if the `TSQLRestServer` instance did resolve itself its dependencies using `Services.Resolve()`.

A safer (and slightly faster) alternative is to implement your service by inheriting from the `TInjectableObjectRest` class.

This class has its own `Resolve()` overloaded methods (inherited from `TInjectableObject`), but also two additional properties:

```
TInjectableObjectRest = class(TInjectableObject)
...
public
  property Factory: TServiceFactoryServer read fFactory;
  property Server: TSQLRestServer read fServer;
end;
```

Those properties will be injected by `TServiceFactoryServer.CreateInstance`, i.e. when the service implementation object will be instantiated on the server side. They will give direct and safe access to the underlying REST server, e.g. all its ORM methods.

16.4.5. Using services on the Server side

Once the service is registered on the server side, it is very easy to use it in your code.

In a complex *Service-Oriented Architecture (SOA)* (page 90), it is not a good practice to have services calling each other. Code decoupling is a key to maintainability here. But in some cases, you'll have to consume services on the server side, especially if your software architecture has several layers (like in a *Domain-Driven Design* (page 99)): your application services could be decoupled, but the *Domain-Driven* services (those implementing the business model) could be on another Client-Server level, with a dedicated protocol, and could have nested calls.

In this case, according to the *SOLID design principles* (page 390), you'd better rely on abstraction in your code, i.e. not call the service implementation (i.e. the `TInterfacedObject` instances or even worse directly the low-level classes or functions), but the service abstract interface. You can use the following method of your `TSQLRest.Services` instance (note that this method is available on both client and server sides as abstract `TServiceFactory`, so is the right access point to all services):

```
function TServiceFactory.Get(out Obj): Boolean;
```

You have several methods to retrieve a `TServiceFactory` instance, either from the service name, its

GUID, or its index in the list.

That is, you may code:

```
var I: ICalculator;  
begin  
  if ServiceContext.Request.Server.Services['Calculator'].Get(I) then  
    result := I.Add(10,20);  
end;
```

or, for a more complex service:

```
var CN: IComplexNumber;  
begin  
  if not ServiceContext.Request.Server.Services.Resolve(IComplexNumber,CN) then  
    exit; // IComplexNumber interface not found  
  CN.Real := 0.01;  
  CN.Imaginary := 3.1415;  
  CN.Add(100,200);  
  assert(SameValue(CN.Real,100.01));  
  assert(SameValue(CN.Imaginary,203.1415));  
end; // here CN will be released
```

For newer generic-aware versions of *Delphi* (i.e. *Delphi* 2010 and up, since *Delphi* 2009 is buggy about generics), you can use such a method, which enables compile-time checking:

```
var I: ICalculator;  
begin  
  I := Server.Service<ICalculator>;  
  if I<>nil then  
    result := I.Add(10,20);  
end;
```

You can of course cache/store your *TServiceFactory* or *TSQLRest* instances within a local field, if you wish. Using *ServiceContext.Request.Server* is verbose and error-prone.

But you may consider instead to *Implement your service from TInjectableObjectRest* (page 434): the *TInjectableObjectRest* class has already its built-in *Resolve()* overloaded methods, and direct access to the underlying *Server: TSQLRestServer* instance. So you will be able to write directly both SOA and ORM code:

```
var I: ICalculator;  
begin  
  if Resolve(ICalculator,I) then  
    Server.Add(TSQLRecordExecution,['Add',I.Add(10,20)]);  
end;
```

If the service has been defined as *sicPerThread*, the instance you will retrieve on the server side will also be specific to the running thread - in this case, caching the instance may be source of confusion, since there will be one dedicated instance per thread.

16.5. Client side

There is no implementation at all on the client side. This is the magic of *mORMot*'s services: no Wizard to call (as in *DataSnap*, *RemObjects* or *WCF*), nor client-side methods to write - as with our *Client-Server services via methods* (page 374).

You just register the existing interface definition (e.g. our *ICalculator* type), and you can remotely access to all its methods, executed on the server side.

In fact, a hidden "fake" *TInterfaceObject* class will be created by the framework (including its internal *VTable* and low-level assembler code), and used to interact with the remote server. But you do not have to worry about this process: it is transparent to your code.

16.5.1. Set up the Client factory

On the client side, you have to register the corresponding interface to initialize its associated factory, as such:

```
Client.ServiceRegister([TypeInfo(ICalculator)],sicShared);
```

You may prefer *Direct use of interface types without TypeInfo()* (page 411), if the type has previously been registered:

```
Client.ServiceDefine([ICalculator],sicShared);
```

It is very close to the Server-side registration, despite the fact that we do not provide any implementation class here. Implementation will remain on the server side.

Note that the implementation mode (here *sicShared*) shall match the one used on the server side. An error will occur if this setting is not coherent.

The other interface we talked about, i.e. *IComplexNumber*, is registered as such for the client:

```
Client.ServiceDefine([IComplexNumber],sicClientDriven);
```

This will create the corresponding *TServiceFactoryClient* instance, ready to serve fake implementation classes to the client process.

To be more precise, this registration step is indeed not mandatory on the client side. If you use the *TServiceContainerClient.Info()* method, the client-side implementation will auto-register the supplied interface, in *sicClientDriven* implementation mode.

16.5.2. Using services on the Client side

Once the service is registered on the client side, it is very easy to use it in your code.

You can use the same methods as on the server side to retrieve a *TServiceFactory* instance.

That is, you may code:

```
var I: ICalculator;  
begin  
  if Client.Services['Calculator'].Get(I) then  
    result := I.Add(10,20);  
end;
```

For *Delphi* 2010 and up, you can use a generic-based method, which enables compile-time checking:

```
var I: ICalculator;  
begin
```

```
I := Client.Service<ICalculator>;  
if I<>nil then  
  result := I.Add(10,20);  
end;
```

For a more complex service, initialized as `sicClientDriven`:

```
var CN: IComplexNumber;  
begin  
  if not Client.Services.Resolve(IComplexNumber,CN) then  
    exit; // IComplexNumber interface not found  
  CN.Real := 0.01;  
  CN.Imaginary := 3.1415;  
  CN.Add(100,200);  
  assert(SameValue(CN.Real,100.01));  
  assert(SameValue(CN.Imaginary,203.1415));  
end; // here CN will be released on both client AND SERVER sides
```

The code is just the same as on the server. The only functional change is that the execution will take place on the server side (using the registered `TServiceComplexNumber` implementation class), and the corresponding class instance will remain active until the CN local interface will be released on the client.

You can of course cache your `TServiceFactory` instance within a local field, if you wish. On the client side, even if the service has been defined as `sicPerThread`, you can safely cache and reuse the same instance, since the *per-thread* process will take place on the server side only.

As we stated in the previous paragraph, since the `IComplexNumber` is to be executed as `sicClientDriven`, it is not mandatory to call the `Client.ServiceRegister` or `ServiceDefine` method for this interface. In fact, during `Client.Services.Info(TypeInfo(IComplexNumber))` method execution, the registration will take place, if it has not been done explicitly before. For code readability, it may be a good idea to explicitly register the interface on the client side also, just to emphasize that this interface is about to be used, and in which mode.

16.6. Sample code

You can find in the "SQLite3/Samples/14 - Interface based services" folder of the supplied source code distribution, a dedicated sample about this feature.

Purpose of this code is to show how to create a client-server service, using interfaces, over named pipe communication.

16.6.1. The shared contract

First, you'll find a common unit, shared by both client and server applications:

```
unit Project14Interface;

interface

type
  ICalculator = interface(IInvokable)
    ['{9A60C8ED-CEB2-4E09-87D4-4A16F496E5FE}']
    function Add(n1,n2: integer): integer;
  end;

const
  ROOT_NAME = 'service';
  PORT_NAME = '888';
  APPLICATION_NAME = 'RestService';

implementation

uses mORMot;

initialization
  TInterfaceFactory.RegisterInterfaces([TypeInfo(ICalculator)]);
end.
```

Unique purpose of this unit is to define the service interface, and the ROOT_NAME used for the ORM Model (and therefore RESTful URI scheme), and the APPLICATION_NAME used for named-pipe communication.

This ICalculator type is also registered for the internal interface factory system, so that you could use the framework methods directly with ICalculator instead of TypeInfo(ICalculator).

16.6.2. The server sample application

The server is implemented as such:

```
program Project14Server;

{$APPTYPE CONSOLE}

uses
  SysUtils,
  mORMot,
  mORMotSQLite3,
  Project14Interface;

type
  TServiceCalculator = class(TInterfacedObject, ICalculator)
  public
```

```

    function Add(n1,n2: integer): integer;
    end;

function TServiceCalculator.Add(n1, n2: integer): integer;
begin
  result := n1+n2;
end;

var
  aModel: TSQLModel;
begin
  aModel := TSQLModel.Create([],ROOT_NAME);
  try
    with TSQLRestServerDB.Create(aModel,ChangeFileExt(paramstr(0),'.db'),true) do
      try
        CreateMissingTables; // we need AuthGroup and AuthUser tables
        ServiceDefine(TServiceCalculator,[ICalculator],sicShared);
        if ExportServerNamedPipe(APPLICATION_NAME) then
          writeln('Background server is running.'#10) else
          writeln('Error launching the server'#10);
        write('Press [Enter] to close the server.');
        readln;
      finally
        Free;
      end;
    finally
      aModel.Free;
    end;
  end.

```

It will instantiate a TSQLRestServerDB class, containing a *SQLite3* database engine. In fact, since we need authentication, both AuthGroup and AuthUser tables are expected to be available.

Then a call to ServiceDefine() will define the ICalculator contract, and the TServiceCalculator class to be used as its implementation. The sicShared mode is used, since the same implementation class can be shared during all calls (there is no shared nor private data to take care).

Note that since the database expectations of this server are basic (only CRUD commands are needed to handle authentication tables), we may use a TSQLRestServerFullMemory class instead of TSQLRestServerDB. This is what is the purpose of the Project14ServerInMemory.dpr sample:

```

program Project14ServerInMemory;
(...)
  with TSQLRestServerFullMemory.Create(aModel,'test.json',false,true) do
    try
      ServiceDefine(TServiceCalculator,[ICalculator],sicShared);
      if ExportServerNamedPipe(APPLICATION_NAME) then
        (...)

```

Using this class will include the CreateMissingTables call to create both AuthGroup and AuthUser tables needed for authentication. But the resulting executable will be lighter: only 200 KB when compiled with *Delphi 7* and our LVCL classes, for a full service provider.

16.6.3. The client sample application

The client is just a simple form with two TEdit fields (edtA and edtB), and a "Call" button, which OnClick event is implemented as:

```

procedure TForm1.btnCallClick(Sender: TObject);
var a,b: integer;
    err: integer;
    I: ICalculator;
begin
  val(edtA.Text,a,err);

```

```

if err<>0 then begin
  edtA.SetFocus;
  exit;
end;
val(edtB.Text,b,err);
if err<>0 then begin
  edtB.SetFocus;
  exit;
end;
if Client=nil then begin
  if Model=nil then
    Model := TSQLModel.Create([],ROOT_NAME);
    Client := TSQLRestClientURINamedPipe.Create(Model,APPLICATION_NAME);
    Client.SetUser('User','synapse');
    Client.ServiceDefine([ICalculator],sicShared);
  end;
  if Client.Services['Calculator'].Get(I) then
    lblResult.Caption := IntToStr(I.Add(a,b));
end; // here local I will be released

```

The client code is initialized as such:

- A TSQLRestClientURINamedPipe instance is created, with an associate TSQLModel and the given APPLICATION_NAME to access the proper server via a named pipe communication;
- The connection is authenticated with the default 'User' rights;
- The ICalculator interface is defined in the client's internal factory, in sicShared mode (just as in the server).

Once the client is up and ready, the local I: ICalculator variable instance is retrieved, and the remote service is called directly via a simple I.Add(a,b) statement.

You can imagine how easy and safe it will be to implement a *Service-Oriented Architecture (SOA)* (page 90) for your future applications, using *mORMot*.

16.6.4. Enhanced sample: remote SQL access

You will find in the SQLite3\Samples\16 - Execute SQL via services folder of *mORMot* source code a Client-Server sample able to access any external database via JSON and HTTP. It is a good demonstration of how to use a non-trivial interface-based service between a client and a server. It will also show how our SynDB.pas classes have a quite abstract design, and are easy to work with, whatever database provider you need to use.

The corresponding service contract has been defined:

```

TRemoteSQLEngine = (rseOleDb, rseODBC, rseOracle, rseSQLite3, rseJet, rseMSSQL);

IRemoteSQL = interface(IInvokable)
  ['{9A60C8ED-CEB2-4E09-87D4-4A16F496E5FE}']
  procedure Connect(aEngine: TRemoteSQLEngine; const aServerName, aDatabaseName,
    aUserID, aPassword: RawUTF8);
  function GetTableNames: TRawUTF8DynArray;
  function Execute(const aSQL: RawUTF8; aExpectResults, aExpanded: Boolean): RawJSON;
end;

```

Purpose of this service is:

- To Connect() to any external database, given the parameters as expected by a standard TSQLDBConnectionProperties.Create() constructor call;
- Retrieve all table names of this external database as a list;
- Execute any SQL statement, returning the content as JSON array, ready to be consumed by AJAX applications (if aExpanded is true), or a *Delphi* client (e.g. via a TSQLTableJSON and the mORMotUI unit).

Of course, this service will be defined in `sicClientDriven` mode. That is, the framework will be able to manage a client-driven `TSQLDBProperties` instance life time.

Benefit of this service is that no database connection is required on the client side: a regular HTTP connection is enough. No need to neither install nor configure any database provider.

Due to *mORMot* optimized JSON serialization, it will probably be faster to work with such plain HTTP / JSON services, instead of a database connection through a VPN. In fact, database connections are made to work on a local network, and do not like high-latency connections, which are typical on the Internet. On the contrary, the *mORMot* Client-Server process is optimized for such kind of connection.

Note that the `Execute()` method returns a `RawJSON` kind of variable, which is in fact a sub-type of `RawUTF8`. Its purpose is to transmit the UTF-8 encoded content directly, with no translation to a JSON string, as will be the case with a `RawUTF8` variable. In fact, escaping some JSON array within a JSON string is quite verbose. Using `RawJSON` in this case ensure the best client-side and server-side speed, and also reduce the transmission bandwidth.

The server part is quite easy to follow:

```
type
  TServiceRemoteSQL = class(TInterfacedObject, IRemoteSQL)
  protected
    fProps: TSQLDBConnectionProperties;
  public
    destructor Destroy; override;
  public // implements IRemoteSQL methods
    procedure Connect(aEngine: TRemoteSQLEngine; const aServerName, aDatabaseName,
      aUserID, aPassword: RawUTF8);
    function GetTableNames: TRawUTF8DynArray;
    function Execute(const aSQL: RawUTF8; aExpectResults, aExpanded: Boolean): RawJSON;
  end;

{ TServiceRemoteSQL }

procedure TServiceRemoteSQL.Connect(aEngine: TRemoteSQLEngine;
  const aServerName, aDatabaseName, aUserID, aPassword: RawUTF8);
const // rseOLEDB, rseODBC, rseOracle, rseSQLite3, rseJet, rseMSSQL
  TYPES: array[TRemoteSQLEngine] of TSQLDBConnectionPropertiesClass = (
    ToleDBConnectionProperties, TODBCConnectionProperties,
    TSQLDBOracleConnectionProperties, TSQLDBSQLite3ConnectionProperties,
    ToleDBJetConnectionProperties, ToleDBMSSQL2008ConnectionProperties);
begin
  if fProps<>nil then
    raise Exception.Create('Connect called more than once');
  fProps := TYPES[aEngine].Create(aServerName, aDatabaseName, aUserID, aPassword);
end;

function TServiceRemoteSQL.Execute(const aSQL: RawUTF8; aExpectResults, aExpanded: Boolean): RawJSON;
var res: ISQLDBRows;
begin
  if fProps=nil then
    raise Exception.Create('Connect call required before Execute');
  res := fProps.ExecuteInlined(aSQL, aExpectResults);
  if res=nil then
    result := '' else
    result := res.FetchAllAsJSON(aExpanded);
end;

function TServiceRemoteSQL.GetTableNames: TRawUTF8DynArray;
begin
  if fProps=nil then
    raise Exception.Create('Connect call required before GetTableNames');
```

```
fProps.GetTableNames(result);
end;

destructor TServiceRemoteSQL.Destroy;
begin
  FreeAndNil(fProps);
  inherited;
end;
```

Any exception during SynDB.pas process, or raised manually in case of wrong use case will be transmitted to the client, just as expected. The fProps instance life-time is handled by the client, so all we need is to release its pointer in the service implementation destructor.

The services are initialized on the server side with the following code:

```
var
  aModel: TSQLModel;
  aServer: TSQLRestServer;
  aHTTPServer: TSQLHttpServer;
begin
  // define the log level
  with TSQLLog.Family do begin
    Level := LOG_VERBOSE;
    EchoToConsole := LOG_VERBOSE; // log all events to the console
  end;
  // manual switch to console mode
  AllocConsole;
  TextColor(ccLightGray);
  // create a Data Model
  aModel := TSQLModel.Create([], ROOT_NAME);
  try
    // initialize a TObjectList-based database engine
    aServer := TSQLRestServerFullMemory.Create(aModel, 'users.json', false, true);
    try
      // register our IRemoteSQL service on the server side
      aServer.ServiceRegister(TServiceRemoteSQL, [TypeInfo(IRemoteSQL)], sicClientDriven).
        // fProps should better be executed and released in the one main thread
        SetOptions([], [optExecInMainThread, optFreeInMainThread]);
      // Launch the HTTP server
      aHTTPServer := TSQLHttpServer.Create('888', [aServer], '+', useHttpApiRegisteringURI);
      try
        aHTTPServer.AccessControlAllowOrigin := '*'; // for AJAX requests to work
        writeln(#10'Background server is running.'#10);
        writeln('Press [Enter] to close the server.'#10);
        ConsoleWaitForEnterKey;
      finally
        aHTTPServer.Free;
      end;
    finally
      aServer.Free;
    end;
  finally
    aModel.Free;
  end;
end.
```

This is a typical *mORMot* server initialization, published over the HTTP communication protocol (with auto-registration feature, if possible, as stated by the `useHttpApiRegisteringURI` flag). Since we won't use ORM for any purpose but authentication, a fast *TObjectList*-based engine (i.e. *TSQLRestServerFullMemory*) is enough for this sample purpose.

In the above code, you can note that *IRemoteSQL* service is defined with the `optExecInMainThread` and `optFreeInMainThread` options. It means that all methods will be executed in the main process thread. In practice, since SynDB.pas database access may open one connection per thread (e.g. for *OleDB* / *MS SQL* or *Oracle* providers), it may use a lot of memory. Forcing the database execution in

the main thread will lower the resource consumption, and still will perform with decent speed (since all the internal marshalling and communication will be multi-threaded in the framework units).

From the client point of view, it will be consumed as such:

```
procedure TMainForm.FormShow(Sender: TObject);
(....)
fModel := TSQLModel.Create([], ROOT_NAME);
fClient := TSQLHttpClient.Create('localhost', '888', fModel);
if not fClient.ServerTimestampSynchronize then begin
  ShowLastClientError(fClient, 'Please run Project16ServerHttp.exe');
  Close;
  exit;
end;
if (not fClient.SetUser('User', 'synapse')) or
(not fClient.ServiceRegisterClientDriven(TypeInfo(IRemoteSQL), fService)) then begin
  ShowLastClientError(fClient, 'Remote service not available on server');
  Close;
  exit;
end;
end;
```

Our IRemoteSQL service will be accessed in sicClientDriven mode, so here we need to initialize RESTful authentication - see below (page 547) - with a proper call to SetUser().

Note the use of ShowLastClientError() function of mORMotUILogin unit, which is able to use our SynTaskDialog unit to report standard and detailed information about the latest error.

In this sample, no table has been defined within the ORM model. It is not necessary, since all external process will take place at the SQL level. As we need authentication (see the call to fClient.SetUser method), the ORM core will by itself add the TSQLAuthUser and TSQLAuthGroup tables to the model - no need to add them explicitly.

From now on, we have a fService: IRemoteSQL instance available to connect and process any remote SQL request.

```
procedure TMainForm.btnOpenClick(Sender: TObject);
var TableNames: TRawUTF8DynArray;
(....)
with fSettings do
  fService.Connect(Engine, ServerName, DatabaseName, UserID, Password);
  TableNames := fService.GetTableNames;
  cbbTableNames.Items.Text := UTF8ToString(RawUTF8ArrayToCSV(TableNames, #13#10));
(....)
```

Now we are connected to the database via the remote service, and we retrieved the table names in a TComboBox.

Then a particular SQL statement can be executed as such:

```
procedure TMainForm.btnExecuteClick(Sender: TObject);
var SQL: RawUTF8;
begin
  SQL := trim(StringToUTF8(mmoQuery.Text));
  Screen.Cursor := crHourGlass;
  try
    try
      if isSelect(pointer(SQL)) then begin
        fTableJSON := fService.Execute(SQL, True, False);
        TSQLTableToGrid.Create(drwgrdData,
          TSQLTableJSON.Create([], SQL, pointer(fTableJSON), Length(fTableJSON)), fClient);
      end else
        fService.Execute(SQL, False, False);
    except
      on E: Exception do
```

```
        ShowException(E);  
    end;  
    finally  
        Screen.Cursor := crDefault;  
    end;  
end;
```

Here, `TSQLTableToGrid.Create()`, from the `mORMotUI` unit, will "inject" the returned data to a standard `TDrawGrid`, using a `TSQLTableJSON` instance to un-serialize the returned JSON content.

Note that in case of any exception (connection failure, or server side error, e.g. wrong SQL statement), the `ShowException()` method is used to notify the user with appropriate information.

16.7. Asynchronous callbacks

When publishing SOA services, most of them are defined as *stateless*, in a typical query/answer pattern - see *Service-Oriented Architecture (SOA)* (page 90). This fits exactly with the *RESTful* approach of *Client-Server services via interfaces* (page 420), as proposed by the framework.

But it may happen that a client application (or service) needs to know the state of a given service. In a pure *stateless* implementation, it will have to *query* the server for any state change, i.e. for any pending notification - this is called *polling*.

Polling may take place for instance:

- When a time consuming work is to be processed on the server side. In this case, the client could not wait for it to be finished, without raising a timeout on the HTTP connection: as a workaround, the client may start the work, then ask for its progress status regularly using a timer and a dedicated method call;
- When an unpredictable event is to be notified from the server side. In this case, the client should ask regularly (using a timer, e.g. every second), for any pending event, then react on purpose.

It may therefore sounds preferred, and in some case necessary, to have the ability to let the server *notify* one or several clients without any prior query, nor having the requirement of a client-side timer:

- *Polling* may be pretty resource consuming on both client and server sides, and add some unwanted latency;
- If immediate notification is needed, some kind of "long polling" algorithm may take place, i.e. the server will wait for a long time before returning the notification state if no event did happen: in this case, a dedicated connection is required, in addition to the REST one;
- In an event-driven systems, a lot of messages are sent to the clients: a proper publish/subscribe mechanism is preferred, otherwise the complexity of polling methods may increase and become inefficient and unmaintainable;
- Explicit push notifications may be necessary, e.g. when a lot of potential events, associated with a complex set of parameters, are likely to be sent by the client.

Our *mORMot* framework is therefore able to easily implement asynchronous callbacks over *WebSockets*, defining the callbacks as interface parameters in service method definitions - see *Service Methods Parameters* (page 424).

16.7.1. WebSockets support

By definition, HTTP connections are stateless and one-way, i.e. a client sends a request to the server, which replies back with an answer. There is no way to let the server send a message to the client, without a prior request from the client side.

WebSockets is a communication protocol which is able to *upgrade* a regular HTTP connection into a dual-way communication wire. After a safe handshake, the underlying TCP/IP socket is able to be accessed directly, via a set of lightweight *frames* over an application-defined *protocol*, without the HTTP overhead.

The `SynBidirSock.pas` unit implements low-level server and client *WebSockets* communication.

The `TWebSocketProtocol` class defines an abstract *WebSockets protocol*, currently implemented as several classes:

TWebSocketProtocolJSON classes hierarchy

For our *Client-Server services via interfaces* (page 420), we will still need to make *RESTful* requests, so the basic *WebSockets* framing has been enhanced to support `TWebSocketProtocolRest` REST-compatible protocols, able to use the single connection for both REST queries and asynchronous notifications.

Two classes are available for your SOA applications:

- `TWebSocketProtocolJSON` as a "pure" JSON light protocol;
- `TWebSocketProtocolBinary` as a binary proprietary protocol, with optional frame compression and AES encryption (using AES-NI hardware instructions, if available).

In practice, on the server side, you will start your `TSQLHttpServer` by specifying `useBidirSocket` as kind of server:

```
HttpServer := TSQLHttpServer.Create('8888',[Server],'+',useBidirSocket);
```

Under the hood, it will instantiate a `TWebSocketServer` HTTP server, as defined in `mORMotHttpServer.pas`, based on the sockets API, able to upgrade the HTTP protocol into *WebSockets*. Our *High-performance http.sys* server (page 327) is not yet able to switch to *WebSockets* - and at API level, it will require at least *Windows 8* or *Windows 2012 Server*.

Then you enable *WebSockets* for the `TWebSocketProtocolBinary` protocol, with a symmetric encryption key:

```
HttpServer.WebSocketsEnable(Server,'encryptionkey');
```

On the client side, you will use a `TSQLHttpClientWebsockets` instance, as defined in `mORMotHttpClient.pas`, then explicitly upgrade the connection to use *WebSockets* (since by default, it will stick to the HTTP protocol):

```
Client := TSQLHttpClientWebsockets.Create('127.0.0.1','8888',TSQLModel.Create([]));
Client.WebSocketsUpgrade('encryptionkey');
```

The expected protocol detail should match the one on the server, i.e. 'encryptionkey' encryption over our binary protocol.

Once upgraded to *WebSockets*, you may use regular REST commands, as usual:

```
Client.ServerTimestampSynchronize;
```

But in addition to regular query/answer commands as defined for *Client-Server services via interfaces* (page 420), you will be able to define callbacks using interface parameters to the service methods.

Under the hood, both client and server will communicate using *WebSockets* frames, maintaining the connection active using heartbeats (via ping/pong frames), and with clean connection shutdown, from any side. You can use the `Settings` property of the `TWebSocketServerRest` instance, as returned by `TSQLHttpServer.WebSocketsEnable()`, to customize the low-level *WebSockets* protocol (e.g. timeouts or heartbeats) on the server side. The `TSQLHttpClientWebsockets.WebSockets.Settings`

property will allow the same, on the client side.

We have observed, from our regression tests and internal benchmarking, that using our *WebSockets* may be faster than regular HTTP, since its frames will be sent as once, whereas HTTP headers and body are not sent in the same TCP packet, and compression will be available for the whole frame, whereas HTTP headers are not compressed. The ability to use strong AES encryption will make this mean of communication even safer than plain HTTP, even with *AES encryption over HTTP* (page 334).

16.7.1.1. Using a "Saga" callback to notify long term end-of-process

An example is better than 100 talks.

So let's take a look at the `Project31LongWorkServer.dpr` and `Project31LongWorkClient.dpr` samples, from the `SQLite3\Samples\31 - WebSockets` sub-folder. They will implement a client/server application, in which the client launches a long term process on the server side, then is notified when the process is done, either with success, or failure.

Such a pattern is very common in the SOA world, and also known as "saga" - see <http://www.rgoarchitects.com/Files/SOAPatterns/Saga.pdf..> - but in practice, it may be difficult to implement it safely and easily. Let's see how our framework make writing sagas a breeze.

First we define the interfaces to be used, in a shared `Project31LongWorkCallbackInterface.pas` unit:

```
type
  ILongWorkCallback = interface(IInvokable)
    ['{425BF199-19C7-4B2B-B1A4-A5BE7A9A4748}']
    procedure WorkFinished(const workName: string; timeTaken: integer);
    procedure WorkFailed(const workName, error: string);
  end;

  ILongWorkService = interface(IInvokable)
    ['{09FDFCEF-86E5-4077-80D8-661801A9224A}']
    procedure StartWork(const workName: string; const onFinish: ILongWorkCallback);
    function TotalWorkCount: Integer;
  end;
```

The only specific definition is the `const onFinish: ILongWorkCallback` parameter, supplied to the `ILongWorkService.StartWork()` method. The client will create a class implementing `ILongWorkCallback`, then specify it as parameter to this method. On the server side, a "fake" class will implement `ILongWorkCallback`, then will call back the client using the very same *WebSockets* connection, when any of its methods will be executed.

As you can see, a single callback interface instance may have several methods, with their own set of parameters (here `WorkFinished` and `WorkFailed`), so that the callback may be quite expressive. Any kind of usual parameters will be transmitted, after serialization: `string`, `integer`, but even `record`, *dynamic arrays*, `TSQLRecord` or `TPersistent` values.

When the `ILongWorkCallback` instance will be released on the client side, the server will be notified, so that any further notification won't create a connection error. We will see later how to handle those events.

16.7.1.2. Client service consumption

The client may be connected to the server as such (see the `Project31LongWorkClient.dpr` sample source code for the full details, including error handling):

```
var Client: TSQLHttpClientWebsockets;
    workName: string;
```

```

    Service: ILongWorkService;
    callback: ILongWorkCallback;
begin
  Client := TSQLHttpClientWebsockets.Create('127.0.0.1','8888',TSQLModel.Create([]));
  Client.WebSocketsUpgrade(PROJECT31_TRANSMISSION_KEY);
  Client.ServiceDefine([ILongWorkService],sicShared);
  Client.Services.Resolve(ILongWorkService,Service);

```

Then we define our callback, using a dedicated class:

```

type
  TLongWorkCallback = class(TInterfacedCallback,ILongWorkCallback)
  protected
    procedure WorkFinished(const workName: string; timeTaken: integer);
    procedure WorkFailed(const workName, error: string);
  end;

procedure TLongWorkCallback.WorkFailed(const workName, error: string);
begin
  writeln(#13'Received callback WorkFailed(',workName,') with message "',error, '');
end;

procedure TLongWorkCallback.WorkFinished(const workName: string;
  timeTaken: integer);
begin
  writeln(#13'Received callback WorkFinished(',workName,') in ',timeTaken,'ms');
end;

```

Then we specify this kind of callback as parameter to start a long term work:

```

callback := TLongWorkCallback.Create(Client,ILongWorkCallback);
try
  repeat
    readln(workName);
    if workName='' then
      break;
    Service.StartWork(workName,callback);
  until false;
finally
  callback := nil; // the server will be notified and release its "fake" class
  Service := nil; // release the service local instance BEFORE Client.Free
end;

```

As you can see, the client is able to start one or several work processes, then expects to be notified of the process ending on its callback interface instance, without explicitly polling the server for its state, since the connection was upgraded to *WebSockets* via a call to *TSQLHttpClientWebsockets.WebSocketsUpgrade()*.

16.7.1.3. Server side implementation

The server will define the working thread as such (see the *Project31LongWorkServer.dpr* sample source code for the full details):

```

type
  TLongWorkServiceThread = class(TThread)
  protected
    fCallback: ILongWorkCallback;
    fWorkName: string;
    procedure Execute; override;
  public
    constructor Create(const workName: string; const callback: ILongWorkCallback);
  end;

constructor TLongWorkServiceThread.Create(const workName: string;
  const callback: ILongWorkCallback);
begin

```

```

inherited Create(false);
fCallback := Callback;
fWorkName := workName;
FreeOnTerminate := true;
end;

procedure TLongWorkServiceThread.Execute;
var tix: Int64;
begin
  tix := GetTickCount64;
  Sleep(5000+Random(1000)); // some hard work
  if Random(100)>20 then
    fCallback.WorkFinished(fWorkName,GetTickCount64-tix) else
    fCallback.WorkFailed(fWorkName, 'expected random failure');
end;

```

The callback is expected to be supplied as a `ILongWorkCallback` interface instance, then stored in a `fCallback` protected field for further notification.

Some work is done in the `TLongWorkServiceThread.Execute` method (here just a `Sleep()` of more than 5 seconds), and the end-of-work notification is processed, as success or failure (depending on random in this fake process class), on either of the `ILongWorkCallback` interface methods.

The following class will define, implement and register the `ILongWorkService` service on the server side:

```

type
  TLongWorkService = class(TInterfacedObject, ILongWorkService)
  protected
    fTotalWorkCount: Integer;
  public
    procedure StartWork(const workName: string; const onFinish: ILongWorkCallback);
    function TotalWorkCount: Integer;
  end;

procedure TLongWorkService.StartWork(const workName: string;
  const onFinish: ILongWorkCallback);
begin
  InterlockedIncrement(fTotalWorkCount);
  TLongWorkServiceThread.Create(workName, onFinish);
end;

function TLongWorkService.TotalWorkCount: Integer;
begin
  result := fTotalWorkCount;
end;

var HttpServer: TSQLHttpServer;
  Server: TSQLRestServerFullMemory;
begin
  Server := TSQLRestServerFullMemory.CreateWithOwnModel([]);
  Server.ServiceDefine(TLongWorkService, [ILongWorkService], sicShared);
  HttpServer := TSQLHttpServer.Create('8888', [Server], '+', useBidirSocket);
  HttpServer.WebSocketsEnable(Server, PROJECT31_TRANSMISSION_KEY);
  ...

```

Purpose of those methods is just to create and launch the `TLongWorkServiceThread` process from a client request, then maintain a total count of started works, in a `sicShared` service instance - see *Instances life time implementation* (page 430) - hosted in a `useBidirSocket` kind of HTTP server.

We have to explicitly call `TSQLHttpServer.WebSocketsEnable()` so that this server will be able to upgrade to our *WebSockets* protocol, using our binary framing, and the very same symmetric encryption key as on the client side - shared as a `PROJECT31_TRANSMISSION_KEY` constant in the sample, but which may be safely stored on both sides.

16.7.2. Publish-subscribe for events

In event-driven architectures, the *publish-subscribe* messaging pattern is a way of letting senders (called *publishers*) transmit messages to their receivers (called *subscribers*), without any prior knowledge of who those subscribers are. In practice, the *subscribers* will express interest for a set of messages, which will be sent by the *publisher* to all the *subscribers* of a given message, as soon as it is be notified.

Publish-Subscribe Pattern

In our *Client-Server services via interfaces* (page 420) implementation, messages are gathered in interface types, and each message defined as a single method, their content being the methods parameters.

Most of the SOA alternative (in Java or C#) do require class definition for messages. Our KISS approach will just use method parameters values as message definition.

To maintain a list of *subscribers*, the easiest is to store a *dynamic array* of interface instances, on the *publisher* side.

16.7.2.1. Defining the interfaces

We will now implement a simple *chat* service, able to let several clients communicate together, broadcasting any message to all the other connected instances. This sample is also located in the the SQLite3\Samples\31 - WebSockets sub-folder, as Project31ChatServer.dpr and Project31ChatClient.dpr.

So you first define the callback interface, and the service interface:

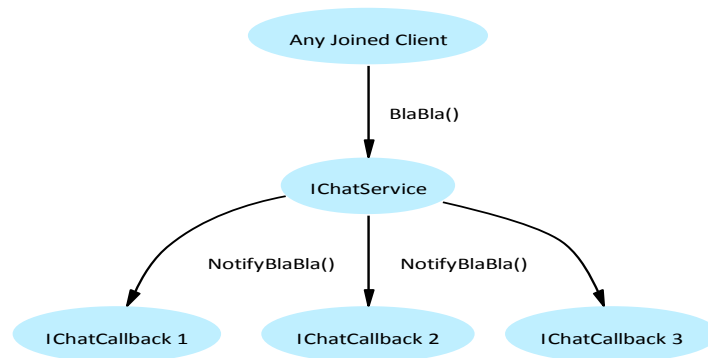

```

type
  IChatCallback = interface(IInvokable)
    ['{EA7EFE51-3EBA-4047-A356-253374518D1D}']
    procedure NotifyBlaBla(const pseudo, msg: string);
  end;

  IChatService = interface(IInvokable)
    ['{C92DCBEA-C680-40BD-8D9C-3E6F2ED9C9CF}']
    procedure Join(const pseudo: string; const callback: IChatCallback);
    procedure BlaBla(const pseudo, msg: string);
    procedure CallbackReleased(const callback: IInvokable; const interfaceName: RawUTF8);
  end;
  
```

The main command of the IChatService service is BlaBla(), which should be propagated to all client instance having Joined the conversation, via IChatCallback.NotifyBlaBla() events.

Those interface types will be shared by both server and client sides, in the common Project31ChatCallbackInterface.pas unit. The definition is pretty close to what we wrote when *Using a "Saga" callback to notify long term end-of-process* (page 447). For instance, if 3 people did join the chat room, the following process should take place:

Chat Application using Publish-Subscribe

The only additional method is `IChatServer.CallbackReleased()`, which, by convention, will be called on the server side when any callback interface instance is released on the client side.

As such, the `IChatService.Join()` method will implement the *subscription* to the chat service, whereas `IChatServer.CallbackReleased()` will be called when the client-side callback instance will be released (i.e. when its variable will be assigned to `nil`), to *unsubscribe* for the chat service.

16.7.2.2. Writing the Publisher

On the server side, each call to `IChatService.Join()` will *subscribe* to an internal list of connections, simply stored as an array of `IChatCallback`:

```

type
  TChatService = class(TInterfacedObject, IChatService)
  protected
    fConnected: array of IChatCallback;
  public
    procedure Join(const pseudo: string; const callback: IChatCallback);
    procedure BlaBla(const pseudo, msg: string);
    procedure CallbackReleased(const callback: IInvokable; const interfaceName: RawUTF8);
  end;

procedure TChatService.Join(const pseudo: string;
  const callback: IChatCallback);
begin
  InterfaceArrayAdd(fConnected, callback);
end;

```

The `InterfaceArrayAdd()` function, as defined in `SynCommons.pas`, is a simple wrapper around any *dynamic array* of interface instances, so that you may use it, or the associated `InterfaceArrayFind()` or `InterfaceArrayDelete()` functions, to maintain the list of subscriptions.

Then a remote call to the `IChatService.BlaBla()` method should be broadcasted to all connected clients, just by calling the `IChatCallback.BlaBla()` method:

```

procedure TChatService.BlaBla(const pseudo, msg: string);
var i: integer;
begin
  for i := 0 to high(fConnected) do
    fConnected[i].NotifyBlaBla(pseudo, msg);
  end;
end;

```

Note that every call to `IChatCallback.BlaBla()` within the loop will be made via *WebSockets*, in an asynchronous and non blocking way, so that even in case of huge number of clients, the `IChatService.BlaBla()` method won't block. In case of high numbers of messages, the framework is

even able to *gather* push notification messages into a single bigger message, to reduce the resource use - see *Real-time synchronization* (page 183).

If you are a bit paranoid, you may ensure that the notification process will continue, if any of the event failed:

```
procedure TChatService.BlaBla(const pseudo,msg: string);
var i: integer;
begin
  for i := high(fConnected) downto 0 do // downwards for InterfaceArrayDelete()
    try
      fConnected[i].NotifyBlaBla(pseudo,msg);
    except
      InterfaceArrayDelete(fConnected,i); // unsubscribe the callback on failure
    end;
  end;
```

This safer implementation will unregister any failing callback. If the notification raised an exception, it will ensure that this particular invalid subscriber won't be notified any more. Note that since we may reduce the fConnected[] array size on the fly, the loop is processed *downwards*, to avoid any access violation.

On the server side, the service implementation has been registered as such:

```
Server.ServiceDefine(TChatService,[IChatService],sicShared).
  SetOptions([], [optExecLockedPerInterface]);
```

Here, the optExecLockedPerInterface option has been set, so that all method calls will be made thread-safe: concurrent access to the internal fConnected[] list will be protected by a lock. Since a global list of connections is to be maintained, the service life time has been defined as sicShared - see *Instances life time implementation* (page 430).

The following method will be called by the server, when a client callback instance is released (either explicitly, or if the connection is broken), so could be used to *unsubscribe* to the notification, simply by deleting the callback from the internal fConnected[] array:

```
procedure TChatService.CallbackReleased(const callback: IInvokable; const interfaceName: RawUTF8);
begin
  if interfaceName='IChatCallback' then
    InterfaceArrayDelete(fConnected,callback);
end;
```

The framework will in fact recognize the following method definition in any interface type for a service (it will check the method name, and the method parameters):

```
procedure CallbackReleased(const callback: IInvokable; const interfaceName: RawUTF8);
```

When a callback interface parameter (in our case, IChatCallback) will be released on the client side, this method will be called with the corresponding interface instance and type name as parameters. You do not have to call explicitly any method on the client side to *unsubscribe* a service: assigning *nil* to a callback variable, or freeing the class instance owning it as a field on the *subscriber* side, will automatically unregister it on the *publisher* side.

16.7.2.3. Consuming the service from the Subscriber side

On the client side, you implement the IChatCallback callback interface:

```
type
  TChatCallback = class(TInterfacedCallback,IChatCallback)
  protected
    procedure NotifyBlaBla(const pseudo, msg: string);
  end;
```

```
procedure TChatCallback.NotifyBlaBla(const pseudo, msg: string);
begin
  writeln(#13'@',pseudo, ' ',msg);
end;
```

The TInterfacedCallback type defines a TInterfacedObject sub-class, which will automatically notify the REST server when it is released. By providing the client TSQLRest instance to the TChatCallback.Create() constructor, you will ensure that the IChatService.CallbackReleased method will be executed on the server side, when the TChatCallback/IChatCallback instance will be released on the client side.

Then you subscribe to your remote service as such:

```
var Service: IChatService;
    callback: IChatCallback;
...
Client.ServiceDefine([IChatService],sicShared);
if not Client.Services.Resolve(IChatService,Service) then
  raise EServiceException.Create('Service IChatService unavailable');
...
callback := TChatCallback.Create(Client,IChatCallback);
Service.Join(pseudo,callback);
...
try
  repeat
    readln(msg);
    if msg='' then
      break;
    Service.BlaBla(pseudo,msg);
  until false;
finally
  callback := nil; // will unsubscribe from the remote publisher
  Service := nil; // release the service local instance BEFORE Client.Free
end;
```

You could easily implement more complex *publish/subscribe* mechanisms, including filtering, time to live or tuned broadcasting, by storing some additional information to the interface instance (e.g. some value to filter, a timestamp). A dynamic array of dedicated records - see *TDynArray dynamic array wrapper* (page 107), or a list of class instances, may be used to store the *subscribers* expectations.

16.7.2.4. Subscriber multiple redirection

Sometimes, in a complex business system, you will define several uncoupled parts of your code subscribing to the same service events. In a DDD architecture, it will be typically happen when several domain bounded contexts subscribe to a single event source, implemented in the infrastructure layer.

The easiest implementation path is to have each part registering from its side. But it will induce some redundant traffic with the publisher. And it will most probably end-up with duplicated code on subscribers side.

You may try TSQLRest.MultiRedirect and register once to a remote service, then use an internal registration mechanism to have every part of your business logic registering and consuming the events. The method returns an IMultiCallbackRedirect interface, allowing registration of sub-callbacks, with an optional set of method names, if only a sub-set of events are needed.

Note that sub-callbacks do not need to inherit from the TInterfacedCallback type: a regular TInterfacedObject is enough. They will be automatically unregistered from the internal list, if they raise an exception.

16.7.2.5. Proper threaded implementation

A *mORMot* multi-threaded server will use critical sections to protect shared data, and avoid potential race conditions. But even on client side, callbacks will be executed in the context of the *WebSockets* transmission thread. And in a typical micro-services or event-driven architecture, most nodes are clients and servers at the same time, creating a peer-to-peer mesh of services. So you should prevent any race conditions in each and every node, by protecting access to any shared data.

Likewise, if your callback triggers another method which shares the same critical section in another thread, you may encounter deadlock issues. If an event triggers a callback within a critical section used to protect a shared resource, and if this callback runs a blocking REST request, the REST answer will be received in the context of the transmission thread. If this answer tries to access the same shared resource, there will be a conflict with the main critical section lock, so the execution will lock.

To implement proper thread-safety of your callback process you could follow some patterns.

- Use several small critical sections, protecting any shared data, with the smallest granularity possible. You may use *TSynLocker* mutex or *TLockedDocVariant* schema-less storage.
- In your regression tests, ensure you run multi-threaded scenarios, with parallel requests. You may find in *TSynParallelProcess* an easy way of running concurrent client/server tests. It will help finding out most obvious implementation issues.
- By definition, most deadlocks are difficult to reproduce - they are some kind of "Heisenbugs". You may ensure proper logging of the callback process, so that you will be able to track for any deadlock which may occur on production.
- A good idea may be to gather all non-blocking callback process in a background thread using *TSQLRest.AsyncRedirect*. This method will implement any interface via a fake class, which will redirect all methods calls into calls of another interface, but as a FIFO in a background thread. So you will ensure that all callback process will take place in a single thread, avoiding most concurrency issues. As a side effect, the internal FIFO will leverage other threads, so may help scaling your system. For a client application using some User Interface, see below (page 454) a lock-free alternative.

Multi-threading is the key to performance. But it is also hard to properly implement. By following those simple rules, you may reduce the risk of concurrency issues.

16.7.2.6. Interacting with UI/VCL

As we have stated, all callback notifications do take place in the transmission thread, i.e. in the *TWebSocketProcessClientThread* instance corresponding to each connected client.

You may be tempted to use the *VCL Synchronize()* method, as usual, to forward the notifications to the UI layer. Unfortunately, this may trigger some unexpected concurrency issue, e.g. when asynchronous notifications (e.g. *TChatCallback.NotifyBlaBla()*) are received during a blocking REST command (e.g. *Service.BlaBla()*). The *Synchronize* call within the blocking command will avoid any incoming asynchronous notification wait for the main thread to be available, and will block the reception of the answer of the pending REST command...

If you experiment random hangouts of your User Interface, and 404 errors corresponding to a low-level *WebSockets* timeout, even when closing the application, you have certainly hit such a deadlock.

Get rid of all your *Synchronize()* calls! Use *Windows* messages instead: they are safe, efficient and fast. The framework allows to forward all incoming notifications as a dedicated *Windows* message in a single line:

```
Client.ServiceNotificationMethodViaMessages(MainForm.Handle,WM_SERVICENOTIFICATION);
```

The WM_SERVICENOTIFICATION should have been defined as a custom user message:

```
const
WM_SERVICENOTIFICATION = WM_USER; // may be WM_USER+1, +2, ...
```

Then, the TFormMain should execute the message, as a regular event handler:

```
TFormMain = class(TForm)
...
procedure ServiceNotification(var Msg: TMessage); message WM_SERVICENOTIFICATION;
...
procedure TFormMain.ServiceNotification(var Msg: TMessage);
begin
  TSQLRestClientURI.ServiceNotificationMethodExecute(Msg);
end;
```

Thanks to these two lines, the callbacks will be executed asynchronously in the main UI thread, using the optimized *Message* queue of the Operating System, without any blocking execution, nor race condition.

16.7.3. Interface callbacks instead of class messages

If you compare with existing client/server SOA solutions (in Delphi, Java, C# or even in Go or other frameworks), this interface-based callback mechanism sounds pretty unique and easy to work with.

Most *Events Oriented* solutions do use a set of dedicated messages to propagate the events, with a centralized *Message Bus* (like *MSMQ* or *JMS*), or a P2P approach (see e.g. *ZeroMQ* or *NanoMsg*). In practice, you are expected to define one class per message, the class fields being the message values. You will define e.g. one class to notify a successful process, and another class to notify an error. SOA services will eventually tend to be defined by a huge number of individual classes, with the temptation of re-using existing classes in several contexts.

Our interface-based approach allows to gather all messages:

- In a single interface type per *notification*, i.e. probably per *service operation*;
- With one *method* per *event*;
- Using method *parameters* defining the event *values*.

Since asynchronous notifications are needed most of the time, method parameters will be one-way, i.e. only const. Blocking request may also be defined, as we will see below (page 457). And an evolved algorithm will transparently gather outgoing messages, to enhance scalability.

Behind the scene, the framework will still transmit raw messages over IP sockets, like other systems, but events notification will benefit from using interfaces, on both server and client sides.

16.7.3.1. Using service and callback interfaces

For instance, you may define the following generic service and callback to retrieve a file from a remote camera, using *mORMot*'s interface-based approach:

```
type
// define some custom types to make the implicit explicit
TCameraID = RawUTF8;
TPictureID = RawUTF8;
// mORMot notifications using a callback interface definition
IMyCameraCallback = interface(IInvokable)
  ['{445F967F-79C0-4735-A972-0BED6CC63D1D}']
  procedure Started(const Camera: TCameraID; const Picture: TPictureID);
  procedure Progressed(const Camera: TCameraID; const Picture: TPictureID;
    CurrentSize, TotalSize: cardinal);
  procedure Finished(const Camera: TCameraID; const Picture: TPictureID);
```

```

    const PublicURI: RawUTF8; TotalSize: cardinal);
    procedure ErrorOccured(const Camera: TCameraID; const Picture: TPictureID;
      const MessageText: RawUTF8);
  end;
  // mORMot main service, also defined as an interface
  IMyCameraService = interface(IInvokable)
    ['{3CE61E74-A01D-41F5-A414-94F204F140E1}']
    function TakePicture(const Camera: TCameraID; const Callback: IMyCameraCallback): TPictureID;
  end;

```

Take a deep breath, and keep in mind those two type definitions as reference. In a single look, I guess you did get the expectation of the "Camera Service". We will now compare with a classical message-based pattern.

16.7.3.2. Classical message(s) event

With a class-based message kind of implementation, you will probably define a single class, containing all potential information:

```

type
  // a single class message will need a status
  TMyCameraCallbackState = (
    ccsStarted, ccsProgressed, ccsFinished, ccsErrorOccured);
  // the single class message
  TMyCameraCallbackMessage = class
  private
    fCamera: TCameraID;
    fPicture: TPictureID;
    fTotalSize: cardinal;
    fMessageText: RawUTF8;
    fState: TMyCameraCallbackState;
  published
    property State: TMyCameraCallbackState read fState write fState;
    property Camera: TCameraID read fCamera write fCamera;
    property Picture: TPictureID read fPicture write fPicture;
    property TotalSize: cardinal read fTotalSize write fTotalSize;
    property MessageText: RawUTF8 read fMessageText write fMessageText;
  end;

```

This single class is easy to write, but makes it a bit confusing to consume the notification. Which field comes with which state? The client-side code will eventually consist of a huge case aMessage.State of ... block, with potential issues. The business logic does not appear in this type definition. Easy to write, difficult to read - and maintain...

In order to have an implementation closer to *SOLID design principles* (page 390), you may define a set of classes, as such:

```

type
  // all classes will inherit from this one, to have common properties
  TMyCameraCallbackAbstract = class
  private
    fCamera: TCameraID;
    fPicture: TPictureID;
  published
    property Camera: TCameraID read fCamera write fCamera;
    property Picture: TPictureID read fPicture write fPicture;
  end;
  // message class when the picture acquisition starts
  TMyCameraCallbackStarted = class(TMyCameraCallbackAbstract);
  // message class when the picture is acquired
  TMyCameraCallbackFinished = class(TMyCameraCallbackAbstract)
  private
    fPublicURI: RawUTF8;
    fTotalSize: cardinal;
  published

```

```
    property TotalSize: cardinal read fTotalSize write fTotalSize;
    property PublicURI: RawUTF8 read fPublicURI write fPublicURI;
end;
// message during picture download
TMyCameraCallbackProgressed = class(TMyCameraCallbackFinished)
private
    fCurrentSize: cardinal;
published
    property CurrentSize: cardinal read fCurrentSize write fCurrentSize;
end;
// error message
TMyCameraCallbackErrorOccured = class(TMyCameraCallbackAbstract)
private
    fMessageText: RawUTF8;
published
    property MessageText: RawUTF8 read fMessageText write fMessageText;
end;
```

Inheritance makes this class hierarchy not as verbose as it may have been with plain "flat" classes, but it is still much less readable than the `IMyCameraCallback` type definition.

In both cases, such `class` definitions make it difficult to guess to which message matches which service. You must be very careful and consistent about your naming conventions, and uncouple your service definitions in clear name spaces.

When implementing SOA services, DDD's *Ubiquitous Language* tends to be polluted by the `class` definition (getters and setters), and implementation details of the messages-based notification: your *Domain* code will be tied to the message oriented nature of the *Infrastructure* layer. We will see below (page 622) how interface callbacks will help implementing DDD's *Event-Driven* pattern, in a cleaner way.

16.7.3.3. Workflow adaptation

Sometimes, it may be necessary to react to some unexpected event. The consumer may need to change the workflow of the producer, depending on some business rules, an unexpected error, or end-user interaction.

By design, message-based implementations are asynchronous, and non-blocking: messages are sent and stored in a message broker/bus, and its internal processing loop propagates the messages to all subscribers. In such an implementation, there is no natural place for "reverse" feedback messages.

A common pattern is to have a dedicated set of "answer/feedback" messages, to notify the service providers of a state change - it comes with potential race conditions, or unexpected rebound phenomena, for instance when you add a node to an existing event-driven system.

Another solution may be to define explicit *rules* for service providers, e.g. when the service is called. You may define a set of workflows, injected to the provider/bus service at runtime. It will definitively tend to break the *Single Responsibility Principle* (page 390), and put logic in the infrastructure layer.

On the other hand, since *mORMot*'s callbacks are true interface methods, they may return some values (as a function result or a var/out parameter). On the server side, such callbacks will block and wait for the client end to respond.

So by writing an additional method like:

```
IMyCameraCallback = interface(IInvokable)
...
    function ShouldRetryIfBusy(const Camera: TCameraID; const Picture: TPictureID): boolean;
...
```

... you will be able to implement any needed complex workflow adaptation, in real time. The server side code will still be very readable and efficient, with no complex plumbing, wait queue or state machine to set up.

16.7.3.4. From interfaces comes abstraction and ease

As an additional benefit, integration with the Delphi language is clearly implementation agnostic: you are not even tied to use the framework, when working with such interface type definitions. In fact, this is a good way of implementing callbacks conforming to *SOLID design principles* (page 390) on the server side, and let the *mORMot* framework publish this mechanism in a client/server way, by using *WebSockets*, only if necessary.

The very same code could be used on the server side, with no transmission nor marshalling overhead (via direct interface instance calls), and over a network, with optimized use of resource and bandwidth (via "fake" interface calls, and binary/JSON marshalling over TCP/IP).

On the server side, your code - especially your *Domain* code - may interact directly with the lower level services, defined in the *Domain* as interface types, and implemented in the *infrastructure* layer. You may host both *Domain* and *Infrastructure* code in a single server executable, with direct assignment of local `class` instance as callbacks. This will minimize the program resources, in both CPU and memory terms - which is always a very valuable goal, for any business system.

You may be able to reuse your application and business logic in a stand-alone application, with similar direct calls from the UI to the application interface. On need, the interface variable may point to a remote *mORMot* server, without touching VCL/FMX code.

Last but not least, using an interface will help implementing the whole callback mechanism using *Stubs and mocks* (page 408), e.g. for easy unit testing via *Calls tracing* (page 416).

You may also write your unit tests with real local callback `class` instances, which will be much easier to debug than over the whole client/server stack. Once you identified a scenario which fails the system, you could reproduce it with a dedicated test, even in an aggressive multi-threaded way, then use the debugger to trace the execution and identify the root cause of the issue.

16.8. Implementation details

16.8.1. Error handling

Usually, in Delphi applications (like in most high-level languages), errors are handled via *exceptions*. By default, any Exception raised on the server side, within an interface-based service method, will be intercepted, and transmitted as an HTTP error to the client side, then a safe but somewhat obfuscated EInterfaceFactoryException will be raised, containing additional information serialized as JSON.

You may wonder why exceptions are not transmitted and raised directly on the client side, as if they were executed locally.

In fact, Exceptions are not *value* objects, but true *class* instances, with some methods and potentially internal references to other objects. Most of the time, they are tied to a particular execution context, and even some low-level implementation details. A Delphi exception is even something very specific, and will not be easily converted into e.g. a *JavaScript*, *Java* or *C#* exception.

In practice, re-creating and raising an instance of the same Exception *class* which occurred on the server side will induce a strong dependency of the client code towards the server implementation details. For instance, if the server side raises a ESQLDBOracle exception, translating it on the other end will link your client side with the whole SynDBOracle.pas unit, which certainly not worth it. The ESQLDBOracle exception, by itself, contains a link to an *Oracle* statement instance, which will be lost when transmitted over the wire. Some client platforms (e.g. mobile or AJAX) do not even have any knowledge of what an *Oracle* database is...

As such, exception are not good candidate on serialization, and transmission per value, from the server side to the client side. We will NOT be in favor of propagating exceptions to the client side.

This is why exceptions should better be intercepted on the server side, with a `try .. except` block within the service methods, then converted into low level DTO types, specific to the service, then explicitly transmitted as error codes to the client.

The first rule is that raising exception should be *exceptional* - as its name states: exceptional. I mean, service code should not raise an exception in normal execution, even in case of wrong input. For instance, a wrong input parameter should lead into an application level error, transmitted as an enumeration item and/or some additional (probably text) information, but the business logic should never raise any exception. Only in case of low-level unexpected event (e.g. a SQL level failure, a GPF or Access Violation, a communication error with another trusted internal service), the server side may enter in *panic* mode, and raise an exception. Remember that exceptions are intercepted by SynLog.pas and can be easily logged by our below (page 632): you will be able to identify the execution context, and find a full stack trace of the issue. But most common errors should be handled at business logic level, even defined in each service layers.

In practice, you may use an *enumerate*, in conjunction with a variant for additional structured information (as a string or a more complex TDocVariant), to transmit an error to the client side. You may define dedicated types at every layer, e.g. with interface types for *Domain* services, or *Application* services.

See for instance how ICQRSservice, and its associated TCQRSResult enumeration, are defined in mORMotDDD.pas:

```
type
  TCQRSResult =
    (cQRSSuccess, cQRSSuccessWithData,
     cQRSUnspecifiedError, cQRSBadRequest,
```

```
cqrsNotFound, cqrsNoMoreData, cqrsDataLayerError,  
cqrsInternalServerError, cqrsDDDValidationFailed,  
cqrsInvalidContent, cqrsAlreadyExists,  
...  
  
ICQRSService = interface(IInvokable)  
  ['{923614C8-A639-45AD-A3A3-4548337923C9}']  
  function GetLastError: TCQRSResult;  
  function GetLastErrorInfo: variant;  
end;
```

The first `cqrsSuccess` item of the `TCQRSResult` enumerate will be the default one (mapped and transmitted to a 0 JSON number), so in case of any stub or mock of the interfaces, fake methods will return as successful, as expected - see *Stubs and mocks* (page 408).

When any exception is raised in a service method, a `TCQRSResult` enumeration value can be returned as result, so that error will be transmitted directly:

```
function TDDDDMonitoredDaemon.Stop(out Information: variant): TCQRSResult;  
...  
begin  
  CqrsBeginMethod(qaNone, result);  
  try  
    ...  
    CqrsSetResult(cqrsSuccess, result);  
  except  
    on E: Exception do  
      CqrsSetResult(E, cqrsInternalServerError, result);  
  end;  
end;
```

But such exception should be exceptional, as we already stated.

The `mORMotDDD.pas` unit defines, in the `TCQRSQueryObject` abstract class, some protected methods to handle errors and exceptions as expected by `ICQRSService`. For instance, the `TCQRSQueryObject.CqrsSetResult()` method will set `result := cqrsInternalServerError` and serialize the `E: Exception` within the internal variant used for additional error, ready to be retrieved using `ICQRSService.GetLastErrorInfo`.

Exceptions are very useful to interrupt a process in case of a catastrophic failure, but they are not the best method for transmitting errors over remote services. Some newer languages (e.g. *Google's Go*), will even not define any exception type at language or RTL level, but rely on returned values, to transmit the errors in between execution contexts - see <https://golang.org/doc/faq#exceptions:..> in our client-server error handling design, we followed the same idea.

16.8.2. Security

As stated in the features grid of *Client-Server services via interfaces* (page 420), a complete security pattern is available when using client-server services. In a *Service-Oriented Architecture (SOA)* (page 90), securing messages between clients and services is essential to protecting data.

Security is implemented at several levels, following the main security patterns of *mORMot* - see below (page 545):

- *Process safety*, mainly for communication stream - e.g. when using HTTPS protocol at the *Client-Server process* (page 319), or a custom cypher within HTTP content-encoding;
- At RESTful / URI *authentication* level - see below (page 547) about *Session*, *Group* and *User* notions;
- Via *authorization* at interface or method (service/operation) level to allow or forbid a given operation.

Let us discuss the two last points now (*authentication* and *authorization*).

By default, the settings are the following for interface-based services:

- All services (i.e. all interfaces) expect one *authentication scheme* to be validated (at least `TSQLRestServerAuthenticationWeak`), i.e. a light session to have been initiated by the client - in short, explicit authentication is mandatory;
- All operations (i.e. all methods) are allowed to execution - in short, authorization is enabled but opened.

You can change these settings on the server side (it's an implementation detail - so it does not make any sense to tune it on the client side) via the `TServiceFactoryServer` instance corresponding to each interface. You can access those instances e.g. from the `TSQLRestServer.Services` property.

To disable the whole service / interface need of authentication, you can use the `ByPassAuthentication` property of the `TServiceFactoryServer` instance corresponding to a given interface. It may be useful e.g. for simple web services which do not expose any sensitive data (e.g. a service catalog, or a service returning public information or even HTML content).

Then, to tune the authorization process at operational (method) level, `TServiceFactoryServer` provides the following methods to change the security policy for each interface:

- `AllowAll()` and `Allow()` to enable methods execution globally;
- `DenyAll()` and `Deny()` to disable methods execution globally;
- `AllowAllByID()` and `AllowByID()` to enable methods execution by Group IDs;
- `DenyAllByID()` and `DenyByID()` to disable methods execution by Group IDs;
- `AllowAllByName()` and `AllowByName()` to enable methods execution by Group names;
- `DenyAllByName()` and `DenyByName()` to disable methods execution by Group names.

The first four methods will affect everybody. The next `*ByID()` four methods accept a list of *authentication Group* IDs (i.e. `TSQLAuthGroup.ID` values), where as the `*ByName()` methods will handle `TSQLAuthGroup.Ident` property values.

In fact, the execution can be authorized for a particular group of authenticated users. Your service can therefore provide some basic features, and then enables advanced features for administrators or supervisors only. Since the User / Group policy is fully customizable in our RESTful authentication scheme - see below (page 547), *mORMot* provides a versatile and inter-operable security pattern.

Here is some extract of the supplied regression tests:

```
(...)  
S := fClient.Server.Services['Calculator'] as TServiceFactoryServer;  
Test([1,2,3,4,5], 'by default, all methods are allowed');  
S.AllowAll;  
Test([1,2,3,4,5], 'AllowAll should change nothing');  
S.DenyAll;  
Test([], 'DenyAll will reset all settings');  
S.AllowAll;  
Test([1,2,3,4,5], 'back to full access for everybody');  
S.DenyAllByID([GroupID]);  
Test([], 'our current user shall be denied');  
S.AllowAll;  
Test([1,2,3,4,5], 'restore allowed for everybody');  
S.DenyAllByID([GroupID+1]);  
Test([1,2,3,4,5], 'this group ID won''t affect the current user');  
S.DenyByID(['Add'], GroupID);  
Test([2,3,4,5], 'exclude a specific method for the current user');  
S.DenyByID(['totext'], GroupID);  
Test([2,3,5], 'exclude another method for the current user');  
(...)
```

In the above regression tests code, the `Test()` local procedure is used to validate the corresponding methods of `ICalculator` according to a set of method indexes (1=*Add*, 2=*Multiply*, 3=*Subtract*, 4=*ToText...*).

In this code, the `GroupID` value was retrieved as such:

```
GroupID := fClient.MainFieldID(TSQLAuthGroup, 'User');
```

And the current authenticated user on the client side has been defined to be a member of the 'User' group:

```
fClient.SetUser('User','synapse'); // default user for Security tests
```

Since `TSQLRestServer.ServiceRegister` and `TSQLRestServer.ServiceDefine` methods return the first created `TServiceFactoryServer` instance, and since all `Allow*` / `AllowAll*` / `Deny*` / `DenyAll*` methods return also a `TServiceFactoryServer` instance, you can use some kind of "fluent interface" in your code to set the security policy, as such:

```
Server.ServiceDefine(TServiceCalculator,[ICalculator],sicShared).  
  DenyAll.AllowAllByName(['Supervisor']);
```

This will allow access to the `ICalculator` methods only for the *Supervisor* group of users.

16.8.3. Implementation class types

Most of the time, your implementation class will inherit from `TInterfacedObject`. As stated above, you could in fact inherit from any plain *Delphi* class: the only condition is that it implements the expected interface, and has a GUID.

But if you need a special process to take place during the class instance initialization, you can inherit from the `TInterfacedObjectWithCustomCreate` class, which provides the following virtual constructor, ready to be overridden with your customized initialization:

```
TInterfacedObjectWithCustomCreate = class(TInterfacedObject)  
public  
  /// this virtual constructor will be called at instance creation  
  constructor Create; virtual;  
end;
```

But from the SOA point of view, it could make sense to use a dedicated method with proper parameters to initialize your instance, e.g. in you are in `sicClientDriven` execution mode. See in *Enhanced sample: remote SQL access* (page 440) some sample code implementing a `IRemoteSQL` service, with a dedicated `Connect()` method to be called before all other methods to initialize a `sicClientDriven` instance.

16.8.4. Server-side execution options (threading)

When a service is registered on the server side, some options can be defined in order to specify its execution details, using the `TServiceFactoryServer.SetOptions()` method.

By default, service methods are called within the thread which received them. That is, when hosted by multi-threaded server instances (e.g. `TSQLite3HttpServer` or `TSQLRestServerNamedPipeResponse`), the method context can be re-entrant - unless it has been defined with `sicSingle` or `sicPerThread` instance lifetime modes. It allows better response time and CPU use, but drawback is that the method implementation shall be thread-safe. This is the technical reason why service implementation methods have to handle multi-threading safety carefully, e.g. by using *Safe locks for multi-thread applications* (page 123) on purpose.

The following execution options are available:

TServiceMethodOptions	Description
<i>none</i> (default)	All methods are re-entrant and shall be coded to be thread-safe
optExecLockedPerInterface	Each interface will be protected/locked by its own <i>mutex</i>
optExecInMainThread optFreeInMainThread	Methods will be executed in the process main thread Interface will be released in the process main thread
optExecInPerInterfaceThread optFreeInPerInterfaceThread	Each interface will execute its methods in its own thread Each interface will be freed in its own thread

Of course, `SetOption()` accepts an optional list of method names, if you want to tune the execution at the method level.

Setting `optExecLockedPerInterface` option will *lock* the specified method(s) execution at the interface level. That is, it won't be possible to have two methods of the same interface be executed concurrently. This option uses a `TRTLCriticalSection` mutex, so is at the same time safe and using very little resources. But it won't guaranty that the method execution will always take place in the same thread: so if you need some per-thread initialization/finalization (e.g. for COM objects), you should better use the other options.

Setting `optExecInMainThread` option will force the specified method(s) to be called within a `RunningThread.Synchronize()` call - it can be used e.g. if your implementation rely heavily on COM objects, or if you want to ensure that your code will work correctly, without the need to worry about thread safety, which can be quite difficult to deal with. The `optFreeInMainThread` option will also ensure that the service class instance will be released in the main thread (i.e. its `Free` method called via `Synchronize`). Since the main thread will be used by all interfaces, it could result into an execution bottleneck.

Setting `optExecInPerInterfaceThread` option will force the specified method(s) to be called within a thread (to be more precise, a `TSynBackgroundThreadSQLRestServerProcedure` class, which will notify the `TSQLSQLRestServer` for the thread context) dedicated to the interface. An associated `optFreeInPerInterfaceThread` option will also ensure that the service class instance will be released in the same thread: it is pretty convenient to use this threading model, for instance if you want to maintain a dedicated `SynDB.pas`-based database connection, or initialize some COM objects.

For instance, if you want all the methods of your `TServiceCalculator` class to be executed in the main thread, you can define:

```
Server.ServiceDefine(TServiceCalculator,[ICalculator],sicShared).
  SetOptions([], [optExecInMainThread]);
```

Or if only the `TServiceCalculator.Add` method has to be protected, you can write:

```
Server.ServiceDefine(TServiceCalculator,[ICalculator],sicShared).
  SetOptions(['Add'], [optExecInMainThread]);
```

In fact, the `SetOptions()` method follows a call signature similar to the one used for defining the service security.

For best performance, you may define your service methods be called without any locking, but rely on some convenient classes defined in `SynCommons.pas` - as the `TAutoLocker` class or the `TLockedDocVariant` kind of storage, for efficient multi-thread process.

A similar thread safety concern also applies to MVVM methods - see below (page 530).

16.8.5. Audit Trail for Services

We have seen previously how the ORM part of the framework is able to provide an *Audit Trail for change tracking* (page 178). It is a very convenient way of storing the change of state of the data. On the other side, in any modern SOA solution, data is not at the center any more, but services. Sometimes, the data is not stored within your server, but in a third-party *Service-Oriented Architecture (SOA)* (page 90). Being able to monitor the service execution of the whole system becomes sooner or later mandatory. Our framework allows to create an *Audit Trail* of any incoming or outgoing service operation, in a secure, efficient and automated way.

16.8.5.1. When logging is not enough

By default, any interface-based service process will be logged by the framework - see below (page 642) - in dedicated `s11ServiceCall` and `s11ServiceReturn` log levels. You may see output similar to the following:

```
18:03:18 Enter    mORMot.TSQLRestServerFullMemory(024500A0).URI(POST
root/DomUserQuery.SelectByLogonName/1 inlen=7)
18:03:18 Service call    mORMot.TSQLRestServerFullMemory(024500A0)
DomUserQuery.SelectByLogonName["979"]
18:03:18 Server      mORMot.TSQLRestServerFullMemory(024500A0)  POST
root/DomUserQuery.SelectByLogonName SOA-Interface -> 200 with outlen=21 in 16 us
18:03:18 Service return    mORMot.TSQLRestServerFullMemory(024500A0) {"result":[0],"id":1}
18:03:18 Leave      00.000.017
```

The above lines match the execution of the following method, as defined in `dddDomUserCQRS.pas`:

```
IDomUserQuery = interface(ICQRSservice)
  ['{198C01D6-5189-4B74-AAF4-C322237D7D53}']
  /// will select a single TUser from its Logon name
  // - then use Get() method to retrieve its content
  function SelectByLogonName(const aLogonName: RawUTF8): TCQRSResult;
  ...
```

The actual execution was:

```
IDomUserQuery.SelectByLogonName('979') -> cqrSuccess
```

Here `cqrSuccess` is the first item of the enumeration result, returned as an integer JSON value `"result":[0]` by the method:

```
TCQRSResult =
  (cqrSuccess, cqrSuccessWithMoreData,
   cqrUnspecifiedError, cqrBadRequest, cqrNotFound,
   ...
```

This detailed log (including micro-second timing on the *"Leave"* rows) is very helpful for support, especially to investigate about any error occurring on a production server. But it will not be enough (or on the contrary provide "too much information" which "kills the information") to monitor the higher level of the process, especially on a server with a lot of concurrent activity.

16.8.5.2. Tracing Service Methods

The framework allows to optionally store each SOA method execution in a database, with the input and output parameters, and accurate timing.

You could enable this automated process:

- Either at service level, using `TServiceFactoryServer.SetServiceLog()`;
- Or for all services of a `TSQLRestServer.ServiceContainer` instance, via `TServiceContainerServer.SetServiceLog()`.

For instance, you may enable it for a whole REST server:

```
(aRestSOAServer.ServiceContainer as TServiceContainerServer).SetServiceLog(
  aRestLogServer, TSQLRecordServiceLog);
```

This single command will create an Audit Trail with all service calls made on aRestSOAServer to the TSQLRecordServiceLog ORM class of aRestLogServer. Keeping a dedicated REST server for the log entries will reduce the overhead on the main server, and ease its maintenance.

Actual storage takes place within a class inheriting from TSQLRecordServiceLog:

```
TSQLRecordServiceLog = class(TSQLRecord)
...
published
  /// the 'interface.method' identifier of this call
  /// - this column will be indexed, for fast SQL queries, with the MicroSec
  /// column (for performance tuning)
  property Method: RawUTF8 read fMethod write fMethod;
  /// the input parameters, as a JSON document
  /// - will be stored in JSON_OPTIONS_FAST_EXTENDED format, i.e. with
  /// shortened field names, for smaller TEXT storage
  /// - content may be searched using JsonGet/JsonHas SQL functions on a
  /// SQLite3 storage, or with direct document query under MongoDB/PostgreSQL
  property Input: variant read fInput write fInput;
  /// the output parameters, as a JSON document, including result: for a function
  /// - will be stored in JSON_OPTIONS_FAST_EXTENDED format, i.e. with
  /// shortened field names, for smaller TEXT storage
  /// - content may be searched using JsonGet/JsonHas SQL functions on a
  /// SQLite3 storage, or with direct document query under MongoDB/PostgreSQL
  property Output: variant read fOutput write fOutput;
  /// the Session ID, if there is any
  property Session: integer read fSession write fSession;
  /// the User ID, if there is an identified Session
  property User: integer read fUser write fUser;
  /// will be filled by the ORM when this record is written in the database
  property Time: TModTime read fTime write fTime;
  /// execution time of this method, in micro seconds
  property MicroSec: integer read fMicroSec write fMicroSec;
end;
```

The ORM will therefore store the following table on its database:

ID : TID
Input : variant
Method : RawUTF8
MicroSec : integer
Output : variant
Session : integer
Time : TModTime
User : integer

ServiceLog Record Layout

As you can see, all input and output parameters are part of the record, as two TDocVariant instances. Since they are stored as JSON/TEXT, you could perform some requests directly on their content, especially if actual storage take place in a *MongoDB* database: you may even use dedicated indexes on the parameter values, and/or run advanced *map/reduce* queries. You can use *optNoLogInput* or *optNoLogOutput* settings with *TInterfaceFactory.SetOptions()* to hide all input or output parameters values, or define some value types as containing *Sensitive Personal Information* (SPI), using *TInterfaceFactory.RegisterUnsafeSPIType*.

Since very accurate timing, with a micro-second resolution, is part of the information, you will be able to make filtering or advanced statistics using simple SQL clauses. It has never been easier to monitor your SOA system, and identify potential issues. You may easily extract this information from your

database, and feed a real-time visual monitoring chart system, for instance. Or identify and spy unusual execution patterns (e.g. unexpected timing or redounding error codes), which will match some SQL requests: those SQL statements may be run automatically on a regular basis, to prevent any problem before it actually happen.

16.8.5.3. Tracing Asynchronous External Calls

Sometimes, your server may be the client of another process. In an SOA environment, you may interface with a third-party REST service for an external process, e.g. sending a real-time notification.

On the REST client instance, you can execute the `TServiceFactoryClient.SendNotifications()` method for a given service:

```
aNotificationClientService.SendNotifications(aServicesLogRest,
    TSQLRecordServiceNotifications, fSettings.NotificationsRetrySeconds);
```

This single command will create an Audit Trail with all notification calls sent to `aNotificationClientService`, in the `TSQLRecordServiceNotifications` ORM class of `aServicesLogRest`.

You may use the following `TSQLRecordServiceNotifications` class:

```
TSQLRecordServiceNotifications = class(TSQLRecordServiceLog)
...
published
    /// when this notification has been sent
    /// - equals 0 until it was actually notified
    property Sent: TTimeLog read fSent write fSent;
end;
```

Which will be stored in the following table:

ID : TID
Sent : TTimeLog
Input : variant
Method : RawUTF8
MicroSec : integer
Output : variant
Session : integer
Time : TModTime
User : integer

ServiceNotifications Record Layout

The additional `Sent` property will contain the `TTimeLog` time-stamp on which the notification will have taken place.

In fact, all methods executed via this notification service will now be first stored in this table, then the remote HTTP notifications will take place asynchronously in the background. Transmission will be in order (first-in-first-out), and in case of any connection problem (e.g. the remote server not returning a 200 HTTP SUCCESS status code), it won't move to the next entry, and will retry after the `NotificationsRetrySeconds` period, as supplied to the `SendNotifications()` method.

Of course, you may define your own sub-class, to customize the destination Audit Trail table:

```
type
    TSQLMyNotifications = class(TSQLRecordServiceNotifications);
```

Thanks to those `TSQLRecordServiceLog` classes, high-level support and analysis has never become easier. The actual implementation of those features has been tuned to minimize the impact on main

performance, by using e.g. delayed write operations via *BATCH sequences for adding/updating/deleting records* (page 351), or a dedicated background thread for the asynchronous notification process.

16.8.6. Transmission content

All data is transmitted as JSON arrays or objects, according to the requested URI.

We'll discuss how data is expected to be transmitted, at the application level.

16.8.6.1. Request format

As stated above, there are several available modes of routing, defined by a given class, inheriting from `TSQLRestServerURIContext`:

Routing via TSQLRestServerURIContext classes hierarchy

The corresponding description may be:

	TSQLRestRoutingREST	TSQLRestRoutingJSON_RPC
Mode	RESTful	JSON-RPC
Default	Yes	No
URI scheme	/Model/Interface.Method[/ClientDrivenID] or /Model/Interface/Method[/ClientDrivenID] + optional URI-encoded params	/Model/Interface
Body content	JSON array of parameters or void if parameters were encoded at URI	{"method": "MethodName", "params": [...] [, "id": ClientDrivenID]}
Body content (alternative)	JSON object of parameters or void if parameters were encoded at URI	{"method": "MethodName", "params": ... [, "id": ClientDrivenID]}
Security	RESTful authentication for each method or for the whole service (interface)	RESTful authentication for the whole service (interface)
Speed	10% faster	10% slower

Most of the time, the input parameters will be transmitted as a JSON array of values, following the exact order of `const / var` method parameters.

As an alternative, a JSON object storing the input parameters by name will be accepted. This will be slightly slower than a JSON array of parameters, but could be handy, depending on the client side.

Last but not least, `TSQLRestRoutingREST` is able to decode parameters encoded at URI level, as most regular historic HTTP requests.

The routing to be used is defined globally in the `TSQLRest.ServiceRouting` property, and should match on both client and server side, of course. By design, you should *never* assign the abstract `TSQLRestServerURIContext` to this property.

The `TSQLRestServerURIContext` abstract class defines the following methods, which will be overridden by inherited implementations to reflect the expected behavior on all aspects of the RESTful routing and transmission:

```
TSQLRestServerURIContext = class
protected
...
  /// retrieve RESTful URI routing
  function URIDecodeREST: boolean; virtual;
  /// retrieve method-based SOA URI routing with optional RESTful mode
  procedure URIDecodeSOAByMethod; virtual;
  /// retrieve interface-based SOA
  procedure URIDecodeSOAByInterface; virtual; abstract;
  /// process authentication
  function Authenticate: boolean; virtual;
  /// direct launch of a method-based service
  procedure ExecuteSOAByMethod; virtual;
  /// direct launch of an interface-based service
  procedure ExecuteSOAByInterface; virtual; abstract;
  /// handle GET/LOCK/UNLOCK/STATE verbs for ORM/CRUD process
  procedure ExecuteORMGet; virtual;
  /// handle POST/PUT/DELETE/BEGIN/END/ABORT verbs for ORM/CRUD process
  procedure ExecuteORMWrite; virtual;
...
```

Most of the time, the supplied `TSQLRestRoutingREST` and `TSQLRestRoutingJSON_RPC` classes will meet your requirements.

16.8.6.1.1. REST mode

16.8.6.1.1.1. Parameters transmitted as JSON array

In the default `TSQLRestRoutingREST` mode, both service and operation (i.e. interface and method) are identified within the URI. And the message body is a standard JSON array of the supplied parameters (i.e. all const and var parameters).

Here is typical request for `ICalculator.Add`:

```
POST /root/Calculator.Add
(...)
[1,2]
```

Here we use a POST verb, but the framework will also allows other methods like GET, if needed (e.g. from a regular browser). The pure *Delphi* client implementation will use only POST.

For a `sicClientDriven` mode service, the needed instance ID is appended to the URI:

```
POST /root/ComplexNumber.Add/1234
(...)
[20,30]
```

Here, 1234 is the identifier of the server-side instance ID, which is used to track the instance life-time, in `sicClientDriven` mode. One benefit of transmitting the Client Session ID within the URI is that it will be more secure in our RESTful authentication scheme - see below (page 547): each method (and even any client driven session ID) will be signed properly.

16.8.6.1.1.2. Parameters transmitted as JSON object

The *mORMot* server will also accept the incoming parameters to be encoded as a JSON object of named values, instead of a JSON array:

```
POST /root/Calculator.Add
(...)
{"n1":1,"n2":2}
```

Of course, order of the values is not mandatory in a JSON object, since parameters will be lookup by name. As a result, the following request will be the same as the previous one:

```
POST /root/Calculator.Add
(...)
{"n2":2,"n1":1}
```

For a *sicClientDriven* mode service, the needed instance ID is appended to the URI:

```
POST /root/ComplexNumber.Add/1234
(...)
{"aReal":20,"aImaginary":30}
```

In some cases, naming the parameters could be useful, on the client side. But this should not be the default, since it will be slightly slower (for parsing and checking the names), and use more bandwidth at transmission.

Any missing parameter in the incoming JSON object will be replaced by its default value. For instance, the following will run *IComplexNumber.Add(0,2)*:

```
POST /root/Calculator.Add
(...)
{"n2":2}
```

Any unknown parameter in the incoming JSON object will just be ignored. It could be handy, if you want to transmit some generic execution context (e.g. a global "data scope" in a MVC model), and let the service use only the values it needs.

```
POST /root/ComplexNumber.Add/1234
(...)
{"Session":"1234","aImaginary":30,"aReal":20,"UserLogged":"Nikita"}
```

Of course, the extra values will consume some bandwidth for nothing, but the process cost on the server side will be negligible, since our implementation will just ignore those unexpected properties, without allocating any memory for them.

16.8.6.1.1.3. Parameters encoded at URI level

In this *TSQLEstRoutingREST* mode, the server is also able to retrieve the parameters from the URI, if the message body is left void. This is not used from a *Delphi* client (since it will be more complex and therefore slower), but it can be used for a client, if needed:

```
POST root/Calculator.Add?+%5B+1%2C2+%5D
GET root/Calculator.Add?+%5B+1%2C2+%5D
```

In the above line, *+%5B+1%2C2+%5D* will be decoded as *[1,2]* on the server side. In conjunction with the use of a GET verb, it may be more suitable for a remote AJAX connection.

As an alternative, you can encode and name the parameters at URI level, in a regular HTML fashion:

```
GET root/Calculator.Add?n1=1&n2=2
```

Since parameters are named, they can be in any order. And if any parameter is missing, it will be replaced by its default value (e.g. 0 for a number or '' for a string).

This may be pretty convenient for simple services, consumed from any kind of client.

Note that there is a known size limitation when passing some data with the URI over HTTP. Official RFC 2616 standard advises to limit the URI size to 255 characters, whereas in practice, it sounds safe to transmit up to 2048 characters within the URI. If you want to get rid of this limitation, just use the default transmission of a JSON array as request body.

As an alternative, the URI can be written as `/RootName/InterfaceName/MethodName`. It may be more RESTful-compliant, depending on your client policies. The following URIs will therefore be equivalent to the previous requests:

```
POST /root/Calculator/Add
POST /root/ComplexNumber/Add/1234
POST /root/Calculator/Add?+%5B+1%2C2+%5D
GET /root/Calculator/Add?+%5B+1%2C2+%5D
GET /root/Calculator/Add?n1=1&n2=2
```

From a *Delphi* client, the `/RootName/InterfaceName.MethodName` scheme will always be used.

16.8.6.1.1.4. Sending a JSON object

By default, the *mORMot* client will send all values, transmitted as a JSON array without any parameter name, as we have seen:

```
POST /root/Calculator.Add
(...)
[1,2]
```

But if `TServiceFactoryClient.ParamsAsJSONObject` is set to true, the transmitted values from the client side will be encoded as a JSON object:

```
POST /root/Calculator.Add
(...)
{"n1":1,"n2":2}
```

This may help transmitting some values to a non-*mORMot* server, in another format, for a given service.

16.8.6.1.1.5. Sending raw binary

If your purpose is to upload some binary data, `RawByteString` and `TSQLRawBlob` input parameters will by default be transmitted as Base64 encoded JSON text.

You may define *Client-Server services via methods* (page 374) to transmit raw binary, without the Base64 encoding overhead. It would allow low-access to the input content type and encoding, even with multi-part file upload from HTTP.

As an alternative, if you use default `TSQLRestRoutingREST` routing, and defined a single `RawByteString` or `TSQLRawBlob` input parameter, it will be processed as a raw POST with binary body defined with mime-type 'application/octet-stream'. This may be more optimized for remote access over the Internet.

16.8.6.1.2. JSON-RPC

16.8.6.1.2.1. Parameters transmitted as JSON array

If `TSQLRestRoutingJSON_RPC` mode is used, the URI will define the interface, and then the method name will be inlined with parameters, e.g.

```
POST /root/Calculator
(...)
{"method":"Add","params":[1,2],"id":0}
```

Here, the "id" field can be not set (and even not existing), since it has no purpose in sicShared mode.

For a sicClientDriven mode service:

```
POST /root/ComplexNumber
(...)
{"method": "Add", "params": [20, 30], "id": 1234}
```

16.8.6.1.2.2. Parameters transmitted as JSON object

As an alternative, you may let the values be transmitted as a JSON object containing the named parameters values, instead of a JSON array:

```
POST /root/Calculator
(...)
{"method": "Add", "params": {"n1": 1, "n2": 2}, "id": 0}
```

Here, the same rules applies than in TSQLRestRoutingREST mode:

- Any missing parameter will be replaced by its default value;
- Properties order is not sensitive anymore;
- Unexpected parameters will just be ignored.

Note that by definition, TSQLRestRoutingJSON_RPC mode is not able to handle URI-encoded parameters. In fact, the JSON-RPC mode expects the URI to be used only for identifying the service, and have the whole execution context transmitted as body.

16.8.6.1.3. REST mode or JSON-RPC mode?

For a standard *mORMot* Delphi client, or any supported *Cross-Platform* client - see below (page 482) - TSQLRestRoutingREST is preferred. The supplied libraries, even for *Smart Mobile Studio*, fully implement this routing scheme. It is the faster, safer and most modular mode available.

In practice, TSQLRestRoutingJSON_RPC mode has been found to be a little bit slower. Since the method name will be part of the URI, the signature will have a bigger extent than in JSON-RPC mode, so it will be more secure. Its ability to retrieve URI-encoded parameters could be also useful, e.g. to server some dynamic HTML pages in addition to the SOA endpoints, with proper HTTP caching abilities.

Of course, TSQLRestRoutingJSON_RPC mode may be used as an alternative, depending on the client expectations, and technology limitations, e.g. if your client expect a JSON-RPC compatible communication.

It's up to you to select the right routing scheme to be used, depending on your needs.

16.8.6.2. Response format

16.8.6.2.1. Standard answer as JSON object

16.8.6.2.1.1. JSON answers

16.8.6.2.1.1.1. Returning as JSON array

The framework will always return the data in the same format, whatever the routing mode used.

Basically, this is a JSON object, with one nested "result": property, and the client driven "id": value (e.g. always 0 in sicShared mode):

```
POST /root/Calculator.Add
(...)
[1,2]
```

will be answered as such:

```
{"result":[3]}
```

For a `sicClientDriven`, `sicPerSession`, `sicPerUser`, `sicPerGroup` or `sicPerThread` mode service, the answer will contain an additional `"id":...` member, which will identify the corresponding session:

```
{"result":[3],"id":1234}
```

In `sicSingle` and `sicShared` modes, the `"id":0` member is just not emitted.

The *result* JSON array contains all var and out parameters values (in their declaration order), and then the method main result.

For instance, here is a transmission stream for a `ICalculator.ComplexCall` request in `TSQLEstRoutingREST` mode:

```
POST root/Calculator.ComplexCall
(...)
[[288722014,1231886296], ["one","two","three"], ["ABC","DEF","GHIJK"],
"if{BgAAAAAAAAAAAAAAAAAACNE01xEZXZcbG1iXFNRtG10ZTNcZXh1XFRlc3RTUuwzLmV4ZQ==",
"if{Xow1EdkXbUkDYWJj}"]
```

will be answered as such:

```
'{"result":["ABC","DEF","GHIJK","one,two,three"], "if{X4w1EdgXbUkUMjg4NzIyMDE0LDEyMzE4ODYyOTY=",
"if{Xow1EdkXbUkYRDpcRGV2XGxpY1xTUUxpdGUzXGV4ZVxUZXR0U1FMMy5leGU="}]}'
```

It matches the `var / const / out` parameters declaration of the method:

```
function ComplexCall(const Ints: TIntegerDynArray; Strs1: TRawUTF8DynArray;
  var Str2: TWideStringDynArray; const Rec1: TVirtualTableModuleProperties;
  var Rec2: TSQLEstCacheEntryValue): TSQLEstCacheEntryValue;
```

And its implementation:

```
function TServiceCalculator.ComplexCall(const Ints: TIntegerDynArray;
  Strs1: TRawUTF8DynArray; var Str2: TWideStringDynArray; const Rec1: TVirtualTableModuleProperties;
  var Rec2: TSQLEstCacheEntryValue): TSQLEstCacheEntryValue;
var i: integer;
begin
  result := Rec2;
  result.JSON := StringToUTF8(Rec1.FileExtension);
  i := length(Str2);
  SetLength(Str2,i+1);
  Str2[i] := UTF8ToWideString(RawUTF8ArrayToCSV(Strs1));
  inc(Rec2.ID);
  dec(Rec2.Timestamp);
  Rec2.JSON := IntegerDynArrayToCSV(Ints,length(Ints));
end;
```

Note that `TIntegerDynArray`, `TRawUTF8DynArray` and `TWideStringDynArray` values were marshaled as JSON arrays, whereas complex records (like `TSQLEstCacheEntryValue`) have been Base64 encoded.

If you want to transmit some binary blob content, consider using a `RawByteString` kind of parameter, which will transmit a Base64-encoded JSON text on the wire.

The framework is able to handle class instances as parameters, for instance with the following interface, using a `TPersistent` child class with published properties (it will be the same for `TSQLEstRecord` ORM instances):

```
type
  TComplexNumber = class(TPersistent)
  private
    fReal: Double;
    fImaginary: Double;
  public
    constructor Create(aReal, aImaginary: double); reintroduce;
  published
    property Real: Double read fReal write fReal;
    property Imaginary: Double read fImaginary write fImaginary;
  end;

  IComplexCalculator = interface(ICalculator)
  ['{8D0F3839-056B-4488-A616-986CF8D4DEB7}']
    /// purpose of this unique method is to subtract two complex numbers
    // - using class instances as parameters
    procedure Subtract(n1,n2: TComplexNumber; out Result: TComplexNumber);
  end;
```

As stated above, it is not possible to return a class as a result of a function (who will be responsible of handling its life-time?). So in this method declaration, the result is declared as out parameter.

During the transmission, published properties of TComplexNumber parameters will be serialized as standard JSON objects within the "result":[...] JSON array:

```
POST root/ComplexCalculator.Subtract
(...)
[{"Real":2,"Imaginary":3},{ "Real":20,"Imaginary":30}]
```

will be answered as such:

```
{"result":[{"Real":-18,"Imaginary":-27}]}
```

16.8.6.2.1.1.2. Returning a JSON object

Note that if TServiceFactoryServer.ResultAsJSONObject is set to true, the outgoing values won't be emitted within a "result":[...] JSON array, but via a "result":{"..."} JSON object, with the var/out parameter names as object fields, and "Result": for a function result:

```
{"result":{"Result":{"Real":-18,"Imaginary":-27}}}
```

The TServiceFactoryServer.ResultAsJSONObjectWithoutResult property may be used to avoid the main "Result": object.

Instead of this JSON array content, returned by default:

```
GET root/Calculator/Add?n1=1&n2=2
...
{"result":[3]}
```

The following JSON will be returned if TServiceFactoryServer.ResultAsJSONObject is true:

```
GET root/Calculator/Add?n1=1&n2=2
...
{"result":{"Result":3}}
```

Or, if TServiceFactoryServer.ResultAsJSONObjectWithoutResult is true:

```
GET root/Calculator/Add?n1=1&n2=2
...
{"Result":3}
```

All those JSON array or object contents fulfill perfectly standard JSON declarations, so can be generated and consumed directly by any AJAX client. The TServiceFactoryServer.ResultAsJSONObject option make it even easier to consume mORMot services, since all outgoing values will be named in the "result": JSON object.

16.8.6.2.1.2. Returning raw JSON content

By default, if you want to transmit a JSON content with interface-based services, using a RawUTF8 will convert it to a JSON string. Therefore, any JSON special characters (like " or \ or []) will be escaped. This will slow down the process on both server and client side, and increase transmission bandwidth.

For instance, if you define such a method:

```
function TServiceRemoteSQL.Execute(const aSQL: RawUTF8; aExpectResults, aExpanded: Boolean): RawUTF8;
var res: ISQLDBRows;
begin
  if fProps=nil then
    raise Exception.Create('Connect call required before Execute');
  res := fProps.ExecuteInlined(aSQL,aExpectResults);
  if res=nil then
    result := '' else
    result := res.FetchAllAsJSON(aExpanded);
end;
```

The FetchAllAsJSON() method will return a JSON array content, but will be escaped as a JSON string when transmitted via a RawUTF8 variable.

A dedicated RawJSON type has been defined, and will specify to the mORMot core that the UTF-8 text is a valid JSON content, and should not be escaped.

That is, defining the method as followed will increase process speed and reduce used bandwidth:

```
function TServiceRemoteSQL.Execute(const aSQL: RawUTF8; aExpectResults, aExpanded: Boolean): RawJSON;
```

See sample "16 - Execute SQL via services" for some working code using this feature.

As a consequence, using RawJSON will also make the transmitted content much more AJAX friendly, since the returned value will be a valid JSON array or object, and not a JSON string which will need JavaScript "unstringification".

16.8.6.2.1.3. Returning errors

In case of an error, the standard message object will be returned:

```
{
  "ErrorCode":400,
  "ErrorText":"Error description"
}
```

The following error descriptions may be returned by the service implementation from the server side:

ErrorText	Description
Method name required	TSQLRestRoutingJSON_RPC call without "method": field
Unknown method	TSQLRestRoutingJSON_RPC call with invalid method name (in this mode, there is no specific message, since a JSON answer may be a valid request)
Parameters required	The server expect at least a void JSON array (aka []) as parameters
Unauthorized method	This method is not allowed with the current authenticated user group - see <i>Security</i> above

Not allowed to publish signature	The client requested the interface signature, but this has not been allowed on the server policy (see <code>TServiceContainerServer. PublishSignature</code>)
... instance id:? not found or deprecated	The supplied "id": parameter points to a wrong instance (in <code>sicPerSession</code> / <code>sicPerUser</code> / <code>sicPerGroup</code> mode)
ExceptionClass: Exception Message (with 500 Internal Server Error)	An exception was raised during method execution

On the client side, you may encounter the following `EInterfaceFactoryException` messages, starting with the generic 'Invalid fake IInterfaceName.MethodName interface call' text:

ErrorText	Description
unexpected self	<code>self</code> does exist as low-level implementation detail, but is not intended to be transmitted
JSON array/object result expected	content returned from the Server was neither a JSON array nor a JSON object
unexpected parameter "..."	the Server returned a JSON object with an unknown or invalid member name
returned object record variant array RawJSON	a returned <code>class</code> , record, variant, dynamic array of <code>RawJSON</code> value was not properly serialized
missing or invalid value	a returned string or numerical value is not valid JSON content

16.8.6.2.2. Returning content as XML

By default, interface-based services of a *mORMot* server will always return a JSON array. But you may (or a JSON object, if `TServiceFactoryServer.ResultAsJSONObject` or `ResultAsJSONObjectWithoutResult` is true).

With some kind of clients (e.g. if they are made by a third party), it could be useful to return XML content instead.

Your *mORMot* server is able to let its interface-based services return XML context instead, or in addition to the default JSON format.

16.8.6.2.2.1. Always return XML content

If you want all methods of a given interface to return XML content instead of JSON, you can set `TServiceFactoryServer.ResultAsXMLObject` to true.

Instead of this JSON array content, returned by default:

```
GET root/Calculator/Add?n1=1&n2=2
...
{"result": [3]}
```

The following XML will be returned if `TServiceFactoryServer.ResultAsXMLObject` is true:

```
GET root/Calculator/Add?n1=1&n2=2
...
```

```
<?xml version="1.0" encoding="UTF-8"?>
<result><Result>3</Result></result>
```

Conversion is processed from the JSON content generated by the *mORMot* kernel, via a call to `JSONBufferToXML()` function, which performs the XML generation without almost no memory allocation. So only a slightly performance penalty may be noticed (much faster in practice than most node-based XML producers available).

One drawback of using this `TServiceFactoryServer.ResultAsXMLObject` property is that your regular *Delphi* or *AJAX* clients won't be able to consume the service any more, since they expect JSON content.

If you want your service to be consumed either by XML and JSON, you will need two services. You can therefore define a dedicated interface to return XML, and then register this interface to return only XML:

```
type
  ICalculator = interface(IInvokable)
    ['{9A60C8ED-CEB2-4E09-87D4-4A16F496E5FE}']
    /// add two signed 32-bit integers
    function Add(n1,n2: integer): integer;
  end;
  ICalculatorXML = interface(ICalculator)
    ['{0D682D65-CE0F-441B-B4EC-2AC75E357EFE}']
  end; // no additional method, just new name and GUID

  TServiceCalculator = class(TInterfacedObject, ICalculator, ICalculatorXML)
  public // implementation class should implement both interfaces
    function Add(n1,n2: integer): integer;
  end;

...
aServer.ServiceRegister(TServiceCalculator,[TypeInfo(ICalculator)],sicShared);
aServer.ServiceRegister(TServiceCalculator,[TypeInfo(ICalculatorXML)],sicShared).
  ResultAsXMLObject := True;
...
```

There will therefore be two running service instances (e.g. here two instances of `TServiceCalculator`, one for `ICalculator` and one for `ICalculatorXML`). It could be an issue, in some cases.

And such a dedicated interface may need more testing and code on the server side, since they will be accessible from two URIs:

```
GET root/Calculator/Add?n1=1&n2=2
...
{"result":{"Result":3}}
```

and for `ICalculatorXML` interface:

```
GET root/CalculatorXML/Add?n1=1&n2=2
...
<?xml version="1.0" encoding="UTF-8"?>
<result><Result>3</Result></result>
```

16.8.6.2.2. Return XML content on demand

As an alternative, you can let the *mORMot* server inspect the incoming HTTP headers, and return the content as XML if the "Accept: " header is exactly "application/xml" or "text/xml".

You can set the `TServiceFactoryServer.ResultAsXMLObjectIfAcceptOnlyXML` property to enable this HTTP header detection:

```
aServer.ServiceRegister(TServiceCalculator,[TypeInfo(ICalculator)],sicShared).
```

```
ResultAsXMLObjectIfAcceptOnlyXML := true;
```

For standard requests, the incoming HTTP header will be either void, either "Accept: */*", so will return JSON content.

But if the client set either "Accept: application/xml" or "Accept: text/xml" in its header, then it will return an XML document.

Instead of this JSON content:

```
GET root/Calculator/Add?n1=1&n2=2
Accept: */*
...
{"result":{"Result":3}}
```

The following XML will be returned:

```
GET root/Calculator/Add?n1=1&n2=2
Accept: application/xml
...
<?xml version="1.0" encoding="UTF-8"?>
<result><Result>3</Result></result>
```

as it will with "text/xml":

```
GET root/Calculator/Add?n1=1&n2=2
Accept: text/xml
...
<?xml version="1.0" encoding="UTF-8"?>
<result><Result>3</Result></result>
```

Note that the header is expected to be "Accept: application/xml" or "Accept: text/xml" as *exact value*.

For instance "Accept: text/html,application/xml,*/*" won't be detected by the server, and will return regular JSON:

```
GET root/Calculator/Add?n1=1&n2=2
Accept: text/html,application/xml,*/*
...
{"result":{"Result":3}}
```

Your XML client should therefore be able to force the exact content of the HTTP "Accept:" header.

Together with parameter values optionally encoded at URI level - available with TSQLRestRoutingREST default routing scheme (see ?n1=1&n2=2 above)- it could be an useful alternative to consume *mORMot* services from any XML-based client.

16.8.6.2.3. Custom returned content

Note that even if the response format is a JSON object by default, and expected as such by our TServiceContainerClient implementation, there is a way of returning any content from a remote request.

It may be used by AJAX or HTML applications to return any kind of data, i.e. not only JSON results, but pure text, HTML or even binary content. Our TServiceFactoryClient instance is also able to handle such requests, and will save client-server bandwidth when transmitting some BLOB data (since it won't serialized the content with Base64 encoding).

In order to specify a custom format, you can use the following TServiceCustomAnswer record type as the result of an interface function:

```
TServiceCustomAnswer = record
  Header: RawUTF8;
  Content: RawByteString;
```

```
Status: cardinal;  
end;
```

The Header field shall be not null (i.e. not equal to ""), and contains the expected content type header (e.g. TEXT_CONTENT_TYPE_HEADER or HTML_CONTENT_TYPE_HEADER).

Then the Content value will be transmitted back directly to the client, with no JSON serialization. Of course, no var nor out parameter will be transmitted (since there is no JSON result array any more).

Finally, the Status field could be overridden with a property HTML code, if the default HTTP_SUCCESS is not enough for your purpose. Note that when consumed from *Delphi* clients, HTTP_SUCCESS is expected to be returned by the server: you should customize Status field only for plain AJAX / web clients.

In order to implement such method, you may define such an interface:

```
IComplexCalculator = interface(ICalculator)  
  ['{8D0F3839-056B-4488-A616-986CF8D4DEB7}']  
  function TestBlob(n: TComplexNumber): TServiceCustomAnswer;  
end;
```

This may be implemented for instance as such:

```
function TServiceComplexCalculator.TestBlob(n: TComplexNumber): TServiceCustomAnswer;  
begin  
  Result.Header := TEXT_CONTENT_TYPE_HEADER;  
  Result.Content := FormatUTF8('%',%, [n.Real, n.Imaginary]);  
  // leave Result.Header to its default value  
end;
```

This will return not a JSON object, but a plain TEXT content.

Regression tests will make the following process:

```
with CC.TestBlob(C3) do begin  
  Check(Header=TEXT_CONTENT_TYPE_HEADER);  
  Check(Content=FormatUTF8('%',%, [C3.Real, C3.Imaginary]));  
end;
```

Note that since there is only one BLOB content returned, no var nor out parameters are allowed to be defined for this method. If this is the case, an exception will be raised during the interface registration step. But you can define any const parameter needed, to specify your request.

You may also be able to use this feature to implement custom UTF-8 HTML creation, setting the Header value to HTML_CONTENT_TYPE_HEADER constant, and using our fast below (page 506) for the rendering.

Remember that in TSQLRestRoutingJSON mode, you can encode any simple parameter value at URI level, to transmit your browsing context.

16.9. Comparison with WCF

Microsoft *Windows Communication Foundation* is the unified programming model provided by Microsoft for building service-oriented applications.

See <http://msdn.microsoft.com/en-us/library/dd456779..>

Here is a short reference table of WCF / *mORMot* SOA features and implementation of the RESTful pattern.

Feature	WCF	mORMot
Internal design	SOAP with REST integration	RESTful
Hosting	exe/service/ISS/WAS	in-process/exe/service
Scalability/balancing	up to WAS	by dedicated hosting
MetaData	WSDL+XML	JSON contract
Service contract	interface	interface
Data contract	class	class/record
ORM integration	separated	integrated in the model
URI definition	attribute-driven	REST/JSON-RPC convention-driven, or class-driven
Service contract	interface + attributes	interface + shared Model
Versioning	XML name-space	interface signature
Message protocol	SOAP/custom	RESTful
Messaging	single/duplex	stateless (like HTTP)
Sequence	attributes on methods	interface life time
Transactional	fully transactional	on implementation side
Instance life time	per call, per session, single	per call, per session, per user, per group, per thread, single, client-driven
Configuration	.config file or code	<i>convention over configuration</i> optionally tuned by code
Client access	Layer source should be generated	No layer, but direct registration
End points	One end-point per contract	Unique or shared end-point
Operation	synchronous/asynchronous	synchronous (REST)
Session	available (optional)	available (optional)

Encryption	at Service level	at communication level
Compression	at Service level	at communication level
Serialization	XML/binary/JSON	JSON/XML/custom
Communication protocol	HTTP/HTTPS/TCP/pipe/MSMQ	HTTP/HTTPS/TCP/pipe/messages /in-process
HTTP/HTTPS server	<i>http.sys</i>	<i>http.sys</i> /native (winsock)
Authentication	Windows or custom	Windows, ORM-based, or class-driven
Authorization	by attribute or config files	per user group, or class-driven
Threading	by attributes	at service/method level
Weight	middle (GC, JIT, .dll)	low
Speed	good	high
Extensibility	verbose but complete	customizable
Standard	de facto	KISS design (e.g. JSON, HTTP)
Source code	closed	published
License	proprietary	Open
Price	depends	Free
Support	official + community	Synapse + community
Runtime required	.Net framework (+ISS/WAS)	none (blank OS)

About instance life time, note that in WCF InstanceContextMode.Single is in fact the same as sicShared within *mORMot* context: only one instance is used for all incoming calls and is not recycled subsequent to the calls. Therefore, sicSingle mode (which is *mORMot*'s default) maps InstanceContextMode.PerCall in WCF, meaning that one instance is used per call.

We may be tempted to say that *mORMot* SOA architecture is almost complete, even for a young and *Open Source* project. Some features (like *per user*, *per group* or *client-driven* instance life time, or Windows Messages local communication) are even unique to *mORMot*. In fact, sicClientDriven is pretty convenient when implementing a Service Oriented Architecture.

Of course, WCF features its SOAP-based architecture. But WCF also suffers from it: due to this ground-up message design, it will always endure its SOAP overweight, which is "Simple" only by name, not by reputation.

If you need to communicate with an external service provider, you can easily create a SOAP gateway from *Delphi*, as such:

- Import the WSDL (Web Service Definition Language) definition of a web service and turn it into a *Delphi* import unit;
- Publish the interface as a *mORMot* server-side implementation class.

Since SOAP features a lot of requirements, and expects some plumping according to its format

(especially when services are provided from C# or Java), we choose to not re-invent the wheel this time, and rely on existing *Delphi* libraries (available within the *Delphi* IDE) for this purpose. If you need a cross-platform SOAP 1.1 compatible solution, or if your version of *Delphi* does not include SOAP process, you may take a look at http://wiki.freepascal.org/Web_Service_Toolkit.. which is a web services package for FPC, Lazarus and *Delphi*.

But for service communication within the *mORMot* application domain, the RESTful / JSON approach gives much better performance and ease of use. You do not have to play with WSDL or unit wrappers, just share some interface definition between clients and servers. Once you have used the `ServiceRegister()` or `ServiceDefine()` methods of *mORMot*, you will find out how the WCF plumbing is over-sized and over-complicated: imagine that WCF allows only one end-point per interface/contract - in a *SOLID design principles* (page 390) world, where *interface segregation* should reign, it is not the easier way to go!

Optionally, *mORMot*'s interface based services allow to publish their result as XML, and encode the incoming parameters at URI level. It makes it a good alternative to SOAP, in the XML world.

At this time, the only missing feature of *mORMot*'s SOA is transactional process, which must be handled on server side, within the service implementation (e.g. with explicit commit or rollback).

17. Cross-Platform clients

Adopt a mORMot

Current version of the main framework units target only *Win32 / Win64* systems under Delphi, and (in a preliminary state) *Windows* or *Linux* under FPC.

It allows to make easy self-hosting of *mORMot* servers for local business applications in any corporation, or pay cheap hosting in the Cloud, since *mORMot* CPU and RAM expectations are much lower than a regular IIS-WCF-MSSQL - .Net stack.

But in a *Service-Oriented Architecture (SOA)* (page 90), you will probably need to create clients for platforms outside the support platform sets world, especially mobile devices or AJAX applications.

A set of cross-platform client units is therefore available in the *CrossPlatform* sub-folder of the source code repository. It allows writing any client in modern *object pascal* language, for:

- Any version of *Delphi*, on any platform (*Mac OSX*, or any mobile supported devices);
- *FreePascal* Compiler (in 2.6.4, 2.7.1 or 3.x branches - preferred is 3.2 fixes);
- *Smart Mobile Studio* (2.1 and up), to create AJAX or mobile applications (via *PhoneGap*, if needed).

The units are the following:

Unit Name	Description
<code>SynCrossPlatformREST.pas</code>	Main unit, implementing secured ORM and SOA RESTful client
<code>SynCrossPlatformCrypto.pas</code>	SHA256 and crc32 algorithms, used for authentication
<code>SynCrossPlatformJSON.pas</code>	Optimized JSON process (not used by <i>Smart</i>)
<code>SynCrossPlatformSpecific.pas</code>	System-specific functions, e.g. HTTP clients

This set of units will provide a solid and shared ground for the any kind of clients:

- Connection to a *mORMot* server via HTTP, with full REST support;
- Support of weak or default authentication to secure the transfer - see below (page 547);
- Definition of the *TSQLRecord* class, using RTTI when available on *Delphi* or *FreePascal*, and generated code for *Smart Mobile Studio*;
- Remote CRUD operations, via JSON and REST, with a *TSQLRestClientURI* class, with the same methods as with the *mORMot .pas* framework unit;
- Optimized *TSQLTableJSON* class to handle a JSON result table, as returned by *mORMot*'s REST server ORM - see *JSON (not) expanded layouts* (page 317);
- Batch process - see *BATCH sequences for adding/updating/deleting records* (page 351) - for transactional and high-speed writes;
- *Client-Server services via methods* (page 374) with parameters marshalling;
- *Client-Server services via interfaces* (page 420) with parameters marshalling and instance-life time;
- Mapping of most supported field types, including e.g. ISO 8601 date/time encoding, BLOBs and *TModTime/TCreateTime* - see *TSQLRecord fields definition* (page 131);
- Complex record types are also exported and consumed via JSON, on all platforms (for both ORM and SOA methods);
- Integrated debugging methods, used by both ORM and SOA process, able to log into a local file or to a remote server - see below (page 640);
- Some cross-platform low-level functions and types definitions, to help share as much code as possible between your projects.

In the future, C# or Java clients may be written.

The *CrossPlatform* sub-folder code could be used as reference, to write minimal and efficient clients on any platform. Our REST model is pretty straightforward and standard, and use of JSON tends to leverage a lot of potential marshalling issues which may occur with XML or binary formats.

In practice, a code generator embedded in the *mORMot* server can be used to create the client wrappers, using the below (page 506) included on the server side. With a click, you can generate and download a client source file for any supported platform. A set of *.mustache* templates is available, and can be customized or extended to support any new platform: any help is welcome, especially for targeting Java or C# clients.

17.1. Available client platforms

17.1.1. Delphi FMX / FreePascal FCL cross-platform support

Latest versions of *Delphi* include the *FireMonkey* (FMX) framework, able to deliver multi-device, true native applications for *Windows*, *Mac OSX*, *Android* and *iOS (iPhone/iPad)*.

Our *SynCrossPlatform** units are able to easily create clients for those platforms.

Similarly, these units can be compiled with FreePascal, so that any *mORMot* server could be consumed from the numerous supported platforms of this compiler.

In order to use those units, ensure in your IDE that the *CrossPlatform* sub-folder of the *mORMot* source code repository is defined in your *Library Search Path*.

17.1.1.1. Cross-platform JSON

We developed our own cross-platform JSON process unit in *SynCrossPlatformJSON.pas*, shared with *Delphi* and *FreePascal*.

In fact, it appears to be easier to use (since it is variant-based and with *late-binding* abilities) and run much faster than the official *DBXJSON.pas* unit shipped with latest versions of *Delphi*, as stated by the "25 - JSON performance" sample:

2.2. Table content:

```
- Synapse crossplatform: 41,135 assertions passed 20.56ms 400,048/s 1.9 MB
- DBXJSON: 41,136 assertions passed 240.84ms 34,159/s 9.9 MB
```

Our *TSQLTableJSON* class is more than 10 times faster than standard *DBXJSON* unit, when processing a list of results as returned by a *mORMot* server.

The latest value on each line above is the memory consumption. It should be of high interest on mobile platforms, where memory allocation tends to be much slower and sensitive than on Windows (where the *FastMM4* memory manager does wonders). Our unit consumes 5 times less memory than the RTL's version.

We did not include *XSuperObject* here, which is cross-platform, but performs even worse than *DBXJSON* in terms of speed. Other libraries - as *SuperObject* or *dwsJSON* - are not cross-platform.

See <http://blog.synapse.info/post/json-benchmark-delphi-mormot-superobject-dwsjson-dbxjson..> for details about this comparison.

A special mention is due to *dwsJSON*, which performs very well, but only on Windows, and is slower than *mORMot*'s implementation:

```
- Synapse ORM loop: 41,135 assertions passed 6.18ms 1,330,153/s 1.1 MB
- Synapse ORM list: 41,135 assertions passed 6.47ms 1,270,775/s 952 KB
- Synapse crossplatform: 41,135 assertions passed 20.56ms 400,048/s 1.9 MB
- Super object properties: 41,136 assertions passed 2.20s 3,739/s 6.3 MB
- dwsJSON: 41,136 assertions passed 32.05ms 256,628/s 4.7 MB
- DBXJSON: 41,136 assertions passed 240.84ms 34,159/s 9.9 MB
```

The "Synapse ORM" lines stand for the *TSQLTableJSON* class as implemented in *mORMot.pas*. It uses our optimized UTF-8 functions and classes, in-place escaping together with our *RawUTF8* custom string type as implemented in *SynCommons.pas*, so that it is 3 times faster than our cross-platform units, and 40 times than *DBXJSON*, using much less memory. Some tricks used by Synapse ORM rely on pointers and are not compatible with the *NextGen* compiler or the official *Delphi* road-map, so the Synapse crossplatform uses diverse algorithm, but offers still pretty good performance.

This unit features a *TJSONVariantData* custom variant type, similar to *TDocVariant custom variant*

type (page 112), available in the main *mORMot* framework.
It allows writing such nice and readable code, with late-binding:

```
var doc: variant;
    json, json2: string;
...
doc := JSONVariant('{"test":1234,"name":"Joh\\n\\r","zero":0.0}');
assert(doc.test=1234);
assert(doc.name='Joh"n"#13);
assert(doc.name2=null);
assert(doc.zero=0);
json := doc; // conversion to JSON text when assigned to a string variable
assert(json='{"test":1234,"name":"Joh\\n\\r","zero":0}');
doc.name2 := 3.1415926;
doc.name := 'John';
json := doc;
assert(json='{"test":1234,"name":"John","zero":0,"name2":3.1415926}');
```

The unit is also able to serialize any *TPersistent* class, i.e. all published properties could be written or read from a JSON object representation. It also handles nested objects, stored as *TCollection*.
See for instance in the *SynCrossPlatformTests* unit:

```
type
  TMainNested = class(TCollectionItem)
  private
    fNumber: double;
    fIdent: RawUTF8;
  published
    property Ident: RawUTF8 read fIdent write fIdent;
    property Number: double read fNumber write fNumber;
  end;

  TMain = class(TPersistent)
  private
    fName: RawUTF8;
    fNested: TCollection;
    fList: TStringList;
  public
    constructor Create;
    destructor Destroy; override;
  published
    property Name: RawUTF8 read fName write fName;
    property Nested: TCollection read fNested;
    property List: TStringList read fList;
  end;

  obj1 := TMain.Create;
  obj2 := TMain.Create;
...
obj1.Name := IntToStr(i);
item := obj1.Nested.Add as TMainNested;
item.Ident := obj1.Name;
item.Number := i/2;
obj1.list.Add(obj1.Name);
json := ObjectToJSON(obj1);
if i=1 then
  assert(json='{"Name":"1","Nested":[{"Ident":"1","Number":0.5}],"List":["1"]}');
JSONToObject(obj2, json);
assert(obj2.Nested.Count=i);
json2 := ObjectToJSON(obj2);
assert(json2=json);
...
```

Of course, this serialization feature is used for the *TSQLRecord* ORM class.

Due to lack of RTTI, record serialization is supported via some functions generated by the server with

the code wrappers.

17.1.1.2. Delphi OSX and NextGen

In order to be compliant with the *NextGen* revision, our SynCrossPlatform* units follow the expectations of this new family of cross-compilers, which targets *Android* and *iOS*.

In particular, we rely only on the string type for text process and storage, even at JSON level, and we tried to make object allocation ARC-compatible. Some types have been defined, e.g. THttpBody, TUTF8Buffer or AnsiChar, to ensure that our units will compile on all supported platforms.

On *Delphi*, the *Indy* library is used for HTTP requests. It is cross-platform by nature, so should work on any supported system. For SSL support with *iOS* and *Android* clients, please follow instructions at http://blog.marcocantu.com/blog/using_ssl_delphi_ios.html.. you may also download the needed libcrypto.a and libssl.a files from <http://indy.fulgan.com/SSL/OpenSSLStaticLibs.7z>..

Feedback is needed for the mobile targets, via FMX.

In fact, we rely for our own projects on *Smart Mobile Studio* for our mobile applications, so the Synapse team did not test *Delphi NextGen* platforms (i.e. *iOS* and *Android*) as deep as other systems. Your input will be very valuable and welcome, here!

17.1.1.3. FreePascal clients

SynCrossPlatform* units support the *FreePascal* Compiler, in its 2.7.1 / 3.x branches. Most of the code is shared with *Delphi*, including RTTI support and all supported types.

Some restrictions apply, though.

Due to a bug in *FreePascal* implementation of variant late binding, the following code won't work as expected on older revisions of FPC:

```
doc.name2 := 3.1415926;  
doc.name := 'John';
```

Under oldest *FreePascal*, you have to write:

```
TJSONVariantData(doc)['name2'] := 3.1415926;  
TJSONVariantData(doc)['name'] := 'John';
```

In fact, the way late-binding properties are implemented in the *FreePascal* in some fully compatible with *Delphi* expectations. The *FreePascal* maintainers did some initial fix (the variant instance is now passed by reference), so above code seems to work on current FPC trunk.

As a result, direct access to TJSONVariantData instances, and not a variant variable, may be both safer and faster when using FPC.

In the Lazarus IDE, we also observed that the debugger is not able to handle our custom variant type. If you look at any TJSONVariantData instance with the debugger, an error message "*unsupported variant type*" will appear. As far as we found out, this is a Lazarus limitation. Delphi, on its side, is able to display any custom variant type in its debugger, after conversion to string, i.e. its JSON representation.

Another issue with the 2.7.1 / 3.1.1 revisions is how the new string type is implemented.

In fact, if you use a string variable containing an UTF-8 encoded text, then the following line will reset the result code page to the system code page:

```
function StringToJSON(const Text: string): string;  
...  
result := ''+copy(Text,1,j-1); // here FPC 2.7.1 erases UTF-8 encoding
```

...

It sounds like if `''''` will force the code page of `result` to be not an UTF-8 content.

With *Delphi*, this kind of statements work as expected, even for `AnsiString` values, and `''''` constant is handled as `RawByteString`. We were not able to find an easy and safe workaround for FPC yet. Input is welcome in this area, from any expert!

You have to take care of this limitation, if you target the *Windows* operating system with FPC (and *Lazarus*). Under other systems, the default code page is likely to be UTF-8, so in this case our `SynCrossPlatform*` units will work as expected.

We found out the *FreePascal* compiler to work very well, and result in small and fast executables. For most common work, timing is comparable with *Delphi*. The memory manager is less optimized than *FastMM4* for rough simple threaded tests, but is cross-platform and designed to be more efficient in multi-thread mode: in fact, it has no giant lock, as *FastMM4* suffers.

17.1.1.4. Local or remote logging

You can use the `TSQLRest.Log()` overloaded methods to log any content into a file or a remote server.

All ORM and SOA functions of the `TSQLRest` instance will create the expected log, just with the main *mORMot* units running on Win32/Win64 - see below (page 637).

For instance, here are some log entries created during the `RegressionTest.dpr` process:

```
16:47:15 Trace POST root/People status=201 state=847 in=92 out=0
16:47:15 DB People.ID=200 created from
{"FirstName": "First200", "LastName": "Last200", "YearOfBirth": 2000, "YearOfDeath": 2025, "Sexe": 0}
16:47:15 SQL select RowID, FirstName, LastName, YearOfBirth, YearOfDeath, Sexe from People
16:47:15 Trace GET
root?sql=select+RowID%2CFirstName%2CLastName%2CYearOfBirth%2CYearOfDeath%2CSexe+from+People
status=200 state=847 in=0 out=21078
16:47:15 SQL select RowID, YearOfBirth, YearOfDeath from People
16:47:15 Trace GET root?sql=select+RowID%2CYearOfBirth%2CYearOfDeath+from+People status=200
state=847 in=0 out=10694
16:47:15 SQL select RowID, FirstName, LastName, YearOfBirth, YearOfDeath, Sexe from People where
yearofbirth=: (1900):
16:47:15 Trace GET
root?sql=select+RowID%2CFirstName%2CLastName%2CYearOfBirth%2CYearOfDeath%2CSexe+from+People+where+
yearofbirth%3D%3A%281900%29%3A status=200 state=847 in=0 out=107
16:47:15 Trace DELETE root/People/16 status=200 state=848 in=0 out=0
16:47:15 DB Delete People.ID=16
```

Then, our *Log View* tool is able to run as a remote log server, and display the incoming events in real-time - see below (page 640).

Having such logs available will be pretty convenient, especially when debugging applications on a mobile device, or a remote computer.

17.1.2. Smart Mobile Studio support

Smart Mobile Studio - see <http://www.smartmobilestudio.com..> - is a complete RAD environment for writing cutting edge HTML5 mobile applications. It ships with a fully fledged compiler capable of compiling *Object Pascal* (in a modern dialect call *SmartPascal*) into highly optimized and raw *JavaScript*.

There are several solutions able to compile to *JavaScript*.

In fact, we can find several families of compilers:

- *JavaScript* super-sets, adding optional *strong typing*, and classes, close to the *ECMAScript Sixth*

Edition: the current main language in this category is certainly *TypeScript*, designed by Anders Hejlsberg (father of both the *Delphi* language and *C#*), and published by *Microsoft*;

- New languages, dedicated to make writing *JavaScript* programs easier, with an alternative syntax and new concepts (like classes, lambdas, scoping, splats, comprehensions...): most relevant languages of this family are *CoffeeScript* and *Dart*;
- High-level languages, like *Google Web Toolkit* (compiling *Java* code), *JSIL* (from *C#* via *Mono*), or *Smart Mobile Studio* (from *object pascal*);
- Low-level languages, like *Emscripten* (compiling *C/C++* from *LLVM* byte-code, using *asm.js*).

Of course, from our point of view, use of modern *object pascal* is of great interest, since it will leverage our own coding skills, and make us able to share code between client and server sides.

17.1.2.1. Beyond JavaScript

The *Smart Pascal* language brings strong typing, true OOP to *JavaScript*, including classes, partial classes, interfaces, inheritance, polymorphism, virtual and abstract classes and methods, helpers, closures, lambdas, enumerations and sets, getter/setter expressions, operator overloading, contract programming. But you can still unleash the power of *JavaScript* (some may say "the good parts"), if needed: the variant type is used to allow dynamic typing, and you can write some *JavaScript* code as an `asm .. end block`.

See http://en.wikipedia.org/wiki/The_Smart_Pascal_programming_language..

The resulting HTML5 project is self-sufficient with no external *JavaScript* library, and is compiled as a single `index.html` file (including its `css`, if needed). The *JavaScript* code generated by the compiler (written in *Delphi* by Eric Grange), is of very high quality, optimized for best execution performance (either in JIT or V8), has low memory consumption, and can be compressed and/or obfuscated.

The *SmartCL* runtime library encapsulate HTML5 APIs in a set of pure pascal classes and functions, and an IDE with an integrated form designer is available. You can debug your application directly within the IDE (since revision 2.1 - even if it is not yet always stable) or within your browser (IE, Chrome or FireBug have great debuggers), with step-by-step execution of the *object pascal* code (if you define "Add source map (for debugging)" in Project Options / Linker).

Using a third-party tool like *PhoneGap* - see <http://phonegap.com..> - you will be able to supply your customers with true native *iOS* or *Android* applications, running without any network, and accessing the full power of any modern *Smart Phone*. Resulting applications will be much smaller in size than the one generated by *Delphi* FMX (a simple *Smart* RESTful client with a login form and ORM + SOA tests is zipped as 40 KB), and will work seamlessly on all HTML5 platforms, including most mobile (like Windows Phone, Blackberry, Firefox OS, or webOS) or desktop (Windows, Linux, BSD, MacOS) architectures.

Smart Mobile Studio is therefore a great platform for implementing rich client-side AJAX or *Mobile* applications, to work with our client-server *mORMot* framework.

17.1.2.2. Using Smart Mobile Studio with mORMot

There is no package to be installed within the *Smart Mobile Studio* IDE. The client units will be generated directly from the *mORMot* server.

Any edition of *Smart* - see <http://smartmobilestudio.com/feature-matrix..> - is enough: you do not need to pay for the *Enterprise* edition to consume *mORMot* services. But of course, the *Professionnal* edition is recommended, since the *Basic* edition does not allow to create forms from the IDE, which is the main point for an AJAX application.

In contrast to the wrappers available in the *Professional* edition of Smart, for accessing *RemObjects* or *DataSnap* servers, our *mORMot* clients are 100% written in the *SmartPascal* dialect. There is no need to link an external .js library to your executable, and you will benefit of the obfuscation and smart linking features of the Smart compiler.

The only requirement is to copy the *mORMot* cross-platform units to your *Smart Mobile Studio* installation. This can be done in three copy instructions:

```
xcopy SynCrossPlatformSpecific.pas "c:\ProgramData\Optimale Systemer AS\Smart Mobile Studio\Libraries" /Y
xcopy SynCrossPlatformCrypto.pas "c:\ProgramData\Optimale Systemer AS\Smart Mobile Studio\Libraries" /Y
xcopy SynCrossPlatformREST.pas "c:\ProgramData\Optimale Systemer AS\Smart Mobile Studio\Libraries" /Y
```

You can find a corresponding BATCH file in the CrossPlatform folder, and in SQLite3\Samples\29 - SmartMobileStudio Client\COPYSynCrossPlatformUnits.bat.

In fact, the SynCrossPlatformJSON.pas unit is not used under *Smart Mobile Studio*: we use the built-in JSON serialization features of *JavaScript*, using variant dynamic type, and the standard JSON.Stringify() and JSON.Parse() functions.

17.1.3. Remote logging

Since there is no true file system API available under a HTML5 sand-boxed application, logging to a local file is not an option. Even when packaged with *PhoneGap*, local log files are not convenient to work with.

Generated logs will have the same methods and format as with *Delphi* or *FreePascal* - see *Local or remote logging* (page 487). TSQLRest.Log(E: Exception) method will also log the stack trace of the exception! Our LogView tool - see below (page 640) - is able to run as a simple but efficient remote log server and viewer, shared with regular or cross-platform units of the framework.

A dedicated *asynchronous* implementation has been refined for *Smart Mobile Studio* clients, so that several events will be gathered and sent at once to the remote server, to maximize bandwidth use and let the application be still responsive.

It allows even complex mobile applications to be debugged with ease, on any device, even over WiFi or 3G/4G networks. Your support could ask your customer to enable logging for a particular case, then see in real time what is wrong with your application.

17.2. Generating client wrappers

Even if it is feasible to write the client code by hand, your *mORMot* server is able to create the source code needed for client access, via a dedicated method-based service, and a set of *Mustache*-based templates - see below (page 506).

The following templates are available in the `CrossPlatform\templates` folder:

Unit Name	Compiler Target
<code>CrossPlatform.pas.mustache</code>	<i>Delphi</i> / FPC SynCrossPlatform* units
<code>Delphi.pas.mustache</code>	<i>Delphi</i> Win32/Win64 <i>mORMot</i> units
<code>SmartMobileStudio.pas.mustache</code>	Smart Mobile Studio 2.1

In the future, other wrappers may be added. And you can write your own, which could be included within the framework source! Your input is warmly welcome, especially if you want to write a template for *Java* or *C#* client. The generated data context already contains the data types corresponding to those compilers: e.g. a *mORMot*'s `RawUTF8` field or parameter could be identified as `"typeCS": "string"` or `"typeJava": "String"` in addition to `"typeDelphi": "RawUTF8"` and `"typePascal": "string"`.

17.2.1. Publishing the code generator

By default, and for security reasons, the code generation is not embedded to your *mORMot* RESTful server. In fact, the `mORMotWrapper.pas` unit will link both `mORMot.pas` and `SynMustache.pas` units, and use *Mustache* templates to generate code for a given `SQLRestServer` instance.

We will start from the interface-based service *Sample code* (page 438) as defined in the `"SQLite3\Samples\14 - Interface based services"` folder.

After some minor modifications, we copied the server source code into

`"SQLite3\Samples\27 - CrossPlatform Clients\Project14ServerHttpWrapper.dpr"`:

```
program Project14ServerHttpWrapper;

{$APPTYPE CONSOLE}

uses
  SysUtils,
  Classes,
  SynCommons,
  mORMot,
  mORMotHttpServer,
  mORMotWrappers,
  Project14Interface in '..\14 - Interface based services\Project14Interface.pas';

type
  TServiceCalculator = class(TInterfacedObject, ICalculator)
  public
    function Add(n1,n2: integer): integer;
  end;

function TServiceCalculator.Add(n1, n2: integer): integer;
begin
  result := n1+n2;
end;
```

```
var
  aModel: TSQLModel;
  aServer: TSQLRestServer;
  aHTTPServer: TSQLHttpServer;
begin
  // create a Data Model
  aModel := TSQLModel.Create([], ROOT_NAME);
  try
    // initialize a TObjectList-based database engine
    aServer := TSQLRestServerFullMemory.Create(aModel, 'test.json', false, true);
    try
      // add the http://localhost:888/root/wrapper code generation web page
      AddToServerWrapperMethod(aServer,
        ['..\..\..\CrossPlatform\templates', '....\..\..\CrossPlatform\templates']);
      // register our ICalculator service on the server side
      aServer.ServiceDefine(TServiceCalculator, [ICalculator], sicShared);
      // launch the HTTP server
      aHTTPServer := TSQLHttpServer.Create(PORT_NAME, [aServer], '+', useHttpApiRegisteringURI);
      try
        aHTTPServer.AccessControlAllowOrigin := '*'; // for AJAX requests to work
        writeln(#10'Background server is running. ');
        writeln('You can test http://localhost:', PORT_NAME, '/wrapper');
        writeln(#10'Press [Enter] to close the server.' #10);
        readln;
      finally
        aHTTPServer.Free;
      end;
    finally
      aServer.Free;
    end;
  finally
    aModel.Free;
  end;
end.
```

As you can see, we just added a reference to the mORMotWrappers unit, and a call to `AddToServerWrapperMethod()` in order to publish the available code generators.

Now, if you run the `Project14ServerHttpWrapper` server, and point your favorite browser to `http://localhost:888/root/wrapper` you will see the following page:

Client Wrappers

Available Templates:

* CrossPlatform

`mORMotClient.pas` - [download as file](#) - [see as text](#) - [see template](#)

* Delphi

`mORMotClient.pas` - [download as file](#) - [see as text](#) - [see template](#)

* SmartMobileStudio

`mORMotClient.pas` - [download as file](#) - [see as text](#) - [see template](#)

You can also retrieve the corresponding [template context](#).

Each of the *.mustache template available in the specified folder is listed here. Links above will allow downloading a client source code unit, or displaying it as text in the browser. The template can also be displayed un-rendered, for reference. As true *Mustache* templates, the source code files are

generated from a *data context*, which can be displayed, as JSON, from the "[template context](#)" link. It may help you when debugging your own templates. Note that if you modify and save a *.mustache* template file, just re-load the "[see as text](#)" browser page and your modification is taken in account immediately (you do not need to restart the server).

Generated source code will follow the template name, and here will always be downloaded as *mORMotClient.pas*. Of course, you can change the unit name for your end-user application. It could be even mandatory if the same client will access to several *mORMot* servers at once, which could be the case in a *Service-Oriented Architecture (SOA)* (page 90) project.

Just ensure that you will never change the *mORMotClient.pas* generated content by hand. If necessary, you can create and customize your own *Mustache* template, to be used for your exact purpose. By design, such automated code generation will require to re-create the client unit each time the server ORM or SOA structure is modified. In fact, as stated in the *mORMotClient.pas* comment, any manual modification of this file may be lost after regeneration. You have been warned!

For publishing the wrappers for a REST / ORM oriented program, take a look at the '28 - Simple RESTful ORM Server' sample.

If you feel that the current templates have some issues or need some enhancements, you are very welcome to send us your change requests on our forums. Once you are used at it, *Mustache* templates are fairly easy to work with. Similarly, if you find out that some information is missing in the generated *data context*, e.g. for a new platform or language, we will be pleased to enhance the official *mORMotWrapper.pas* process.

17.2.2. Delphi / FreePascal client samples

The "27 - CrossPlatform Clients.dpr" sample creates a *mORMot* server with its own ORM data model, containing a *TSQLRecordPeople* class, and a set of interface-based SOA services, some including complex types like a record.

Then this sample uses a generated *mORMotClient.pas*, retrieved from the "[download as file](#)" link of the **CrossPlatform** template above.

Its set of regression tests (written using a small cross-platform *TSynTest* unit test class) will then perform remote ORM and SOA calls to the *PeopleServer* embedded instance, over all supported authentication schemes - see below (page 547):

```
Cross Platform Units for mORMot
```

```
-----  
1. Running "Iso8601DateTime"  
   30003 tests passed in 00:00:018  
2. Running "Base64Encoding"  
   304 tests passed in 00:00:000  
3. Running "JSON"  
   18628 tests passed in 00:00:056

Cross Platform Client for mORMot using TSQLRestServerAuthenticationNone
```

```
...
```

```
Cross Platform Client for mORMot using TSQLRestServerAuthenticationDefault
```

```
...
```

The generated `mORMotClient.pas` unit is used for all "Cross Platform Client" tests above, covering both ORM and SOA features of the framework.

17.2.2.1. Connection to the server

You could manually connect to a *mORMot* server as such:

```
var Model: TSQLModel;
    Client: TSQLRestClientHTTP;
...
Model := TSQLModel.Create([TSQLAuthUser,TSQLAuthGroup,TSQLRecordPeople]);
Client := TSQLRestClientHTTP.Create('localhost',SERVER_PORT,Model);
if not Client.Connect then
  raise Exception.Create('Impossible to connect to the server');
if Client.ServerTimestamp=0 then
  raise Exception.Create('Incorrect server');
if not Client.SetUser(TSQLRestAuthenticationDefault,'User','synapse') then
  raise Exception.Create('Impossible to authenticate to the server');
...
```

Or you may use the `GetClient()` function generated in `mORMotClient.pas`:

```
/// create a TSQLRestClientHTTP instance and connect to the server
// - it will use by default port 888
// - secure connection will be established via TSQLRestServerAuthenticationDefault
// with the supplied credentials - on connection or authentication error,
// this function will raise a corresponding exception
function GetClient(const aServerAddress, aUserName,aPassword: string;
  aServerPort: integer=SERVER_PORT): TSQLRestClientHTTP;
```

Which could be used as such:

```
var Client: TSQLRestClientHTTP;
...
Client := GetClient('localhost','User','synapse')
```

The data model and the expected authentication scheme were included in the `GetClient()` function, which will raise the expected `ERestException` in case of any connection or authentication issue.

17.2.2.2. CRUD/ORM remote access

Thanks to `SynCrossPlatform*` units, you could easily perform any remote ORM operation on your *mORMot* server, with the usual `TSQLRest` CRUD methods.

For instance, the RegressionTests.dpr sample performs the following operations

```
fClient.CallBackGet('DropTable',[],Call,TSQLErrorPeople); // call of method-based service
check(Call.OutStatus=HTTP_SUCCESS);
people := TSQLErrorPeople.Create; // create a record ORM
try
  for i := 1 to 200 do begin
    people.FirstName := 'First'+IntToStr(i);
    people.LastName := 'Last'+IntToStr(i);
    people.YearOfBirth := i+1800;
    people.YearOfDeath := i+1825;
    people.Sexe := TPeopleSexe(i and 1);
    check(Client.Add(people,true)=i); // add one record
  end;
finally
  people.Free;
end;
...
people := TSQLErrorPeople.CreateAndFillPrepare(fClient,'',
'yearofbirth=?',[1900]); // parameterized query returning one or several rows
try
  n := 0;
  while people.FillOne do begin
    inc(n);
    check(people.ID=100);
    check(people.FirstName='First100');
    check(people.LastName='Last100');
    check(people.YearOfBirth=1900);
    check(people.YearOfDeath=1925);
  end;
  check(n=1); // we expected only one record here
finally
  people.Free;
end;
for i := 1 to 200 do
  if i and 15=0 then
    fClient.Delete(TSQLErrorPeople,i) else // record deletion
  if i mod 82=0 then begin
    people := TSQLErrorPeople.Create;
    try
      id := i+1;
      people.ID := i;
      people.YearOfBirth := id+1800;
      people.YearOfDeath := id+1825;
      check(fClient.Update(people,'YearOfBIRTH,YearOfDeath')); // record modification
    finally
      people.Free;
    end;
  end;
end;
for i := 1 to 200 do begin
  people := TSQLErrorPeople.Create(fClient,i); // retrieve one instance from ID
  try
    if i and 15=0 then // was deleted
      Check(people.ID=0) else begin
        if i mod 82=0 then
          id := i+1 else // was modified
            id := i;
          Check(people.ID=i);
          Check(people.FirstName='First'+IntToStr(i));
          Check(people.LastName='Last'+IntToStr(i));
          Check(people.YearOfBirth=id+1800);
          Check(people.YearOfDeath=id+1825);
          Check(ord(people.Sexe)=i and 1);
        end;
      finally
        people.Free;
      end;
    end;
```

```
end;
```

As we already stated, BATCH mode is also supported, with the classic *mORMot* syntax:

```
...
  res: TIntegerDynArray;
...
fClient.BatchStart(TSQLRecordPeople);
people := TSQLRecordPeople.Create;
try
  for i := 1 to 200 do begin
    people.FirstName := 'First'+IntToStr(i);
    people.LastName := 'Last'+IntToStr(i);
    people.YearOfBirth := i+1800;
    people.YearOfDeath := i+1825;
    fClient.BatchAdd(people,true);
  end;
finally
  people.Free;
end;
fClient.fBatchSend(res)=HTTP_SUCCESS);
check(length(res)=200);
for i := 1 to 200 do
  check(res[i-1]=i); // server returned the IDs of the newly created records
```

Those BatchAdd / BatchDelete / BatchUpdate methods of TSQLRest have the benefit to introduce at client level:

- Much higher performance, especially on multi-insertion or multi-update of data;
- Transactional support: TSQLRest.BatchStart() has an optional AutomaticTransactionPerRow parameter, set to 10000 by default, which will create a server-side transaction during the write process, enable *Array binding* (page 357) or *Optimized SQL for bulk insert* (page 358) on the server side if available, and an ACID rollback in case of any failure.

You can note that all above code has exactly the same structure and methods than standard *mORMot* clients.

The generated mORMotClient.pas unit contains all needed TSQLRecord types, and its used properties, including enumerations or complex records. The only dependency of this unit are SynCrossPlatform* units, so will be perfectly cross-platform (whereas our main SynCommons.pas and mORMot.pas units do target only Win32 and Win64).

As a result, you are able to *share* server and client code between a Windows project and any supported platform, even AJAX (see "*Smart Mobile Studio client samples*" below). A shared unique code base will eventually reduce both implementation and debugging time, which is essential to unleash your business code potential and maximize your ROI.

17.2.2.3. Service consumption

The ultimate goal of the *mORMot* framework is to publish your business via a *Service-Oriented Architecture (SOA)* (page 90).

As a consequence, those services should be made available from any kind of device or platform, even outside the *Windows* world. The server is able to generate client wrappers code, which could be used to consume any *Client-Server services via interfaces* (page 420) using any supported authentication scheme - see below (page 547).

Here is an extract of the mORMotClient.pas unit as generated for the RegressionTests.dpr sample:

```
type
  /// service implemented by TServiceCalculator
  // - you can access this service as such:
```

```
// !var aCalculator: ICalculator;
// !begin
// !  aCalculator := TCalculator.Create(aClient);
// !  // now you can use aCalculator methods
// !...
ICalculator = interface(IServiceAbstract)
  ['{9A60C8ED-CEB2-4E09-87D4-4A16F496E5FE}']
  function Add(const n1: integer; const n2: integer): integer;
  procedure ToText(const Value: currency; const Curr: string; var Sexe: TPeopleSexe; var Name:
string);
  function RecordToText(var Rec: TTestCustomJSONArraySimpleArray): string;
end;

/// implements ICalculator from http://localhost:888/root/Calculator
// - this service will run in sicShared mode
TServiceCalculator = class(TServiceClientAbstract, ICalculator)
public
  constructor Create(aClient: TSQLRestClientURI); override;
  function Add(const n1: integer; const n2: integer): integer;
  procedure ToText(const Value: currency; const Curr: string; var Sexe: TPeopleSexe; var Name:
string);
  function RecordToText(var Rec: TTestCustomJSONArraySimpleArray): string;
end;
```

As you can see, a dedicated class has been generated to consume the server-side ICalculator interface-based service, in its own ICalculator client-side type.

It is able to handle complex types, like enumerations (e.g. TPeopleSexe) and records (e.g. TTestCustomJSONArraySimpleArray), which are also defined in the very same mORMotClient.pas unit.

You can note that the RawUTF8 type has been changed into the standard *Delphi / FreePascal* string type, since it is the native type used by our SynCrossPlatformJSON.pas unit for all its JSON marshalling. Of course, under latest version of *Delphi* and *FreePascal*, this kind of content may be Unicode encoded (either as UTF-16 for the string = UnicodeString *Delphi* type, or as UTF-8 for the *FreePascal / Lazarus* string type).

The supplied regression tests show how to use remotely those services:

```
var calc: ICalculator;
  i,j: integer;
  sex: TPeopleSexe;
  name: string;
...
calc := TServiceCalculator.Create(fClient);
check(calc.InstanceImplementation=sicShared);
check(calc.ServiceName='Calculator');
for i := 1 to 200 do
  check(calc.Add(i,i+1)=i*2+1);
for i := 1 to 200 do begin
  sex := TPeopleSexe(i and 1);
  name := 'Smith';
  calc.ToText(i, '$', sex, name);
  check(sex=sFemale);
  check(name=format('$ %d for %s Smith',[i,SEX_TEXT[i and 1]]));
end;
...
```

As with regular *mORMot* client code, a TServiceCalculator instance is created and is assigned to a ICalculator local variable. As such, no try ... finally Calc.Free end block is mandatory here, to avoid any memory leak: the compiler will create such an hidden block for the Calc: ICalculator variable scope.

The service-side contract of the ICalculator signature is retrieved and checked within TServiceCalculator.Create, and will raise an ERestException if it does not match the contract

identified in `mORMotClient.pas`.

The cross-platform clients are able to manage the service instance life-time, especially the `sicPerClient` mode. In this case, an implementation class instance will be created on the server for each client, until the corresponding interface instance will be released (i.e. out of scope or assigned to `nil`), which will release the server-side instance - just like with a regular *mORMot* client code.

Note that all process here is executed *synchronously*, i.e. in blocking mode. It is up to you to ensure that your application is able to still be responsive, even if the server does a lot of process, so may be late to answer. A dedicated thread may help in this case.

17.2.3. Smart Mobile Studio client samples

In addition to *Delphi* and *FreePascal* clients, our framework is able to access any *mORMot* server from HTML5 / AJAX rich client, thanks to *Smart Mobile Studio*.

17.2.3.1. Adding two numbers in AJAX

You can find in `SQLite3\Samples\27 - CrossPlatform Clients\SmartMobileStudio` a simple client for the `TServiceCalculator.Add()` interface-based service.

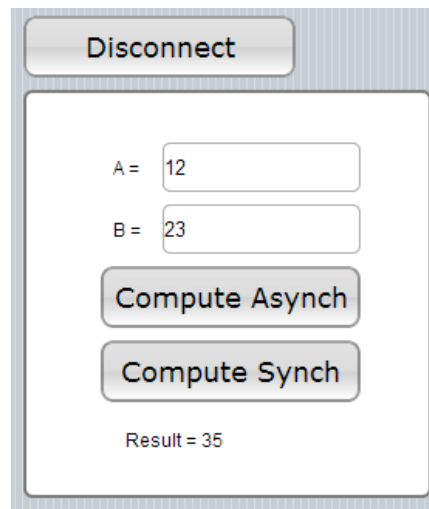

If your `Project14ServerHttpWrapper` server is running, you can just point to the supplied `www\index.html` file in the sub-folder.

You will then see a web page with a "Server Connect" button, and if you click on it, you will be able to add two numbers. This is a full HTML5 web application, connecting securely to your *mORMot* server, which will work from any desktop browser (on *Windows*, *Mac OS X*, or *Linux*), or from any mobile device (either *iPhone* / *iPad* / *Android* / *Windows 8 Mobile*).

In order to create the application, we just clicked on "[download as file](#)" in the **SmartMobileStudio** link in the web page, and copied the generated file in the source folder of a new *Smart Mobile* project.

Of course, we did copy the needed `SynCrossPlatform*.pas` units from the *mORMot* source code tree into the `Smart` library folder, as stated above. Just ensure you run `CopySynCrossPlatformUnits.bat` from the `CrossPlatform` folder at least once from the latest revision of the framework source code.

Then, on the form visual editor, we added a `BtnConnect` button, then a `PanelCompute` panel with two edit fields named `EditA` and `EditB`, and two other buttons, named `BtnComputeAsynch` and `BtnComputeSynch`. A `LabelResult` label will be used to display the computation result. The `BtnConnect` is a toggle which will show or display the `PanelCompute` panel, which is hidden by default, depending on the connection status.

Smart Mobile Studio Calculator Sample

In the Form1.pas unit source code side, we added a reference to our both SynCrossPlatformREST and mORMotClient units, and some events to the buttons:

```
unit Form1;

interface

uses
  SmartCL.System, SmartCL.Graphics, SmartCL.Components, SmartCL.Forms,
  SmartCL.Fonts, SmartCL.Borders, SmartCL.Application, SmartCL.Controls.Panel,
  SmartCL.Controls.Label, SmartCL.Controls.EditBox, SmartCL.Controls.Button,
  SynCrossPlatformREST, mORMotClient;

type
  TForm1 = class(TW3Form)
    procedure BtnComputeSynchClick(Sender: TObject);
    procedure BtnComputeAsynchClick(Sender: TObject);
    procedure BtnConnectClick(Sender: TObject);
  private
    {$I 'Form1:intf'}
  protected
    Client: TSQLRestClientURI;
    procedure InitializeForm; override;
    procedure InitializeObject; override;
    procedure Resize; override;
  end;
```

The BtnConnect event will connect asynchronously to the server, using 'User' as log-on name, and 'synopse' as password (those as the framework defaults).

We just use the GetClient() function, as published in our generated mORMotClient.pas unit:

```
/// create a TSQLRestClientHTTP instance and connect to the server
// - it will use by default port 888
// - secure connection will be established via TSQLRestServerAuthenticationDefault
// with the supplied credentials
// - request will be asynchronous, and trigger onSuccess or onError event
procedure GetClient(const aServerAddress, aUserName, aPassword: string;
  onSuccess, onError: TSQLRestEvent; aServerPort: integer=SERVER_PORT);
```

It uses two callbacks, the first in case of success, and the second triggered on failure. On success, we will set the global Client variable with the TSQLRestClientURI instance just created, then display the two fields and compute buttons:

```
procedure TForm1.BtnConnectClick(Sender: TObject);
```

```
begin
  if Client=nil then
    GetClient('127.0.0.1','User','synapse',
      lambda (aClient: TSQLRestClientURI)
        PanelCompute.Visible := true;
        W3Label1.Visible := true;
        W3Label2.Visible := true;
        LabelConnect.Caption := '';
        BtnConnect.Caption := 'Disconnect';
        LabelResult.Caption := '';
        Client := aClient;
      end,
      lambda
        ShowMessage('Impossible to connect to the server!');
      end)
  else begin
    PanelCompute.Visible := false;
    BtnConnect.Caption := 'Server Connect';
    Client.Free;
    Client := nil;
  end;
end;
```

The `GetClient()` function expects two callbacks, respectively `onSuccess` and `onError`, which are implemented here with two *SmartPascal* lambda blocks.

Now that we are connected to the server, let's do some useful computation!

As you can see in the `mORMotClient.pas` generated unit, our interface-based service can be accessed via a *SmartPascal* `TServiceCalculator` class (and not an interface), with two variations of each methods: one *asynchronous* method - e.g. `TServiceCalculator.Add()` - expecting success/error callbacks, and one *synchronous* (blocking) method - e.g. `TServiceCalculator._Add()`:

```
type
  /// service accessible via http://localhost:888/root/Calculator
  /// - this service will run in sicShared mode
  /// - synchronous and asynchronous methods are available, depending on use case
  /// - synchronous _*() methods will block the browser execution, so won't be
  /// appropriate for long process - on error, they may raise EServiceException
  TServiceCalculator = class(TServiceClientAbstract)
  public
    /// will initialize an access to the remote service
    constructor Create(aClient: TSQLRestClientURI); override;
    procedure Add(n1: integer; n2: integer;
      onSuccess: procedure(Result: integer); onError: TSQLRestEvent);
    function _Add(const n1: integer; const n2: integer): integer;
  end;
```

We can therefore execute asynchronously the `Add()` service as such:

```
procedure TForm1.BtnComputeAsynchClick(Sender: TObject);
begin
  TServiceCalculator.Create(Client).Add(
    StrToInt(EditA.Text), StrToInt(EditB.Text),
    lambda (res: integer)
      LabelResult.Caption := format('Result = %d',[res]);
    end,
    lambda
      ShowMessage('Error calling the method!');
    end);
end;
```

Or execute synchronously the `_Add()` service:

```
procedure TForm1.BtnComputeSynchClick(Sender: TObject);
begin
  LabelResult.Caption := format('Result = %d',
    [TServiceCalculator.Create(Client)._Add(
```

```
StrToInt(EditA.Text),StrToInt(EditB.Text))]);  
end;
```

Of course, the synchronous code is much easier to follow and maintain. To be fair, the *SmartPascal* lambda syntax is not difficult to read nor write. In the browser debugger, you can easily set a break point within any lambda block, and debug your code.

Note that if the server is slow to answer, your whole web application will be unresponsive, and the browser may even complain about the page, proposing the kill its process!

As a consequence, simple services may be written in a synchronous manner, but your serious business code should rather use asynchronous callbacks, just as with any modern AJAX application.

Thanks to the *Smart Linking* feature of its compiler, only the used version of the unit will be converted to *JavaScript* and included in the final `index.html` HTML5 file. So having both synchronous and asynchronous versions of each method at hand is not an issue.

17.2.3.2. CRUD/ORM remote access

If the server did have some ORM model, its `TSQLRecord` classes will also be part of the `mORMotClient.pas` generated unit. All types, even complex record structures, will be marshaled as expected.

For instance, if you run the `RegressionTestsServer.dpr` server (available in the same folder), a much more complete unit could be generated from `http://localhost:888/root/wrapper`:

```
type // define some enumeration types, used below  
  TPeopleSexe = (sFemale, sMale);  
  TRecordEnum = (reOne, reTwo, reLast);  
  
type // define some record types, used as properties below  
  TTestCustomJSONArraySimpleArray = record  
    F: string;  
    G: array of string;  
    H: record  
      H1: integer;  
      H2: string;  
      H3: record  
        H3a: boolean;  
        H3b: TSQLRawBlob;  
      end;  
    end;  
    I: TDateTime;  
    J: array of record  
      J1: byte;  
      J2: TGUID;  
      J3: TRecordEnum;  
    end;  
  end;  
  
type  
  /// service accessible via http://localhost:888/root/Calculator  
  /// - this service will run in sicShared mode  
  /// - synchronous and asynchronous methods are available, depending on use case  
  /// - synchronous _*() methods will block the browser execution, so won't be  
  /// appropriate for long process - on error, they may raise EServiceException  
  TServiceCalculator = class(TServiceClientAbstract)  
  public  
    /// will initialize an access to the remote service  
    constructor Create(aClient: TSQLRestClientURI); override;  
    procedure Add(n1: integer; n2: integer;  
      onSuccess: procedure(Result: integer); onError: TSQLRestEvent);  
    function _Add(const n1: integer; const n2: integer): integer;
```

```

procedure ToText(Value: currency; Curr: string; Sexe: TPeopleSexe; Name: string;
  onSuccess: procedure(Sexe: TPeopleSexe; Name: string); onError: TSQLRestEvent);
procedure _ToText(const Value: currency; const Curr: RawUTF8; var Sexe: TPeopleSexe; var Name:
RawUTF8);
procedure RecordToText(Rec: TTestCustomJSONArraySimpleArray;
  onSuccess: procedure(Rec: TTestCustomJSONArraySimpleArray; Result: string); onError:
TSQLRestEvent);
function _RecordToText(var Rec: TTestCustomJSONArraySimpleArray): string;
end;

/// map "People" table
TSQLRecordPeople = class(TSQLRecord)
protected
  fFirstName: string;
  fLastName: string;
  fData: TSQLRawBlob;
  fYearOfBirth: integer;
  fYearOfDeath: word;
  fSexe: TPeopleSexe;
  fSimple: TTestCustomJSONArraySimpleArray;
  // those overridden methods will emulate the needed RTTI
  class function ComputeRTTI: TRTTIPropInfos; override;
  procedure SetProperty(FieldIndex: integer; const Value: variant); override;
  function GetProperty(FieldIndex: integer): variant; override;
public
  property FirstName: string read fFirstName write fFirstName;
  property LastName: string read fLastName write fLastName;
  property Data: TSQLRawBlob read fData write fData;
  property YearOfBirth: integer read fYearOfBirth write fYearOfBirth;
  property YearOfDeath: word read fYearOfDeath write fYearOfDeath;
  property Sexe: TPeopleSexe read fSexe write fSexe;
  property Simple: TTestCustomJSONArraySimpleArray read fSimple write fSimple;
end;
  
```

In the above code, you can see several methods to the ICalculator service, some involving the complex TTestCustomJSONArraySimpleArray record type. The implementation section of the unit will in fact allow serialization of such records to/from JSON, even with obfuscated *JavaScript* field names.

Some *enumerations* types are also defined, so will help your business code be very expressive, thanks to the *SmartPascal* strong typing. This is a huge improvement when compared to *JavaScript* native weak and dynamic typing.

There is a TSQLRecordPeople class generated, which will map the following *Delphi* class type, as defined in the PeopleServer.pas unit:

```

TSQLRecordPeople = class(TSQLRecord)
protected
  fData: TSQLRawBlob;
  fFirstName: RawUTF8;
  fLastName: RawUTF8;
  fYearOfBirth: integer;
  fYearOfDeath: word;
  fSexe: TPeopleSexe;
  fSimple: TTestCustomJSONArraySimpleArray;
public
  class procedure InternalRegisterCustomProperties(Props: TSQLRecordProperties); override;
published
  property FirstName: RawUTF8 read fFirstName write fFirstName;
  property LastName: RawUTF8 read fLastName write fLastName;
  property Data: TSQLRawBlob read fData write fData;
  property YearOfBirth: integer read fYearOfBirth write fYearOfBirth;
  property YearOfDeath: word read fYearOfDeath write fYearOfDeath;
  property Sexe: TPeopleSexe read fSexe write fSexe;
public
  
```

```
property Simple: TTestCustomJSONArraySimpleArray read fSimple;  
end;
```

Here, a complex `TTestCustomJSONArraySimpleArray` record field has been published, thanks to a manual `InternalRegisterCustomProperties()` registration, as we already stated above. Since *SmartPascal* is limited in terms of RTTI, the code generator did define some `ComputeRTTI()` `GetProperty()` and `SetProperty()` protected methods, which will, at runtime, perform all the properties marshalling to and from JSON.

You can see that types like `RawUTF8` in the original *Delphi* `TSQLRecord` were mapped to the standard *SmartPascal* string type, as expected, when converted to the `mORMotClient.pas` generated unit.

Your AJAX client can then access to this `TSQLRecordPeople` content easily, via standard CRUD operations.

See the `SQLite3\Samples\29 - SmartMobileStudio Client` sample, for instance the following line:

```
people := new TSQLRecordPeople;  
for i := 1 to 200 do begin  
  assert(client.Retrieve(i, people));  
  assert(people.ID=i);  
  assert(people.FirstName='First'+IntToStr(i));  
  assert(people.LastName='Last'+IntToStr(i));  
  assert(people.YearOfBirth=id+1800);  
  assert(people.YearOfDeath=id+1825);  
end;
```

Here, the client variable is a `TSQLRestClientURI` instance, as returned by the `GetClient()` `onSuccess` callback generated in `mORMotClient.pas`.

You have `Add()` `Delete()` `Update()` `FillPrepare()` `CreateAndFillPrepare()` and `Batch*()` methods available, ready to safely access your data from your AJAX client.

If you update your data model on the server, just re-generate your `mORMotClient.pas` unit from `http://localhost:888/root/wrapper`, then rebuild your *Smart Mobile Studio* project to reflect all changes made to your ORM data model, or your SOA available services.

Thanks to the *SmartPascal* strong typing, any breaking change of the server expectations will immediately be reported at compilation, and not at runtime, as it will with regular *JavaScript* clients.

18. MVC pattern

Adopt a mORMot

The *mORMot* framework allows writing rich and/or web MVC applications, relying on regular ORM and SOA methods to implement its business model and its application layer, with an optional dedicated MVC model for the HTML rendering.

18.1. Model

According to the *Model-View-Controller* (MVC) pattern - see *Model-View-Controller* (page 86) - the database schema should be handled separately from the User Interface.

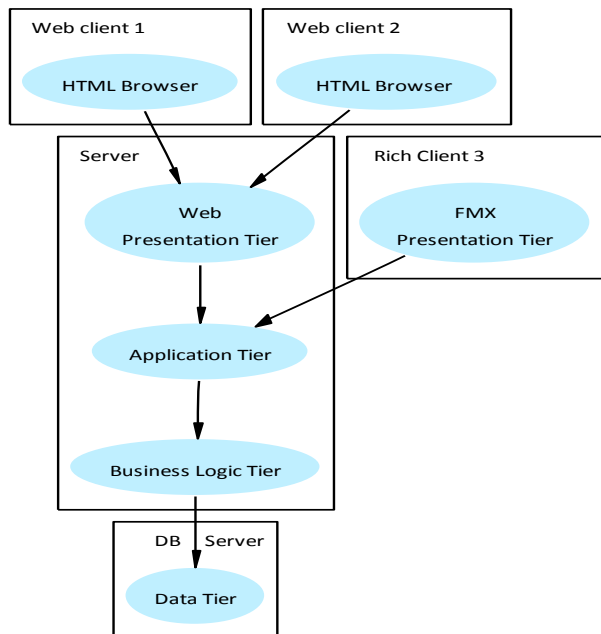

The *TSQLModel* class centralizes all *TSQLRecord* inherited classes used by an application, both database-related and business-logic related.

See *ORM Data Model* (page 171) for how to define the model of your application.

18.2. Views

The *mORMot* framework also features two kinds of *User Interface* generation, corresponding to the MVC Views:

- For Desktop clients written in *Delphi*, it allows creation of Ribbon-like interfaces, with full data view and navigation as visual Grids. Reporting and edition windows can be generated in an automated way. The whole User Interface is designed in code, by some constant definitions.
- For Web clients, an optimized Mustache Template engine in pure *Delphi* has been integrated, and allows easy creation of HTML views, with a clear MVC design.

MVC Web and Rich Clients

The *Web Presentation Tier* will be detailed below (page 520), but we will now present the project-wide implementation proposal.

18.2.1. Desktop clients

18.2.1.1. RTTI

The *Delphi* language (aka Object Pascal) provided Runtime Type Information (RTTI) more than a decade ago. In short, Runtime Type Information is information about an object's data type that is set into memory at run-time. The RTTI support in *Delphi* has been added first and foremost to allow the design-time environment to do its job, but developers can also take advantage of it to achieve certain code simplifications. Our framework makes huge use of RTTI, from the database level to the User Interface. Therefore, the resulting program has the advantages of very fast development (Rails-like), but with the robustness of strong type syntax, and the speed of one of the best compiler available.

In short, it allows the software logic to be extracted from the code itself. Here are the places where this technology was used:

- All database structures are set in the code by normal classes definition, and most of the needed SQL code is created on the fly by the framework, before calling the *SQLite3* database engine, resulting in a true Object-relational mapping (ORM) framework;
- All User Interface is generated by the code, by using some simple data structures, relying on enumerations (see next paragraph);
- Most of the text displayed on the screen does rely on RTTI, thanks to the Camel approach (see below), ready to be translated into local languages;
- All internal Event process (such as Button press) relies on enumerations RTTI;
- Options and program parameters are using RTTI for data persistence and screen display (e.g. the Settings window of your program can be created by pure code): adding an option is a matter of a few code lines.

In *Delphi*, enumeration types or *Enum* provides a way of to define a list of values. The values have no

inherent meaning, and their ordinality follows the sequence in which the identifiers are listed. These values are written once in the code, then used everywhere in the program, even for User Interface generation.

For example, some tool-bar actions can be defined with:

```
type
  /// item toolbar actions
  TBabyAction = (
    paCreateNew, paDelete, paEdit, paQuit);
```

Then this TBabyAction enumerated type is used to create the User Interface ribbon of the main window, just by creating an array of set of this kind:

```
BarEdit: array[0..1] of set of TBabyAction = (
  [paCreateNew, paDelete, paEdit],
  [paQuit] );
```

The caption of the buttons to be displayed on the screen is then extracted by the framework using "Camel Case": the second button, defined by the paCreateNew identifier in the source code, is displayed as "Create new" on the screen, and this "Create new" is used for direct i18n of the software. For further information about "Camel Case" and its usage in Object Pascal, Java, Dot Net, Python see <http://en.wikipedia.org/wiki/CamelCase..>

Advantages of the RTTI can therefore be sum up:

- Software maintainability, since the whole program logic is code-based, and the User Interface is created from it. It therefore avoid RAD (Rapid Application Development) abuse, which mix the User Interface with data logic, and could lead into "write fast, try to maintain" scenarios;
- Enhanced code security, thanks to Object Pascal strong type syntax;
- Direct database access from the language object model, without the need of writing SQL or use of a MVC framework;
- User Interface coherency, since most screen are created on the fly;
- Easy i18n of the software, without additional components or systems.

18.2.1.2. User Interface

User Interface generation from RTTI and the integrated reporting features will be described below (page 2523), during presentation of the Main Demo application design.

In short, such complex model including User Interface auto-creation could be written as such - extracted from unit FileTables.pas:

```
function CreateFileModel(Owner: TSQLRest): TSQLModel;
begin
  result := TSQLModel.Create(Owner,
    @FileTabs,length(FileTabs),sizeof(FileTabs[0]),[],
    TypeInfo(TFileAction),TypeInfo(TFileEvent));
end;
```

All needed TSQLRecord classes are declared in a

```
FileTabs: array[0..4] of TFileRibbonTabParameters = ( ...
```

constant array, and will use TFileAction / TFileEvent enumeration types to handle the User Interface activity and Business Logic.

18.2.2. Web clients

18.2.2.1. Mustache template engine

Mustache - see <http://mustache.github.io..> - is a well-known *logic-less* template engine.

There is plenty of Open Source implementations around (including in *JavaScript*, which can be very convenient for AJAX applications on client side, for instance). For *mORMot*, we created the first pure *Delphi* implementation of it, with a perfect integration with other bricks of the framework.

Generally speaking, a Template system can be used to separate output formatting specifications, which govern the appearance and location of output text and data elements, from the executable logic which prepares the data and makes decisions about what appears in the output.

Most template systems (e.g. PHP, smarty, Razor...) feature in fact a full scripting engine within the template content. It allows powerful constructs like variable assignment or conditional statements in the middle of the HTML content. It makes it easy to modify the look of an application within the template system exclusively, without having to modify any of the underlying "application logic". They do so, however, at the cost of separation, turning the templates themselves into part of the application logic.

Mustache inherits from Google's *ctemplate* library, and is used in many famous applications, including the "main" Google web search, or the Twitter web site.

The *Mustache* template system leans strongly towards preserving the separation of logic and presentation, therefore ensures a perfect MVC - *Model-View-Controller* (page 86) - design, and ready to consume SOA services.

Mustache is intentionally constrained in the features it supports and, as a result, applications tend to require quite a bit of code to instantiate a template: all the application logic will be defined within the *Controller* code, not in the *View* source. This may not be to everybody's tastes. However, while this design limits the power of the template language, it does not limit the power or flexibility of the template system. This system supports arbitrarily complex text formatting.

Finally, *Mustache* is designed with an eye towards efficiency. Template instantiation is very quick, with an eye towards minimizing both memory use and memory fragmentation. As a result, it sounds like a perfect template system for our *mORMot* framework.

18.2.2.2. Mustache principles

There are two main parts to the *Mustache* template system:

- Templates (which are plain text files);
- Data dictionaries (aka *Context*).

For instance, given the following template:

```
<h1>{{header}}</h1>

{{#items}}
  {{#first}}
    <li><strong>{{name}}</strong></li>
  {{/first}}
  {{#link}}
    <li><a href="{{url}}">{{name}}</a></li>
  {{/link}}
{{/items}}
```

```
{{#empty}}  
<p>The list is empty.</p>  
{{/empty}}
```

and the following data context:

```
{  
  "header": "Colors",  
  "items": [  
    {"name": "red", "first": true, "url": "#Red"},  
    {"name": "green", "link": true, "url": "#Green"},  
    {"name": "blue", "link": true, "url": "#Blue"}  
  ],  
  "empty": true  
}
```

The *Mustache* engine will render this data as such:

```
<h1>Colors</h1>  
<li><strong>red</strong></li>  
<li><a href="#Green">green</a></li>  
<li><a href="#Blue">blue</a></li>  
<p>The list is empty.</p>
```

In fact, you did not see any "if" nor "for" loop in the template, but *Mustache* conventions make it easy to render the supplied data as the expected HTML output. It is up to the MVC *Controller* to render the data as expected by the template, e.g. for formatting dates or currency values.

18.2.2.3. Mustache templates

The *Mustache* template logic-less language has five types of tags:

- Variables;
- Sections;
- Inverted Sections;
- Comments;
- Partial.

All those tags will be identified with mustaches, i.e. `{{...}}`. Anything found in a template of this form is interpreted as a template marker. All other text is considered formatting text and is output verbatim at template expansion time.

Marker	Description
<code>{{variable}}</code>	The variable name will be searched recursively within the current context (possibly with dotted names), and, if found, will be written as escaped HTML. If there is no such key, nothing will be rendered.
<code>{{{variable}}}</code> <code>{{& variable}}</code>	The variable name will be searched recursively within the current context, and, if found, will be written directly, <i>without any HTML escape</i> . If there is no such key, nothing will be rendered.

<pre>{{#section}} ... {{/section}}</pre>	<p>Defines a block of text, aka <i>section</i>, which will be rendered depending of the section variable value, as searched in the current context:</p> <ul style="list-style-type: none"> - If section equals false or is an <i>empty list</i> [], the whole block won't be rendered; - If section is non-false but not a list, it will be used as the context for a single rendering of the block; - If section is a non-empty list, the text in the block will be rendered once for each item in the list - the context of the block will be set to the current item for each iteration.
<pre>{{^section}} ... {{/section}}</pre>	<p>Defines a block of text, aka <i>inverted section</i>, which will be rendered depending of the section variable <i>inverted</i> value, as searched in the current context:</p> <ul style="list-style-type: none"> - If section equals false or is an <i>empty list</i>, the whole block <i>will</i> be rendered; - If section is non-false or a non-empty list, it won't be rendered.
<pre>{{! comment}}</pre>	<p>The comment text will just be ignored.</p>
<pre>{{>partial}}</pre>	<p>The partial name will be searched within the registered <i>partials list</i>, then will be executed at run-time (so recursive partials are possible), with the current execution context.</p>
<pre>{{=...=}}</pre>	<p>The delimiters (i.e. by default <code>{{...}}</code>) will be replaced by the specified characters (may be convenient when double-braces may appear in the text).</p>

In addition to those standard markers, the *mORMot* implementation of *Mustache* features:

Marker	Description
<pre>{{helperName value}}</pre>	<p><i>Expression Helper</i>, able to change the value on the fly, before rendering. It could be used e.g. to display dates as text from <code>TDateTime</code> or <code>TTimeLog</code> values.</p>
<pre>{{.}}</pre>	<p>This pseudo-variable refers to the context object itself instead of one of its members. This is particularly useful when iterating over lists.</p>
<pre>{{-index}}</pre>	<p>This pseudo-variable returns the current item number when iterating over lists, starting counting at 1 (<code>{{-index0}}</code> will start counting at 0)</p>
<pre>{{#-first}} ... {{/-first}}</pre>	<p>Defines a block of text (pseudo-section), which will be rendered - or <i>not</i> rendered for inverted <code>{{^-first}}</code> - for the <i>first</i> item when iterating over lists</p>
<pre>{{#-last}} ... {{/-last}}</pre>	<p>Defines a block of text (pseudo-section), which will be rendered - or <i>not</i> rendered for inverted <code>{{^-last}}</code> - for the <i>last</i> item when iterating over lists</p>
<pre>{{#-odd}} ... {{/-odd}}</pre>	<p>Defines a block of text (pseudo-section), which will be rendered - or <i>not</i> rendered for inverted <code>{{^-odd}}</code> - for the <i>odd</i> item number when iterating over lists: it can be very useful e.g. to display a list with alternating row colors</p>
<pre>{{<partial}} ... {{/partial}}</pre>	<p>Defines an in-lined <i>partial</i> - to be called later via <code>{{>partial}}</code> - within the scope of the current template</p>
<pre>{{"some text"}}</pre>	<p>This pseudo-variable will supply the given text to a callback, which will for instance transform its content (e.g. translate it), before writing it to the output</p>

This set of markers will allow to easily write any kind of content, without any explicit logic nor nested code. As a major benefit, the template content could be edited and verified without the need of any *Mustache* compiler, since all those `{{ ... }}` markers will identify very clearly the resulting layout.

18.2.2.3.1. Variables

A typical Mustache template:

```
Hello {{name}}
You have just won {{value}} dollars!
Well, {{taxed_value}} dollars, after taxes.
```

Given the following hash:

```
{
  "name": "Chris",
  "value": 10000,
  "taxed_value": 6000
}
```

Will produce the following:

```
Hello Chris
You have just won 10000 dollars!
Well, 6000 dollars, after taxes.
```

You can note that `{{variable}}` tags are escaped for HTML by default. This is a mandatory security feature. In fact, all web applications which create HTML documents can be vulnerable to Cross-Site-Scripting (XSS) attacks unless data inserted into a template is appropriately sanitized and/or escaped. With Mustache, this is done by default. Of course, you can override it and force to *not-escape* the value, using `{{{variable}}}` or `{{& variable}}`.

For instance:

Template	Context	Output
* {{name}}	{ "name": "Chris", "company": "GitHub" }	* Chris
* {{age}}		*
* {{company}}		* GitHub
* {{{company}}}		* GitHub

Variables resolve names within the current context with an optional dotted syntax, for instance:

Template	Context	Output
* {{people.name}}	{ "people": { "name": "Chris", "company": "GitHub" } }	* Chris
* {{people.age}}		*
* {{people.company}}		* GitHub
* {{{people.company}}}		* GitHub

18.2.2.3.2. Sections

Sections render blocks of text one or more times, depending on the value of the key in the current context.

In our "winning template" above, what happen if we do want to hide the tax details?

In most script languages, we may write an `if ...` block within the template. This is what *Mustache* avoids. So we define a section, which will be rendered on need.

The template becomes:

```
Hello {{name}}
You have just won {{value}} dollars!
{{#in_ca}}
Well, {{taxed_value}} dollars, after taxes.
{{/in_ca}}
```

Here, we created a new section, named `in_ca`.

Given the hash value of `in_ca` (and its presence), the section will be rendered, or not:

Context	Output
<pre>{ "name": "Chris", "value": 10000, "taxed_value": 6000, "in_ca": true }</pre>	<pre>Hello Chris You have just won 10000 dollars! Well, 6000 dollars, after taxes.</pre>
<pre>{ "name": "Chris", "value": 10000, "taxed_value": 6000, "in_ca": false }</pre>	<pre>Hello Chris You have just won 10000 dollars!</pre>
<pre>{ "name": "Chris", "value": 10000, "taxed_value": 6000 }</pre>	<pre>Hello Chris You have just won 10000 dollars!</pre>

Sections also change the context of its inner block. It means that the section variable content becomes the top-most context which will be used to identify any supplied variable key.

Therefore, the following context will be perfectly valid: we can define `taxed_value` as a member of `in_ca`, and it will be rendered directly, since it is part of the new context.

Context	Output
<pre>{ "name": "Chris", "value": 10000, "in_ca": { "taxed_value": 6000 } }</pre>	<pre>Hello Chris You have just won 10000 dollars! Well, 6000 dollars, after taxes.</pre>
<pre>{ "name": "Chris", "value": 10000, "taxed_value": 6000 }</pre>	<pre>Hello Chris You have just won 10000 dollars!</pre>

```
{
  "name": "Chris",
  "value": 10000,
  "taxed_value": 3000,
  "in_ca": {
    "taxed_value": 6000
  }
}
```

Hello Chris
You have just won 10000 dollars!
Well, 6000 dollars, after taxes.

In the latest context above, there are two `taxed_value` variables. The engine will use the one defined by the context in the `in_ca` section, i.e. `in_ca.taxed_value`; the one defined at the root context level (which equals 3000) is just ignored.

If the variable pointed by the section name is a list, the text in the block will be rendered once for each item in the list. The context of the block will be set to the current item for each iteration. In this way we can loop over collections. *Mustache* allows any depth of nested loops (e.g. any level of master/details information).

Template	Context	Output
<pre>{{#repo}} {{name}} {{/repo}}</pre>	<pre>{ "repo": ["name": "resque" , "name": "hub" , "name": "rip"] }</pre>	<pre>resque hub rip</pre>
<pre>{{#repo}} {{.}} {{/repo}}</pre>	<pre>{ "repo": ["resque", "hub", "rip"] }</pre>	<pre>resque hub rip</pre>

The latest template makes use of the `{{.}}` pseudo-variable, which allows to render the current item of the list.

18.2.2.3.3. Inverted Sections

An inverted section begins with a caret (^) and ends as a standard (non-inverted) section. They may render text once, based on the *inverse* value of the key. That is, the text block will be rendered if the key doesn't exist, is false, or is an empty list.

Inverted sections are usually defined after a standard section, to render some message in case no information will be written in the non-inverted section:

Template	Context	Output
<pre>{{#repo}} {{.}} {{/repo}} {{^repo}} No repos :({{/repo}}</pre>	<pre>{ "repo": [] }</pre>	<pre>No repos :(</pre>

18.2.2.3.4. Partial

Partials are some kind of external sub-templates which can be included within a main template, for instance to follow the same rendering at several places. Just like functions in code, they do ease template maintainability and spare development time.

Partials are rendered at runtime (as opposed to compile time), so recursive partials are possible. Just avoid infinite loops. They also inherit the calling context, so can easily be re-used within a list section, or together with plain variables.

In practice, partials shall be supplied together with the data context - they could be seen as "template context".

For example, this "main" template uses a `{{> user}}` partial:

```
<h2>Names</h2>
{{#names}}
  {{> user}}
{{/names}}
```

With the following template registered as "user":

```
<strong>{{name}}</strong>
```

Can be thought of as a single, expanded template:

```
<h2>Names</h2>
{{#names}}
  <strong>{{name}}</strong>
{{/names}}
```

In *mORMot*'s implementations, you can also create some *internal* partials, defined as `{{<partial>}}` ... `{{/partial}}` pseudo-sections. It may decrease the need of maintaining multiple template files, and refine the rendering layout.

For instance, the previous template may be defined at once:

```
<h2>Names</h2>
{{#names}}
  {{>user}}
{{/names}}

{{<user>}}
<strong>{{name}}</strong>
{{/user}}
```

The same file will define both the partial and the main template. Note that we defined the internal partial after the main template, but we may have defined it anywhere in the main template logic: internal partials definitions are ignored when rendering the main template, just like comments.

18.2.2.4. SynMustache unit

Part of our *mORMot* framework, we implemented an optimized *Mustache* template engine in the SynMustache unit:

- It is the first *Delphi* implementation of *Mustache*;
- It has a separate parser and renderer (so you can compile your templates ahead of time);
- The parser features a shared cache of compiled templates;
- It passes all official *Mustache* specification tests, as defined at <http://github.com/mustache/spec..> - including all weird whitespace process;
- External partials can be supplied as `TSynMustachePartials` dictionaries;
- `{{.}}`, `{{-index}}` and `{{"some text"}}` pseudo-variables were added to the standard *Mustache* syntax;

- `{{#-first}}`, `{{#-last}}` and `{{#-odd}}` pseudo-sections were added to the standard *Mustache* syntax;
- Internal partials can be defined via `{{<partial}}` - also a nice addition to the standard *Mustache* syntax;
- It allows the data context to be supplied as JSON or our *TDocVariant custom variant type* (page 112);
- Almost no memory allocation is performed during the rendering;
- It is natively UTF-8, from the ground up, with optimized conversion of any string data;
- Performance has been tuned and grounded in *SynCommons.pas*'s optimized code;
- Each parsed template is thread-safe and re-entrant;
- It follows the *Open/Closed principle* - see *SOLID design principles* (page 390) - so that any aspect of the process can be customized and extended (e.g. for any kind of data context);
- It is perfectly integrated with the other bricks of our *mORMot* framework, ready to implement dynamic web sites with true *Model-View-Controller* (page 86) design, and full separation of concerns in the views written in *Mustache*, the controllers being e.g. interface-based services - see *Client-Server services via interfaces* (page 420), and the models being our *Object-Relational Mapping (ORM)* (page 92) classes;
- API is flexible and easy to use.

18.2.2.4.1. Variables

Now, let's see some code.

First, we define our needed variables:

```
var mustache: TSynMustache;  
    doc: variant;
```

In order to parse a template, you just need to call:

```
mustache := TSynMustache.Parse(  
  'Hello {{name}}'#13#10'You have just won {{value}} dollars!');
```

It will return a compiled instance of the template.

The `Parse()` class method will use the shared cache, so you won't need to release the `mustache` instance once you are done with it: no need to write a `try ... finally mustache.Free; end block`.

You can use a *TDocVariant* to supply the context data (with late-binding):

```
TDocVariant.New(doc);  
doc.name := 'Chris';  
doc.value := 10000;
```

As an alternative, you may have defined the context data as such:

```
doc := _ObjFast(['name', 'Chris', 'value', 1000]);
```

Now you can render the template with this context:

```
html := mustache.Render(doc);  
// now html='Hello Chris'#13#10'You have just won 10000 dollars!'
```

If you want to supply the context data as JSON, then render it, you may write:

```
mustache := TSynMustache.Parse(  
  'Hello {{value.name}}'#13#10'You have just won {{value.value}} dollars!');  
html := mustache.RenderJSON('{value:{name:"Chris",value:10000}}');  
// now html='Hello Chris'#13#10'You have just won 10000 dollars!'
```

Note that here, the JSON is supplied with *MongoDB*-like extended syntax (i.e. field names are unquoted), and that *TSynMustache* is able to identify a dotted-named variable within the execution context.

As an alternative, you could use the following syntax to create the data context as JSON, with a set of parameters, therefore easier to work with in real code storing data in variables (for instance, any string variable is quoted as expected by JSON, and converted into UTF-8):

```
mustache := TSynMustache.Parse(
  'Hello {{name}}'#13#10'You have just won {{value}} dollars!';
html := mustache.RenderJSON('{name:?,value:?}",[],['Chris',10000]);
html='Hello Chris'#13#10'You have just won 10000 dollars!'
```

You can find in the mORMot.pas unit the ObjectToJSON() function which is able to transform any TPersistent instance into valid JSON content, ready to be supplied to a TSynMustache compiled instance.

If the object's published properties have some getter functions, they will be called on the fly to process the data (e.g. returning 'FirstName Name' as FullName by concatenating both sub-fields).

18.2.2.4.2. Sections

Sections are handled as expected:

```
mustache := TSynMustache.Parse('Shown.{{#person}}As {{name}}!{{/person}}end{{name}}');
html := mustache.RenderJSON('{person:{age:?,name:?}",[10,'toto']);
// now html='Shown.As toto!end'
```

Note that the sections change the data context, so that within the #person section, you can directly access to the data context person member, i.e. writing directly {{name}}

It supports also inverted sections:

```
mustache := TSynMustache.Parse('Shown.{{^person}}Never shown!{{/person}}end');
html := mustache.RenderJSON('{person:true}');
// now html='Shown.end'
```

To render a list of items, you can write for instance (using the {{.}} pseudo-variable):

```
mustache := TSynMustache.Parse('{{#things}}{{.}}{{/things}}');
html := mustache.RenderJSON('{things:["one", "two", "three"]}');
// now html='onetwothree'
```

The {{-index}} pseudo-variable allows to numerate the list items, when rendering:

```
mustache := TSynMustache.Parse(
  'My favorite things:{{#things}}{{-index}}. {{.}}'#$A'{{/things}}');
html := mustache.RenderJSON('{things:["Peanut butter", "Pen spinning", "Handstands"]}');
// now html='My favorite things:{{#things}}{{-index}}. {{.}}'#$A'1. Peanut butter'#$A'2. Pen spinning'#$A'
// '3. Handstands'#$A, '-index pseudo variable'
```

18.2.2.4.3. Partial

External partials (i.e. standard Mustache partials) can be defined using TSynMustachePartials. You can define and maintain a list of TSynMustachePartials instances, or you can use a one-time partial, for a given rendering process, as such:

```
mustache := TSynMustache.Parse('{{>partial}}'#$A'3');
html := mustache.RenderJSON('{}',TSynMustachePartials.CreateOwned(['partial','1'#$A'2']));
// now html='1'#$A'23','external partials'
```

Here TSynMustachePartials.CreateOwned() expects the partials to be supplied as name/value pairs.

Internal partials (one of the SynMustache extensions), can be defined directly in the main template:

```
mustache := TSynMustache.Parse('{{<partial}}1'#$A'2{{name}}{{/partial}}{{>partial}}4');
html := mustache.RenderJSON('{name:3}');
// now html='1'#$A'234','internal partials'
```

18.2.2.4.4. Expression Helpers

Expression Helpers are an extension to the standard *Mustache* definition. They allow to define your own set of functions which will be called during the rendering, to transform one value from the context into a value to be rendered.

TSynMustache.HelpersGetStandardList will return a list of standard static helpers, able to convert TDateTime or TTimeLog values into text, or convert any value into its JSON representation. The current list of registered helpers are DateTimeToText, DateToText, DateFmt, TimeLogToText, BlobToBase64, JSONQuote, JSONQuoteURI, ToJSON, EnumTrim, EnumTrimRight, PowerOfTwo, Equals, If, MarkdownToHtml, SimpleToHtml and WikiToHtml. For instance, {{TimeLogToText CreatedAt}} will convert a TCreateTime field value into ready-to-be-displayed text.

The mustache tag syntax is {{helpername value}}. The supplied value parameter may be a variable name in the current context, or could be a constant number ({{helpername 123}}), a constant JSON string ({{helpername "constant text"}}), a JSON array ({{helpername [1,2,3]}}) or a JSON object ({{helpername {name:"john",age:24}}})). The value could be also a comma-separated set of values, which will be translated into a corresponding JSON array, the values being extracted from the current context, as with {{DateFmt DateValue, "dd/mm/yyyy"}}.

You could call recursively the helpers, just like you nest functions: {{helper1 helper2 value}} will call helper2 with the supplied value, which result will be passed as value to helper1.

But you can create your own list of registered *Expression Helpers*, even including some business logic, to compute any data during rendering, via TSynMustache.HelperAdd methods.

The helper should be implemented with such a method:

```
class procedure TSynMustache.JSONQuote(const Value: variant; out result: variant);
var json: RawUTF8;
begin
  QuotedStrJSON(VariantToUTF8(Value), json);
  RawUTF8ToVariant(json, result);
end;
```

Here, the supplied Value parameter will be either from a variable of the context, or a constant, from JSON number, string, array or object - encoded as a *TDocVariant custom variant type* (page 112).

If the parameters were supplied as a comma-separated list, you may write multi-parameter functions as such:

```
class procedure TSynMustache.DateFmt(const Value: variant; out result: variant);
begin
  with _Safe(Value)^ do
    if (Kind=dvArray) and (Count=2) and (TVarData(Values[0]).VType=varDate) then
      result := FormatDateTime(Values[1], TVarData(Values[0]).VDate) else
        SetVariantNull(result);
end;
```

So you could use such expression helper this way:

```
La date courante en France est : {{DateFmt DateValue, "dd/mm/yyyy"}}
```

The Equals helper is defined as such:

```
class procedure TSynMustache.Equals_(const Value: variant; out result: variant);
begin // {{#Equals ., 12}}
  with _Safe(Value)^ do
    if (Kind=dvArray) and (Count=2) and
      (SortDynArrayVariant(Values[0], Values[1])=0) then
      result := true else
        SetVariantNull(result);
end;
```

You may use it in your template to provide additional view logic:

```
{{#Equals Category,"Admin"}}
Welcome, Mister Administrator!
{{/Equals Category,"Admin"}}
```

The section ending may optionally only contain the helper name, so the following syntax is also correct, and perhaps less error-prone:

```
{{#Equals Category,"Admin"}}
Welcome, Mister Administrator!
{{/Equals}}
```

The `#If` helper is even more powerful, since it allows to define some view logic, via `= < > <= >= <>` operators set between two values:

```
{{#if .,"=",6}} Welcome, number six! {{/if}}
{{#if Total,">",1000}} Thanks for your income: your loyalty will be rewarded. {{/if}}
{{#if info,"<>",""}} Warning: {{info}} {{/if}}
```

As an alternative, you could just put the operator without a string parameter:

```
{{#if .=6}} Welcome, number six! {{/if}}
{{#if Total>1000}} Thanks for your income: your loyalty will be rewarded. {{/if}}
{{#if info<>""}} Warning: {{info}} {{/if}}
```

This latest syntax may be pretty convenient to work with. Of course, since *Mustache* is expected to be a *logic-less* templating engine, you should better not use the `#if` helper in most cases, but rather add some dedicated flags in the supplied data context:

```
{{#isNumber6}} Welcome, number six! {{/isNumber6}}
{{#showLoyaltyMessage}} Thanks for your income: your loyalty will be rewarded. {{/showLoyaltyMessage}}
{{#showWarning}} Warning: {{info}} {{/showWarning}}
```

Helpers can be used to convert some *wiki* or *markdown* content into plain HTML, for instance, in the MVC blog sample, a `ContentHtml` boolean flag defines if a content (here the abstract text field) is already HTML-encoded, or if it needs to be converted via the `WikiToHtml` helper:

```
{{#ContentHtml}}{{{abstract}}}{{/ContentHtml}}{{^ContentHtml}}{{{WikiToHtml
abstract}}}{{/ContentHtml}}
```

The framework also offers some built-in optional *Helpers* tied to its ORM, if you create a MVC web application using `mORMotMVC.pas` - see below (page 520) - you can register a set of *Expression Helpers* to let your *Mustache* view retrieve a given `TSQLRecord`, from its ID, or display a given instance fields in an auto-generated table.

For instance, you may write:

```
aMVCMustacheView.RegisterExpressionHelpersForTables(aRestServer,[TSQLMyRecord]);
```

This will define two *Expression Helpers* for the specified table:

- Any `{{#TSQLMyRecord MyRecordID}} ... {{/TSQLMyRecord MyRecordID}}` *Mustache* tag will read a `TSQLMyRecord` from the supplied ID value and put its fields in the current rendering data context, ready to be displayed in the view.
- Any `{{TSQLMyRecord.HtmlTable MyRecord}}` *Mustache* tag which will create a HTML table containing all information about the supplied `MyRecord` fields (from the current data context), with complex field handling (like `TDateTime`, `TTimeLog`, sets or enumerations), and proper display of the field names (and *i18n*).

18.2.2.4.5. Internationalization

You can define `{{"some text"}}` pseudo-variables in your templates, which text will be supplied to a callback, ready to be transformed on the fly: it may be convenient for *i18n* of web applications.

By default, the text will be written directly to the output buffer, but you can define a callback which may be used e.g. for text translation:

```
procedure TTestLowLevelTypes.MustacheTranslate(var English: string);
begin
  if English='Hello' then
    English := 'Bonjour' else
    if English='You have just won' then
      English := 'Vous venez de gagner';
end;
```

Of course, in a real application, you may assign one TLanguageFile.Translate(var English: string) method, as defined in the mORMoti18n.pas unit.

Then, you will be able to define your template as such:

```
mustache := TSynMustache.Parse(
  '{{"Hello"}} {{name}}'#13#10'{{"You have just won"}} {{value}} {{"dollars"}}!');
html := mustache.RenderJSON('name:?,value:?',[],['Chris',10000],nil,MustacheTranslate);
// now html='Bonjour Chris'#$D#$A'Vous venez de gagner 10000 dollars!'
```

All text has indeed been translated as expected.

18.2.2.5. Low-level integration with method-based services

You can easily integrate the *Mustache* template engine with the framework's ORM. To avoid any unneeded temporary conversion, you can use the TSQLRest.RetrieveDocVariantArray() method, and provide its TDocVariant result as the data context of TSynMustache.Render().

For instance, you may write, in any method-based service - see *Client-Server services via methods* (page 374):

```
var template: TSynMustache;
    html: RawUTF8;
...
template := TSynMustache.Parse(
  '<ul>{{#items}}<li>{{Name}} was born on {{BirthDate}}</li>{{/items}}</ul>');
html := template.Render(
  aClient.RetrieveDocVariantArray(TSQLBaby,'items','Name,BirthDate'));
// now html will contain a ready-to-be-displayed unordered list
```

Of course, this TSQLRest.RetrieveDocVariantArray() method accepts an optional WHERE clause, to be used according to your needs. You may even use paging, to split the list in smaller pieces.

Following this low-level method-based services process, you can easily create a high performance web server using *mORMot*, following the MVC pattern as such:

MVC	mORMot
<i>Model</i>	<i>Object-Relational Mapping (ORM)</i> (page 92) and its TSQLModel / TSQLRecord definitions
<i>View</i>	<i>Mustache template engine</i> (page 506) (may be stored as separated files or within the database)
<i>Controller</i>	Method-based services - see <i>Client-Server services via methods</i> (page 374)

But still, a lot of code is needed to glue the MVC parts.

18.2.2.6. MVC/MVVM Design

In practice, the method-based services MVC pattern is difficult to work with. You have a lot of

plumbing to code by yourself, e.g. parameter marshalling, rendering or routing.

The `mORMotMVC.pas` unit offers a true MVVM (*Model View ViewModel*) design, much more advanced, which relies on interface definitions to build the application - see *Interfaces* (page 386):

MVVM	mORMot
<i>Model</i>	<i>Object-Relational Mapping (ORM)</i> (page 92) and its <code>TSQLModel1</code> / <code>TSQLRecord</code> definitions
<i>View</i>	<i>Mustache template engine</i> (page 506) (may be stored as separated files or within the database)
<i>ViewModel</i>	Interface services - see also <i>Client-Server services via interfaces</i> (page 420)

In the MVVM pattern, both *Model* and *View* components do match the classic *Model-View-Controller* (page 86) layout. But the *ViewModel* will define some kind of "model for the view", i.e. the data context to be sent and retrieved from the view.

In the *mORMot* implementation, interface methods are used to define the execution context of any request, following the *convention over configuration* pattern of our framework.

In fact, the following conventions are used to define the *ViewModel*:

ViewModel	mORMot
<i>Route</i>	From the interface name and its method name
<i>Command</i>	Defined by the method name
<i>Controller</i>	Defined by the method implementation
<i>ViewModel Context</i>	Transmitted <i>by representation</i> , as JSON, including complex values like <code>TSQLRecord</code> , records, dynamic arrays or variants (including <code>TDocVariant</code>)
<i>Input Context</i>	Transmitted as method input parameters (const/var) from the <i>View</i>
<i>Output Context</i>	Method output parameters (var/out) are sent to the <i>View</i>
<i>Actions</i>	A method will render the associated view with the output parameters, or go to another command (optionally via <code>EMVCApplication</code>)

This may sound pretty unusual (if you are coming from a *RubyOnRails*, *AngularJS*, *Meteor* or *.Net* implementations), but it has been identified to be pretty convenient to use. Main benefit is that you do not need to define explicit data structures for the *ViewModel* layer. The method parameters will declare the execution context for you at interface level, ready to be implemented in a `TMVCApplication` class. In practice, this implementation uses the interface input and output parameters as an alternate way to define the `$scope` content of an *AngularJS* application.

The fact that the *ViewModel* data context is transmitted as JSON content - *by representation* just like REST - see *REST* (page 312) - allows nice side effects:

- *Views* do not know anything about the execution context, so are very likely to be uncoupled from any business logic - this will enhance security and maintainability of your applications;
- You can optionally see in real time the JSON data context (by using a fake root/methodname/json URI) of a running application, for easier debugging of the *Controller* or the *Views*;
- You can test any *View* by using fake static JSON content, without the need of a real server;

- In fact, *Views* could be even not tied to the web model, but run in a classic rich application, with VCL/FMX User Interface (we still need to automate the binding process to UI components, but this is technically feasible, whereas almost no other MVC web framework do support this);
- Since *interface* are used to define the *Controller*, you could mock and stub them - see *Interfaces in practice: dependency injection, stubs and mocks* (page 407) - for proper unit testing;
- In the *Controller* code, you have access to the *mORMot* ORM methods and services to write the various commands, making it pretty easy to implement a web front-end to any SOA project (also sharing a lot of high-level *Domain* types);
- The associated data *Model* is *mORMot*'s ORM, which is also optimized for JSON processing, so most of memory fragmentation is reduced to the minimum during the rendering (see e.g. the use of *RawJSON* below);
- The *Controller* will be most of the time hosted within the web server application, but *may* be physically hosted in another remote process - this remote *Controller* service may even be shared between web and VCL/FMX clients;
- Several levels of cache could be implemented, based on the JSON content, to leverage the server resources and scale over a huge number of clients.

The next chapter will uncover how to build such solid MVC / MVVM Web Applications using *mORMot*.

19. MVC/MVVM Web applications

Adopt a mORMot

We will now explain how to build a MVC/MVVM web application using *mORMot*, starting from the "30 - MVC Server" sample. Following explanations may be a bit unsynchronized from the current state of the sample source code in the "unstable" branch of the framework repository, but you will get here below the main intangible points.

This little web application publishes a simple BLOG, not fully finished yet (this is a *Sample*, remember!). But you can still execute it in your desktop browser, or any mobile device (thanks to a simple *Bootstrap*-based responsive design), and see the articles list, view one article and its comments, view the author information, log in and out.

This sample is implemented as such:

MVVM	Source	mORMot
<i>Model</i>	MVCModel.pas	TSQLRestServerDB ORM over a <i>SQLite3</i> database
<i>View</i>	*.html	<i>Mustache template engine</i> (page 506) in the <i>Views</i> sub-folder
<i>ViewModel</i>	MVCViewModel.pas	Defined as one <i>IBlogApplication</i> interface

For the sake of the simplicity, the sample will create some fake data in its own local *SQLite3* database, the first time it is executed.

19.1. MVCModel

19.1.1. Data Model

The MVCModel.pas unit defines the database *Model*, as regular TSQLRecord classes. For instance, you will find the following type definitions:

```
TSQLContent = class(TSQLRecordTimestamped)
private ...
```

```
published
  property Title: RawUTF8 index 80 read fTitle write fTitle;
  property Content: RawUTF8 read fContent write fContent;
  property Author: TSQLAuthor read fAuthor write fAuthor;
  property AuthorName: RawUTF8 index 50 read fAuthorName write fAuthorName;
end;

TSQLArticle = class(TSQLContent)
private ...
public
  class function CurrentPublishedMonth: Integer;
  class procedure InitializeTable(Server: TSQLRestServer; const FieldName: RawUTF8;
    Options: TSQLInitializeTableOptions); override;
  procedure TagsAddOrdered(aTagID: integer; var aTags: TSQLTags);
published
  property PublishedMonth: Integer read fPublishedMonth write fPublishedMonth;
  property Abstract: RawUTF8 index 1024 read fAbstract write fAbstract;
  property Tags: TIntegerDynArray index 1 read fTags write fTags;
end;

TSQLComment = class(TSQLContent)
private ...
published
  property Article: TSQLArticle read fArticle write fArticle;
end;
```

Then the whole database model will be created in this function:

```
function CreateModel: TSQLModel;
begin
  result := TSQLModel.Create([TSQLBlogInfo, TSQLAuthor,
    TSQLTag, TSQLArticle, TSQLComment, TSQLArticleSearch], 'blog');
  TSQLArticle.AddFilterNotVoidText(['Title', 'Content']);
  TSQLComment.AddFilterNotVoidText(['Title', 'Content']);
  TSQLTag.AddFilterNotVoidText(['Ident']);
  result.Props[TSQLArticleSearch].FTS4WithoutContent(TSQLArticle);
end;
```

As you can discover:

- We used class inheritance to gather properties for similar tables;
- Some classes are *not* part of the model, since they are just abstract parents, e.g. TSQLContent is not part of the model, but TSQLArticle and TSQLComment are;
- We defined some regular *one-to-one* relationships, e.g. every Content (which may be either an Article or a Comment) will be tied to one Author - see "*One to one*" or "*One to many*" (page 151);
- We defined some regular *one-to-many* relationships, e.g. every Comment will be tied to one Article;
- Article tags are stored as a dynamic array of integer within the record, and not in a separated pivot table: it will make the database smaller, and queries faster (since we avoid a JOIN);
- Some properties are defined (and stored) twice, e.g. TSQLContent defines one AuthorName field in addition to the Author ID field, as a convenient direct access to the author name, therefore avoiding a JOINed query at each Article or a Comment display - see *Shared nothing architecture (or sharding)* (page 155);
- We defined the maximum expected width for text fields (e.g. via Title: RawUTF8 index 80), even if it won't be used by *SQLite3* - it will ease any eventual migration to an external database, in the future - see *Code-first ORM* (page 269);
- Some validation rules are set using TSQLArticle.AddFilterNotVoidText() method, which will be applied before an article is stored in the controller's code (in TBlogApplication.ArticleCommit);
- The whole application will run without writing any SQL, but just high-level ORM methods;
- Even if we want to avoid writing SQL, we tried to modelize the data to fit regular RDBMS expectations, e.g. for most used queries (like the one run from the main page of the BLOG);

- Full Text indexation data, implemented as *FTS3/FTS4/FTS5* (page 215) in the *SQLite3* engine, is stored in a dedicated *TSQLArticleSearch* table - see *FTS4 index tables without content* (page 218) for details about this powerful feature.

Foreign keys and indexes are managed as such:

- The *TSQLRecord.ID* primary key of any ORM class will be indexed;
- For both *one-to-one* and *one-to-many* relationships, indexes are created by the ORM: for instance, *TSQLArticle.Author* and *TSQLComment.Author* will be indexed, just as *TSQLComment.Article*;
- A SQL index will be needed for *TSQLArticle.PublishedMonth* field, which is used to display a list of publication months in the main BLOG page, and link to the corresponding articles.

The following code will take care of it:

```
class procedure TSQLArticle.InitializeTable(Server: TSQLRestServer;  
  const FieldName: RawUTF8; Options: TSQLInitializeTableOptions);  
begin  
  inherited;  
  if (FieldName='') or (FieldName='PublishedMonth') then  
    Server.CreateSQLIndex(TSQLArticle, 'PublishedMonth', false);  
end;
```

19.1.2. Hosted in a REST server over HTTP

The ORM is defined to run over a *SQLite3* database in the main *MVCServer.dpr* program, then served via a HTTP server as defined in *MVCServer.dpr*:

```
aModel := CreateModel;  
try  
  aServer := TSQLRestServerDB.Create(aModel, ChangeFileExt(paramstr(0), '.db'));  
  try  
    aServer.DB.Synchronous := smNormal;  
    aServer.DB.LockingMode := lmExclusive;  
    aServer.CreateMissingTables;  
    aApplication := TBlogApplication.Create;  
    try  
      aApplication.Start(aServer);  
      aHTTPServer := TSQLHttpServer.Create('8092', aServer, '+', useHttpApiRegisteringURI);  
      try  
        aHTTPServer.RootRedirectToURI('blog/default'); // redirect server:8092  
        writeln("MVC Blog Server" launched on port 8092);  
      finally  
        aHTTPServer.Free;  
      end;  
    finally  
      aApplication.Free;  
    end;  
  finally  
    aServer.Free;  
  end;  
except  
  writeln('Error: ' + ExceptionMessage);  
end;
```

In comparison to a regular *Client-Server process* (page 319), we instantiated a *TBlogApplication*, which will *inject* the MVC behavior to *aServer* and *aHTTPServer*. The same *mORMot* program could be used as a RESTful server for remote *Object-Relational Mapping (ORM)* (page 92) and *Service-Oriented Architecture (SOA)* (page 90), and also for publishing a web application, sharing the same data and business logic, over a single HTTP URI and port.

A call to *RootRedirectToURI()* will let any <http://server:8092..> HTTP request be redirected to <http://server:8092/blog/default..> which is our BLOG application main page. The other URIs could be used as usual, as any *mORMot's JSON RESTful Client-Server* (page 296).

You could also use sub-domain hosting, as defined for *Network and Internet access via HTTP* (page 326), to make a difference between the REST methods and the MVC web site. For instance, you may define some per domain / per sub-domain hosting redirection:

```
aHttpServer.DomainHostRedirect('rest.project.com', 'root'); // 'root' is current Model.Root  
aHttpServer.DomainHostRedirect('project.com', 'root/html'); // call the Html() method  
aHttpServer.DomainHostRedirect('www.project.com', 'root/html'); // call the Html() method  
aHttpServer.DomainHostRedirect('blog.project.com', 'root/blog'); // MVC application
```

All ORM/SOA activity should be accessed remotely via *rest.project.com*, then will be handled as

expected by the ORM/SOA methods of the TSQLRestServer instance.
For proper AJAX / JavaScript process, you may have to write:

```
aHttpServer.AccessControlAllowOrigin := '*'; // allow cross-site AJAX queries
```

Any attempt to access to the project.com or www.project.com URI will be redirected to the following method-based service:

```
procedure TMyServer.Html(Ctxt: TSQLRestServerURIContext);
begin
  if fMyFileCache='' then
    fMyFileCache := StringFromFile(ChangeFileExt(paramstr(0),'.html'));
  Ctxt.Returns(fMyFileCache,HTTP_SUCCESS,HTML_CONTENT_TYPE_HEADER,true);
end;
```

This method will serve some static HTML content as the main front end page of this server connected to the Internet. For best performance, this UTF-8 content is cached in memory, and the HTTP 304 command will be handled, if the browser supports it. Of course, your application may return some more complex content, even serving a set of files hosted in a local folder, e.g. by calling Ctxt.ReturnFile() or Ctxt.ReturnFileFromFolder() methods in this Html() service:

```
procedure TMyServer.Html(Ctxt: TSQLRestServerURIContext);
begin
  Ctxt.ReturnFileFromFolder('c:\www');
end;
```

This single method will search for any matching file in the local c:\www folder and its sub-directories, returning the default index.html content if no file is specified at URI level. See the optional parameters to the Ctxt.ReturnFileFromFolder() method for proper tuning, e.g. to change the default file name or disable the HTTP 304 answers. In all cases, the file content will be served by the *High-performance http.sys server* (page 327) directly from the kernel mode, so will be very fast.

In order to have the BLOG content hosted in root/blog URI, you should specify the expected sub-URI when initializing your TMVCApplication:

```
procedure TBlogApplication.Start(aServer: TSQLRestServer);
begin
  ...
  fMainRunner := TMVCRunOnRestServer.Create(self,nil,'blog').
  ...
end;
```

Here, any request to blog.project.com will be redirected to root/blog, so will match the expected TBlogApplication URIs. Note that by default, TMVCRunOnRestServer.RunOnRestServerSub will redirect any root/blog request to root/blog/default, so this URI will be transparent for the user.

19.2. MVCViewModel

19.2.1. Defining the commands

The MVCViewModel.pas unit defines the *Controller* (or *ViewModel*) of the "30 - MVC Server" sample application.

It uses the mORMotMVC.pas unit, which is the main MVC kernel for the framework, allowing to easily create *Controllers* binding the ORM/SOA features (mORMot.pas) to the *Mustache Views* (SynMustache.pas).

First of all, we defined an interface, with the expected methods corresponding to the various *commands* of the web application:

```
IBlogApplication = interface(IMVCApplication)
  procedure ArticleView(
```

```

    ID: integer; var WithComments: boolean; Direction: integer;
    out Article: TSQLArticle; out Author: TSQLAuthor;
    out Comments: TObjectList);
  procedure AuthorView(
    var ID: integer; out Author: variant; out Articles: variant);
  function Login(
    const LogonName, PlainPassword: RawUTF8): TMVCAction;
  function Logout: TMVCAction;
  procedure ArticleEdit(
    var ID: integer; const Title, Content: RawUTF8;
    const ValidationError: variant;
    out Article: TSQLArticle);
  function ArticleCommit(
    ID: integer; const Title, Content: RawUTF8): TMVCAction;
end;
```

In fact, IMVCAApplication is defined as such in mORMotMVC.pas:

```

IMVCAApplication = interface(IInvokable)
  ['{C48718BF-861B-448A-B593-8012DB51E15D}']
  procedure Default(var Scope: variant);
  procedure Error(var Msg: RawUTF8; var Scope: variant);
end;
```

As such, the IBlogApplication will define the following web pages, corresponding to each of its methods: *Default*, *Error*, *ArticleView*, *AuthorView*, *Login*, *Logout*, *ArticleEdit* and *ArticleCommit*. Each command of this application will map an URI, e.g. */blog/default* or */blog/login* - remember that our model defined 'blog' as its root URI. You may let all commands be accessible from a sub-URI (e.g. */blog/web/default*), but here this is not needed, since we are creating a "pure web" application.

Each command will have its own *View*. For instance, you will find *Default.html*, *Error.html* or *ArticleView.html* in the "Views" sub-folder of the sample. If you did not supply any file in this folder, some void files will be created.

Incoming method parameters of each method (i.e. defined as *const* or *var*) will be transmitted on the URI, encoded as regular HTTP parameters, whereas outgoing method parameters (i.e. defined as *var* or *out*) will be transmitted to the *View*, as data context for the rendering. Simple types are transmitted (like *integer* or *RawUTF8*); but you will also find ORM classes (like *TSQLAuthor*), an outgoing *TObjectList*, or some *variant* - which may be either values or a complex *TDocVariant custom variant type* (page 112).

In fact, you may find out that the *Login*, *Logout* and *ArticleCommit* methods do not have any outgoing parameters, but were defined as function returning a *TMVCAction* record.

This type is declared as such in mORMotMVC.pas:

```

TMVCAction = record
  RedirectToMethodName: RawUTF8;
  RedirectToMethodParameters: RawUTF8;
  ReturnedStatus: cardinal;
end;
```

Any method returning a *TMVCAction* content won't render directly any view, but will allow to go directly to another method, for proper rendering, just by providing a method name and some optional parameters.

Note that even the regular views, i.e. the methods which do not have this *TMVCAction* parameter, may break the default rendering process on any error, raising an *EMVCAApplication* exception which will in fact redirect the view to another page, mainly the *Error* page.

To better understand how it works, run the "30 - MVC Server" sample. Remember that to be able to register the port #8092 for the *http.sys* server, you will need to run the *MVCServer.exe* program at least once with *Windows Administrator* rights - see *URI authorization as Administrator* (page 328).

Then point your browser to <http://localhost:8092/> - you will see the main page of the BLOG, filled with some random data. Quite some "blabla", to be sincere!

What you see is the Default page rendered. The `IBlogApplication.Default()` method has been called, then the outgoing Scope data has been rendered by the `Default.html` *Mustache* template.

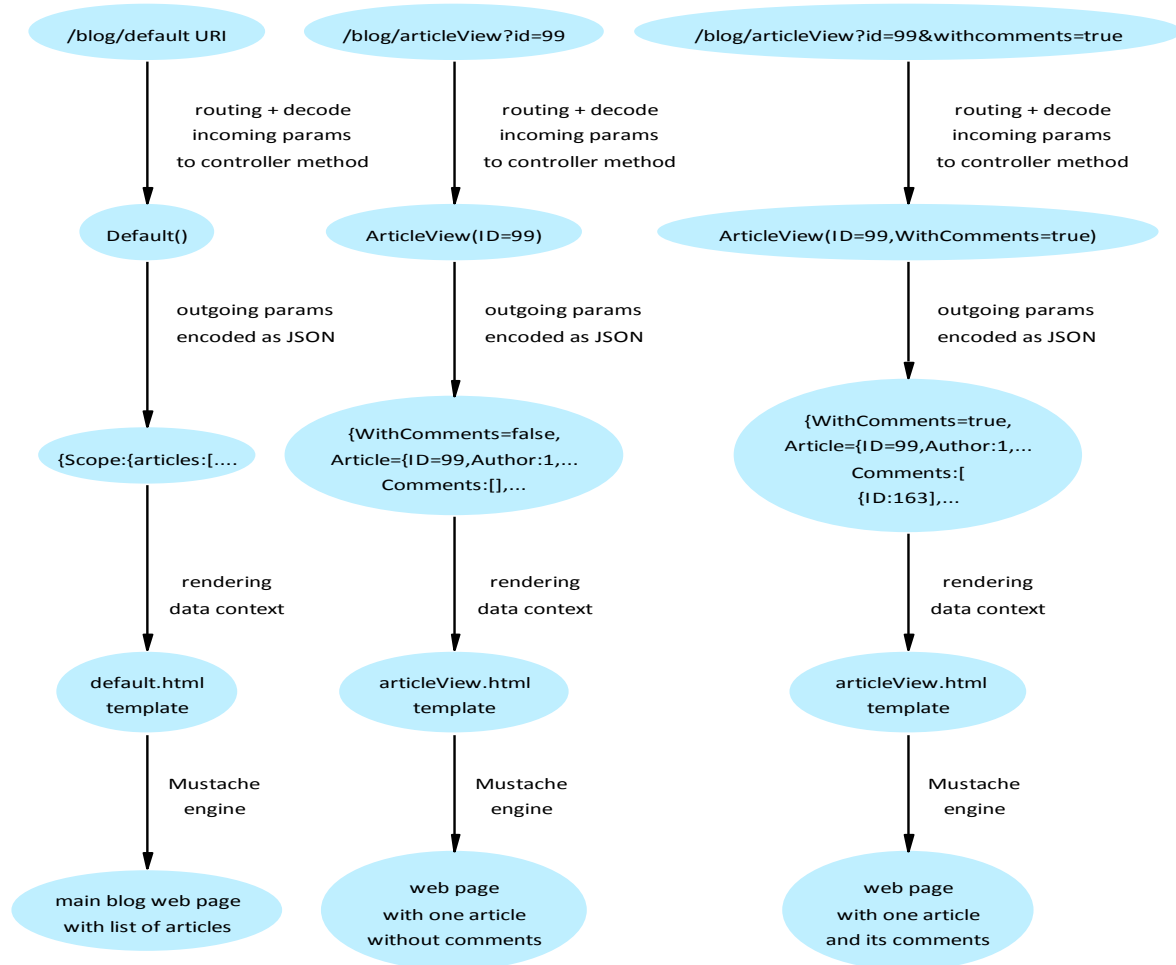

If you click on an article title, it will go to <http://localhost:8092/blog/articleView?id=99..> - i.e. calling `IBlogApplication.ArticleView()` with the ID parameter containing 99, and other incoming parameters (i.e. `WithComments` and `Direction`) set to their default value (i.e. respectively `false` and `0`). The `ArticleView()` method will then read the `TSQLArticle` data from the ORM, then send it to the `ArticleView.html` *Mustache* template.

Now, just change in your browser the URI from <http://localhost:8092/blog/articleView?id=99..> (here we clicked on the Article with ID=99) into <http://localhost:8092/blog/articleView/json?id=99..> (i.e. entering `/articleView/json` instead of `/articleView`, as a fake sub-URI).

Now the browser is showing you the JSON data context, as transmitted to the `ArticleView.html` template. Just check both the JSON content and the corresponding *Mustache* template: I think you will find out how it works. Take a look at *Mustache template engine* (page 506) as reference.

From any blog article view, click on the "Show Comments" button: you are redirected to a new page, at URI <http://localhost:8092/blog/ArticleView?id=99&withComments=true#comments..> and now the comments corresponding to the article are displayed. If you click on the "Previous" or "Next" buttons, a new URI <http://localhost:8092/blog/ArticleView?id=99&withComments=true&direction=1..> will be submitted: in fact, `direction=1` will search for the previous article, and we still have the `withComments=true` parameter set, so that the user will be able to see the comments, as expected. If you click on the "Hide Comments" button, the URI will change to be without any `withComments=true` parameter - i.e. <http://localhost:8092/blog/ArticleView?id=98#comments..> : now the comments won't be displayed.

The sequence is rendered as such:

mORMot MVC/MVVM URI - Commands sequence

In this diagram, we can see that each HTTP request is stateless, uncoupled from the previous. The user experience is created by changing the URI with additional parameters (like `withComments=true`). This is how the web works.

Then try to go to <http://localhost:8092/blog/mvc-info..> - and check out the page which appears. You will get all the information corresponding to your application, especially a list of all available commands:

```

/blog/Default?Scope=..[variant]..
/blog/Error?Msg=..[string]..&Scope=..[variant]..
/blog/ArticleView?ID=..[integer]..&WithComments=..[boolean]..&Direction=..[integer]..
/blog/AuthorView?ID=..[integer]..
/blog/Login?LogonName=..[string]..&PlainPassword=..[string]..
/blog/Logout
/blog/ArticleEdit?ID=..[integer]..&Title=..[string]..&Content=..[string]..&ValidationError=..[variant]..
/blog/ArticleCommit?ID=..[integer]..&Title=..[string]..&Content=..[string]..

```

And every view, including its data context, e.g.

```

/blog/AuthorView?ID=..[integer]..
{{Main}}: variant
{{ID}}: integer
{{Author}}: TSQLEAuthor
{{Articles}}: variant

```

You may use this page as reference when writing your *Mustache* Views. It will reflect the exact state of the running application.

19.2.2. Implementing the Controller

To build the application *Controller*, we will need to implement our *IBlogApplication* interface.

```
TBlogApplication = class(TMVCAApplication,IBlogApplication)
...
public
  procedure Start(aServer: TSQLRestServer); reintroduce;
  procedure Default(var Scope: variant);
  procedure ArticleView(ID: integer; var WithComments: boolean;
    Direction: integer;
    out Article: TSQLArticle; out Author: variant;
    out Comments: TObjectList);
...
end;
```

We defined a new class, inheriting from *TMVCAApplication* - as defined in *mORMotMVC.pas*, and implementing our expected interface. *TMVCAApplication* will do all the low-level plumbing for you, using a set of implementation classes.

Let's implement a simple command:

```
procedure TBlogApplication.AuthorView(var ID: integer; out Author: TSQLAuthor;
  out Articles: variant);
begin
  RestModel.Retrieve(ID,Author);
  if Author.ID<>0 then
    Articles := RestModel.RetrieveListJSON(
      TSQLArticle,'Author=? order by id desc limit 50',[ID],ARTICLE_FIELDS) else
    raise EMVCAApplication.CreateGotoError(HTTP_NOTFOUND);
end;
```

By convention, all parameters are allocated when *TMVCAApplication* will execute a method. So you do not need to allocate or handle the *Author: TSQLAuthor* instance lifetime.

You have direct access to the underlying *TSQLRest* instance via *TMVCAApplication.RestModel*: so all CRUD operations are available. You can let the ORM do the low level SQL work for you: to retrieve all information about one *TSQLAuthor* and get the list of its associated articles, we just use a *TSQLRest* method with the appropriate *WHERE* clause. Here we returned the list of articles as a *TDocVariant*, so that they will be transmitted as a JSON array, without any intermediate marshalling to *TSQLArticle* instances, but with the *Tags* dynamic array published property returned as an array of integers (you may have used *TObjectList* or *RawJSON* instead, as will be detailed below).

In case of any error, an *EMVCAApplication* will be raised: when such an exception happens, the *TMVCAApplication* will handle and convert it into a page change, and a redirection to the *IBlogApplication.Error()* method, which will return an error page, using the *Error.html* view template.

Let's take a look at a bit more complex method, which we talked about in *mORMot MVC/MVVM URI - Commands sequence* (page 526):

```
procedure TBlogApplication.ArticleView(
  ID: integer; var WithComments: boolean; Direction: integer;
  out Article: TSQLArticle; out Author: variant; out Comments: TObjectList);
var newID: TID;
const WHERE: array[1..2] of PUTF8Char = (
  'ID<? order by id desc','ID>? order by id');
begin
  if Direction in [1,2] then // allows fast paging using index on ID
    if RestModel.OneFieldValue(TSQLArticle,'ID',WHERE[Direction],[],[ID],newID) and
```

```

    (newID<>0) then
      ID := newID;
    RestModel.Retrieve(ID,Article);
    if Article.ID<>0 then begin
      Author := RestModel.RetrieveDocVariant(
        TSQLAuthor,'ID=?',[Article.Author.ID],'FirstName,FamilyName');
      if WithComments then begin
        Comments.Free; // we will override the TObjectList created at input
        Comments := RestModel.RetrieveList(TSQLComment,'Article=?',[Article.ID]);
      end;
    end else
      raise EMVCApplication.CreateGotoError(HTTP_NOTFOUND);
end;

```

This method has to manage several use cases:

- Display an Article from the database;
- Retrieve the Author first name and family name;
- Optionally display the associated Comments;
- Optionally get the previous or next Article;
- Trigger an error in case of an invalid request.

Reading the above code is enough to understand how those 5 features are implemented in this method. The incoming parameters, as triggered by the *Views*, are used to identify the action to be taken. Then *TMVCApplication.RestModel* methods are used to retrieve the needed information directly from the ORM. Outgoing parameters (*Article,Author,Comments*) are transmitted to the *Mustache View*, for rendering.

In fact, there are several ways to retrieve your data, using the *RestModel* ORM methods. For instance, in the above code, we used a *TObjectList* to transmit our comments.

But we may have used a *TDocVariant custom variant type* (page 112) parameter:

```

procedure TBlogApplication.ArticleView(
  ID: integer; var WithComments: boolean; Direction: integer;
  out Article: TSQLArticle; out Author: variant; out Comments: variant);
...
  if WithComments then
    Comments := RestModel.RetrieveDocVariantArray(TSQLComment,'','Article=?',[Article.ID], '');

```

In this case, data will be returned *per representation*, as variant values. Any *dynamic array* properties will be identified in the *TSQLRecord*, and converted as proper array of values.

Or with a *RawJSON* kind of output parameter:

```

procedure TBlogApplication.ArticleView(
  ID: integer; var WithComments: boolean; Direction: integer;
  out Article: TSQLArticle; out Author: variant; out Comments: RawJSON);
...
  if WithComments then
    Comments := RestModel.RetrieveListJSON(TSQLComment,'Article=?',[Article.ID], '');

```

Using a *RawJSON* will be in fact the fastest way of processing the information on the server side. But it will return the data directly from the database - as a consequence, dynamic arrays will be returned as a Base64-encoded blob.

It is up to you to choose the method and encoding needed for your exact context.

If your purpose is just to retrieve some data and push it back to the view, *RawJSON* is fast, but a *TDocVariant* will also convert dynamic arrays to a proper JSON array. If you want to process the returned information with some business code, returning a *TObjectList* may be convenient if you need to run some *TSQLRecord* methods on the returned list.

or a *TDocVariant* array may have its needs, if you want to create some meta-object gathering all

information, e.g. for Scope as returned by the Default method:

```
procedure TBlogApplication.Default(var Scope: variant);
...
if not fDefaultData.AddExistingProp('Archives',Scope) then
  fDefaultData.AddNewProp('Archives',RestModel.RetrieveDocVariantArray(
    TSQLArticle,'','group by PublishedMonth order by PublishedMonth desc limit 12',[],
    'distinct(PublishedMonth),max(ID)+1 as FirstID'),Scope);
end;
```

You can notice how the calendar months are retrieved from the database, using a safe `fDefaultData: ILockedDocVariant` private field to store the value as cache, in a thread-safe manner (we will see later more about how to implement thread-safety). If the 'Archives' value is in the `fDefaultData` cache, it will be returned immediately as part of the Scope returned document. Otherwise, it will use `RestModel.RetrieveDocVariantArray` to retrieve the last 12 available months. When a new Article is created, or modified, `TBlogApplication.FlushAnyCache` will call `fDefaultData.Clear` to ensure that the updated information will be retrieved from the database on next `Default()` call.

The above ORM request will generate the following SQL statement:

```
SELECT distinct(PublishedMonth),max(ID)+1 as FirstID FROM Article
group by PublishedMonth order by PublishedMonth desc limit 12
```

The `Default()` method will therefore return the following JSON context:

```
{
  "Scope": {
    ...
    "Archives":
    [
      {
        "PublishedMonth": 24178,
        "FirstID": 101
      },
      {
        "PublishedMonth": 24177,
        "FirstID": 100
      },
      ...
    ]
  }
}
```

... which will be processed by the *Mustache* engine.

If you put a breakpoint at the end of this `Default()` method, and inspect the "Scope" variable, the Delphi debugger will in fact show you in real time the exact JSON content, retrieved from the ORM.

I suspect you just find out how *mORMot*'s ORM/SOA abilities, and JSON / `TDocVariant` offer amazing means of processing your data. You have the best of both worlds: ORM/SOA gives you fixed structures and strong typing (like in C++/C#/Java), whereas `TDocVariant` gives you a flexible object scheme, using late-binding to access its content (like in Python/Ruby/JavaScript).

19.2.3. Variable input parameters

If you want to support a variable number of named parameters, you can define a variant input parameter, and provide the input as a JSON document, using a `TDocVariant` storage. But marshalling the context as JSON will involve using some JavaScript in the HTML page, which may not be very convenient.

If you want to handle a non-fixed set of regular URI or POST value, you can prefix all the incoming parameter names with the dotted name of a single defined variant.

For instance, if you have the following controller method:

```
function TnWebMVCMenu.CadastroSalvar3(const p: variant): TMVCAction;
```

Then you can supply as parameter at URI level:

```
p.a1=5&p.a2=dfasdfa
```

And you will be able to handle them in the controller body:

```
function TnWebMVCMenu.CadastroSalvar3(const p: variant): TMVCAction;
begin
  GotoView(result, 'Cadastro',
    ['pp1', p.a1,
     'pp2', p.a2])
end;
```

You are now free to specify some versatile HTML forms in your views, and provide the controller with any kind of input parameters.

Of course, it may sound safer and easier to explicitly define and name each one of the input parameters, with simple types like integer or RawUTF8. But this convention may help you work with any kind of HTML views.

19.2.4. Using Services in the Controller

Any controller method could retrieve and execute any dependency from its interface, following the *IoC* pattern - see *Dependency Inversion Principle* (page 401).

You have two ways of performing the dependency resolution:

- From the associated TSQLRest.Services container;
- From its own protected Resolve() method, since TMVCApplication inherits from TInjectableObject.

In fact, you can set up your TMVCApplication instance to use any external dependencies, including stubs and mocks, or high-level DDD services (e.g. repository or modelization process), using its CreateInjected() constructor instead of plain Create.

19.2.5. Controller Thread Safety

When run from a TSQLRestServer instance, our MVC application commands will be executed by default without any thread protection. When hosted within a TSQLHttpServer instance - see *High-performance http.sys server* (page 327) - several threads may execute the same *Controller* methods at the same time. It is therefore up to your application code to ensure that your TMVCApplication process is thread safe.

Note that by design, all TMVCApplication.RestModel ORM methods are thread-safe.

If your *Controller* business code only uses ORM methods, sending back the information to the *Views*, without storing any data locally, it will be perfectly thread safe.

See for instance the TBlogApplication.AuthorView method we described above.

But consider this method (simplified from the real "30 - MVC Server" sample):

```
type
  TBlogApplication = class(TMVCApplication, IBlogApplication)
  protected
    fDefaultArticles: variant;
    ...

procedure TBlogApplication.Default(var Scope: variant);
begin
  if VarIsEmpty(fDefaultArticles) then
    fDefaultArticles := RestModel.RetrieveDocVariantArray(
```

```
TSQLEArticle, '', 'order by ID desc limit 20', [], ARTICLE_FIELDS);
_ObjAddProps(['Articles', fDefaultArticles], Scope);
end;
```

In fact, even if this method may sound safe, we have an issue when it is executed by several threads: one thread may be assigning a value to `fDefaultArticles`, whereas another thread may be using the `fDefaultArticles` content. This may result into random runtime errors, very difficult to solve. Even creating a local variable may not be safe, since any access to `fDefaultArticles` should be protected.

A first - and brutal - solution could be to force the `TSQLEstServer` instance to execute all method-based services (including our *MVC* commands) in a giant lock, as stated about *Thread-safety* (page 336):

```
aServer.AcquireExecutionMode[execSOABByMethod] := amLocked; // or amBackgroundThread
```

But this may slow down the whole server process, and reduce its scaling abilities.

You could also lock explicitly the *Controller* method, for instance:

```
procedure TBlogApplication.Default(var Scope: variant);
begin
  Locker.ProtectMethod;
  if VarIsEmpty(fDefaultData) then
  ...
```

Using the `TMVCAApplication.Locker: IAutoLocker` is a simple and efficient way of protecting your method. In fact, `TAutoLocker` class' `ProtectMethod` will return an `IUnknown` variable, which will let the compiler create an hidden `try .. finally` block in the method body, to release the lock when it quits. But this locker will be shared by the whole `TMVCAApplication` instance, so will be like a giant lock on your *Controller* process.

A more tuned and safe implementation may be to use a `ILockedDocVariant` instead of a plain `TDocVariant` for caching the data. You may therefore write:

```
type
  TBlogApplication = class(TMVCAApplication, IBlogApplication)
  protected
    fDefaultData: ILockedDocVariant;
    ...
  procedure TBlogApplication.Start(aServer: TSQLEstServer);
  begin
    fDefaultData := TLockedDocVariant.Create;
    ...

  procedure TBlogApplication.Default(var Scope: variant);
  begin
    if not fDefaultData.AddExistingProp('Articles', Scope) then
      fDefaultData.AddNewProp('Articles', RestModel.RetrieveDocVariantArray(
        TSQLEArticle, '', 'order by ID desc limit 20', [], ARTICLE_FIELDS), Scope);
  end;
```

Using `ILockedDocVariant` will ensure that only access to this resource will be locked (no giant lock any more), and that slow ORM process (like `RestModel.RetrieveDocVariantArray`) will take place lock-free, to maximize the resource usage.

This is in fact the pattern used by the "30 - MVC Server" sample. Even *Client-Server services via interfaces* (page 420) may benefit from this `TLockedDocVariant` kind of storage, for efficient multi-thread process - see *Server-side execution options (threading)* (page 462).

19.2.6. Web Sessions

Sessions are usually implemented via cookies, in web sites. A login/logout procedure enhances security of the web application, and User experience can be tuned via small persistence of

client-driven data. The `TMVCAApplication` class allows creating such sessions.

You can store whatever information you need within the client-side cookie. `TMVCSessionWithCookies` allows to define a record, which will be used to store the information as optimized binary, in the browser cache. You can use this cookie information as a cache to the current session, e.g. storing the logged user display name, his/her preferences or rights - avoiding a round trip to the database.

Of course, you should never trust the cookie content (even if our format uses secure encryption, and a digital signature via a HMAC-CRC32C algorithm). But you can use it as a convenient cache, always checking the real data in the database when you are about to perform any security-related action. The cookie also stores an integer Session ID, and issuing and expiration dates: as such, it matches all JWT (*Javascript Web Token*) - see <http://jwt.io..> - features, as signature, encryption, and *jwi/iat/exp* claims, with a smaller overhead, and without using unsafe Web Local Storage.

For our "30 - MVC Server" sample application, we defined the following record in `MVCViewModel.pas`:

```
TCookieData = packed record
  AuthorName: RawUTF8;
  AuthorID: cardinal;
  AuthorRights: TSQLAuthorRights;
end;
```

This record will be serialized in two ways:

- As raw binary, without the field names, within the cookie, after Base64 encoding of encrypted and digitally signed data;
- As a JSON object, with explicit field names, when transmitted to the *Views* as "Session" data context.

In order to have proper JSON serialization of the record, you will need to specify its structure, if you use a version of Delphi without the new RTTI (i.e. before Delphi 2010) - see *Record serialization* (page 298).

Then we can use the `TMVCAApplication.CurrentSession` property to perform the authentication, after successful login:

```
function TBlogApplication.Login(const LogonName, PlainPassword: RawUTF8): TMVCAAction;
var Author: TSQLAuthor;
    SessionInfo: TCookieData;
begin
  if CurrentSession.CheckAndRetrieve<>0 then begin
    GotoError(result, HTTP_BADREQUEST);
    exit;
  end;
  Author := TSQLAuthor.Create(RestModel, 'LogonName=?', [LogonName]);
  try
    if (Author.ID<>0) and Author.CheckPlainPassword(PlainPassword) then begin
      SessionInfo.AuthorName := Author.LogonName;
      SessionInfo.AuthorID := Author.ID;
      SessionInfo.AuthorRights := Author.Rights;
      CurrentSession.Initialize(@SessionInfo, TypeInfo(TCookieData));
      GotoDefault(result);
    end else
      GotoError(result, sErrorInvalidLogin);
  finally
    Author.Free;
  end;
end;
```

As you can see, this `Login()` method will be triggered from <http://localhost:8092/blog/login..> with `LogonName=...&plainpassword=...` parameters. It will first check that there is no current session, retrieve the ORM Author corresponding to the `LogonName`, check the supplied password, and set the

SessionInfo: TCookieData structure with the needed information.

A call to `CurrentSession.Initialize()` will compute the cookie, then prepare to send it to the client browser.

The `Login()` method returns a `TMVCAAction` structure. As a consequence, the call to `GotoDefault(result)` will let the `TMVCApplication` processor render the `Default()` method, as if the `/blog/default` URI will have been requested. On invalid credential, an error page is displayed instead.

When a web page is computed, the following overridden method will be executed:

```
function TBlogApplication.GetViewInfo(MethodIndex: integer): variant;
begin
  result := inherited GetViewInfo(MethodIndex);
  _ObjAddProps(['blog', fBlogMainInfo,
    'session', CurrentSession.CheckAndRetrieveInfo(TypeInfo(TCookieData))], result);
end;
```

It will append the session information from the cookie to the returned *View* data context, as such:

```
{
  "Scope": {
    "articles":
    ...
  },
  "main": {
    "pageName": "Default",
    "blog": {
      "Title": "mORMot BLOG",
      ...
    },
    "session": {
      "AuthorName": "synapse",
      "AuthorID": 1,
      "AuthorRights": {
        "Comment": true,
        "Post": true,
        "Delete": true,
        "Administrate": true
      },
      "id": 1
    }
  }
}
```

Here, the session object will contain the `TCookieData` information, ready to be processed by the *Mustache View* - e.g. as `session.AuthorName`. In addition, your view may include some buttons for logged-only features, like comments or content edition, using boolean fields defined in `session.AuthorRights`.

For security reasons, before actually performing an action requiring a specific right, it is preferred to check from the Model if the user is effectively allowed. An attacker may have forged a fake cookie - even if it is very unlikely, since cookies are encrypted and signed. It is a good approach to treat all cookies information as an unsafe cache, acceptable for most operation, but which should always be dual-checked.

So your server code will call `CurrentSession.CheckAndRetrieve` then access the data `RestModel` for verification before any sensitive action is performed. Defining a common method could be handy:

```
function TBlogApplication.GetLoggedAuthorID(Right: TSQLAuthorRight;
  ContentToFillAuthor: TSQLContent): TID;
var SessionInfo: TCookieData;
    author: TSQLAuthor;
begin
```

```

result := 0;
if (CurrentSession.CheckAndRetrieve(@SessionInfo,TypeInfo(TCookieData))>0) and
  (Right in SessionInfo.AuthorRights) then
  with TSQLAuthor.AutoFree(author,RestModel,SessionInfo.AuthorID) do
    if Right in author.Rights then begin
      result := SessionInfo.AuthorID;
      if ContentToFillAuthor<>nil then begin
        ContentToFillAuthor.Author := pointer(result);
        ContentToFillAuthor.AuthorName := author.LogonName;
      end;
    end;
  end;
end;

```

It will be used as such, e.g. to verify if a user can comment an article:

```

function TBlogApplication.ArticleComment(ID: TID;
  const Title,Comment: RawUTF8): TMVCAction;
var comm: TSQLComment;
  AuthorID: TID;
  error: string;
begin
  with TSQLComment.AutoFree(comm) do begin
    AuthorID := GetLoggedAuthorID(canComment,comm);
    if AuthorID=0 then begin
      GotoError(result,sErrorNeedValidAuthorSession);
      exit;
    end;
  end;
  ...

```

Eventually, when the browser asks for the /blog/logout URI, the following method will be executed:

```

function TBlogApplication.Logout: TMVCAction;
begin
  CurrentSession.Finalize;
  GotoDefault(result);
end;

```

The session cookie will then be deleted on the browser side.

Note that if any deprecated or invalid cookie is detected by the *mORMot* MVC server, it will also be automatically deleted on the browser side.

19.3. Writing the Views

See *Mustache template engine* (page 506) for a description of how rendering take place in this MVC/MVVM application. You will find the Mustache templates in the "Views" sub-folder of the "30 - MVC Server" sample application.

You will find some *.html files, one per command expecting a View, and some *.partial files, which are some kind of re-usable sub-templates - we use them to easily compute the page header and footer, and to have a convenient way of gathering some piece of template code, to be re-used in several *.html views.

Here is how Default.html is defined:

```

{{>header}}
{{>masthead}}
<div class="blog-header">
  <h1 class="blog-title">{{main.blog.title}}</h1>
  <p class="lead blog-description">{{main.blog.description}}</p>
</div>
<div class="row">
  <div class="col-sm-8 blog-main">
{{#Scope}}
{{>articlerow}}

```

```

{{#lastID}}
<p><a href="default?scope={{.}}" class="btn btn-primary btn-sm">Previous Articles</a></p>
{{/lastID}}
</div>
<div class="col-sm-3 col-sm-offset-1 blog-sidebar">
  <div class="sidebar-module sidebar-module-inset">
    <h4>About</h4>
    {{{WikiToHtml main.blog.about}}}
  </div>
  <div class="sidebar-module">
    <h4>Archives</h4>
    <ol class="list-unstyled">
      {{#Archives}}
      <li><a href="default?scope={{FirstID}}">{{MonthToText PublishedMonth}}</a></li>
      {{/Archives}}
    </ol>
  </div>
</div>
</div>
{{/Scope}}
{{>footer}}

```

The `{{>partials}}` are easily identified, as other `{{...}}` value tags. The main partial is `{{>articlerow}}`, which will display all articles list.

`{{{WikiToHtml main.blog.about}}}` is an *Expression Block* able to render some simple text into proper HTML, using a simple Wiki syntax.

`{{MonthToText PublishedMonth}}` will execute a custom *Expression Block*, defined in our `TBlogApplication`, which will convert the obfuscated `TSQLArticle.PublishedMonth` integer value into the corresponding name and year:

```

procedure TBlogApplication.MonthToText(const Value: variant;
  out result: variant);
const MONTHS: array[0..11] of string = (
  'January', 'February', 'March', 'April', 'May', 'June', 'July', 'August',
  'September', 'October', 'November', 'December');
var month: integer;
begin
  if VariantToInteger(Value, month) and (month > 0) then
    result := MONTHS[month mod 12] + ' ' + IntToStr(month div 12);
end;

```

The page displaying the Author information is in fact quite simple:

```

{{>header}}
{{>masthead}}
  <div class="blog-header">
    <h1 class="blog-title">User {{Author.LogonName}}</h1>
  <div class="lead blog-description">{{Author.FirstName}} {{Author.FamilyName}}
  </div>
  </div>
  <div class="panel panel-default">
    <div class="panel-heading">Information about <strong>{{Author.LogonName}}</strong></div>
    <div class="panel-body">
      {{{TSQLAuthor.HtmlTable Author}}}
    </div>
  </div>
{{>articlerow}}
{{>footer}}

```

It will share the same `{{>partials}}`, for a consistent and maintainable web site design, but in fact most of the process will take place by the magic of two tags:

- `{{{TSQLAuthor.HtmlTable Author}}}` is an *Expression Block* linked to `TMVCAApplication.RestModel ORM`, which will create a HTML table - with the syntax expected by our *Bootstrap* CSS - for a `TSQLAuthor` record, identifying the property types and display them as expected (e.g. for dates or time stamps, or for enumerates or sets).

- `{{>articlerow}}` is a partial also shared with `ArticleView.html`, which will render a list of `TSQLArticle` encoded as `{{#Articles}}...{{/Articles}}` sections.

Take a look at the `mORMotMVC.pas` unit: you will discover that every aspect of the MVC process has been divided into small classes, so that the framework is able to create web applications, but also any kind of MVC applications, including mobile or VCL/FMX apps, and/or reporting - using `mORMotReport.pas`.

20. Hosting

Adopt a mORMot

We could identify several implementation patterns of a *mORMot* server and its clients:

- Stand-alone application, either in the same process or locally on the same computer;
- Private self-hosting, e.g. in a corporate network, with a *mORMot* executable or service publishing some content to clients locally or over the Internet (directly from a DMZ or via a VPN);
- Cloud hosting, using a dedicated server in a data-center, or any cloud solution based on virtualization;
- Mixed hosting, using CDN network services to cache most of the requests of your *mORMot* server.

As we already stated, our *Client-Server process* (page 319) allow all these patterns.

We will now detail some hosting schemes.

20.1. Windows and Linux hosted

The current version of the framework fully supports deploying the *mORMot* servers on the *Windows* platform, either as a *Win32* executable, or - for latest versions of the *Delphi* compiler - as a *Win64* executable.

Linux support (via FPC 3.2.x) is available, but we face some FPC compiler-level issue with FPC 2.x, which does not supply the needed interface RTTI - see <http://bugs.freepascal.org/view.php?id=26774..> - so that the SOA and MVC features are not working directly on old FPC revisions, so you need to generate the RTTI from a Delphi compiler, as stated below (page 656). For the client side, there is no limitation, thanks to our *Cross-Platform clients* (page 482), which is perfectly supported even by oldest FPC compiler under *Linux*. The *Linux* backend available in latest Delphi is not supported, since FPC 2.x gives pretty good results (we use it on production since years), and a Delphi Enterprise licence is required to access it - which we don't have.

In practice, a *mORMot* server expects much lower hardware requirements (in CPU, storage and RAM terms) than a regular IIS-WCF-MSSQL - .Net stack. And it requires almost no maintenance.

As a consequence, the potential implementation schemes could be hosted as such:

- Stand-alone application, without any explicit server;
- Self-hosted service running on the corporate file server, or on a small dedicated VM or recycled computer (for best performance, just put your data on a new SSD on the old hardware PC);
- Cloud services running *Windows Server*, with minimal configuration: IIS, .Net or MS SQL are not necessary at all - a cheap virtual system with 512 MB of memory is enough to run your *mORMot* service and serve hundredths of clients;
- *Linux* servers, with no dependency (even latest version of *SQLite3* is statically linked to the executables), using less hardware resource.

In the cloud, since every resource used is monitored and billed, you would like to minimize RAM use: you should better take a look at <http://www.delphitools.info/2013/11/20/moving-hosts-now-settled..> and <http://www.delphitools.info/2013/11/29/flush-windows-file-cache..> for practical advices and feedbacks.

About the edition of *Windows* to be used, of course IT people will ensure you that *Windows Server* is mandatory. But from our tests, you will obtain pretty good results, even with a regular Windows 7 or 8 version of the operating system. On the other side, it is not serious to envisage hosting a server on Windows XP, which is not supported any more by Microsoft - even if technically a *mORMot* server will work very well on this deprecated platform.

Of course, if you use *External SQL database access* (page 240), the hardware and hosting expectations may vary. It will depend on the database back-end used, and will necessarily be much more demanding than our internal *SQLite3* database engine. In practice, a *mORMot* server using a *SQLite3* engine running on a SSD hardware, in *ImExclusive* mode - see *ACID and speed* (page 222) - runs faster than most SQL or NoSQL engines available, since it will be hosted within the *mORMot* server process itself - see *Highly concurrent clients performance* (page 339).

20.2. Deployment Architecture

About hosting architecture, the easiest is to have your main *TSQLRestServer* class handling the service, in conjunction with other Client-Server process (like ORM). See *General mORMot architecture - Client / Server* (page 74) about this generic Client-Server architecture and the "Shared server" next paragraph.

But you may find out some (good?) reasons which main induce another design:

- For better scalability, you should want to use a dedicated process (or even dedicated hardware) to split the database and the service process;
- For security reasons, you want to expose only services to your Internet clients, and setup a DMZ hosting only services, and separate database with logic instance;
- Services are not the main part of your business, and you would like to enable or disable the published SOA scope, on demand;
- To implement an efficient solution for the most complex kind of application, as provided by *Domain-Driven Design* (page 99);
- Your main data will be hosted on high performance SSD / NAS drives with safe RAID, but some data should better be hosted on cheaper storage (e.g. *Audit Trail for change tracking* (page 178));
- You are selling one product, to be run on several environments (debugging / production, starter / corporate editions, centralized / P2P design...), depending on your clients demand;
- Whatever your IT people or managers want *mORMot* to.

Also consider per-table redirection - see *Redirect to an external TSQLRest* (page 234), or *Master/slave replication* (page 180), for even more advanced hosting abilities. See for instance the *Corporate Servers Redirection* (page 236) and GG diagrams.

The possibilities are endless, so we will here below only present some typical use-cases.

20.2.1. Shared server

This is the easiest configuration: one HTTP server instance, which serves both ORM and Services. On practice, this is perfectly working and scalable.

Service Hosting on mORMot - shared server

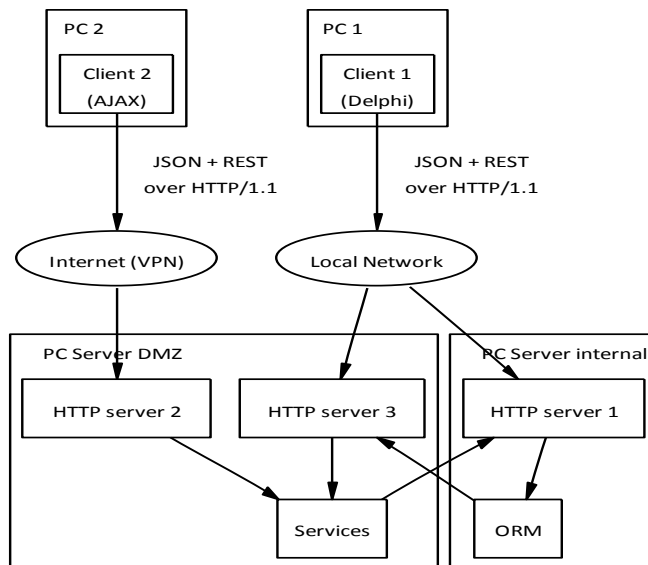

You can tune this solution, as such:

- Setting the group user rights properly - see below (page 547) - you can disable the remote ORM access from the Internet, for the AJAX Clients - but allow rich *Delphi* clients (like PC1) to access the ORM;
- You can have direct in-process access to the service interfaces from the ORM, and vice-versa: if your services and ORM are deeply inter-dependent, direct access will be the faster solution.

20.2.2. Two servers

In this configuration, two physical servers are available:

- A network DMZ is opened to serve only service content over the Internet, via "HTTP server 2";
- Then on the local network, "HTTP server 1" is used by both PC 1 and Services to access the ORM;
- Both "PC Client 1" and the ORM core are able to connect to Services via a dedicated "HTTP server 3".

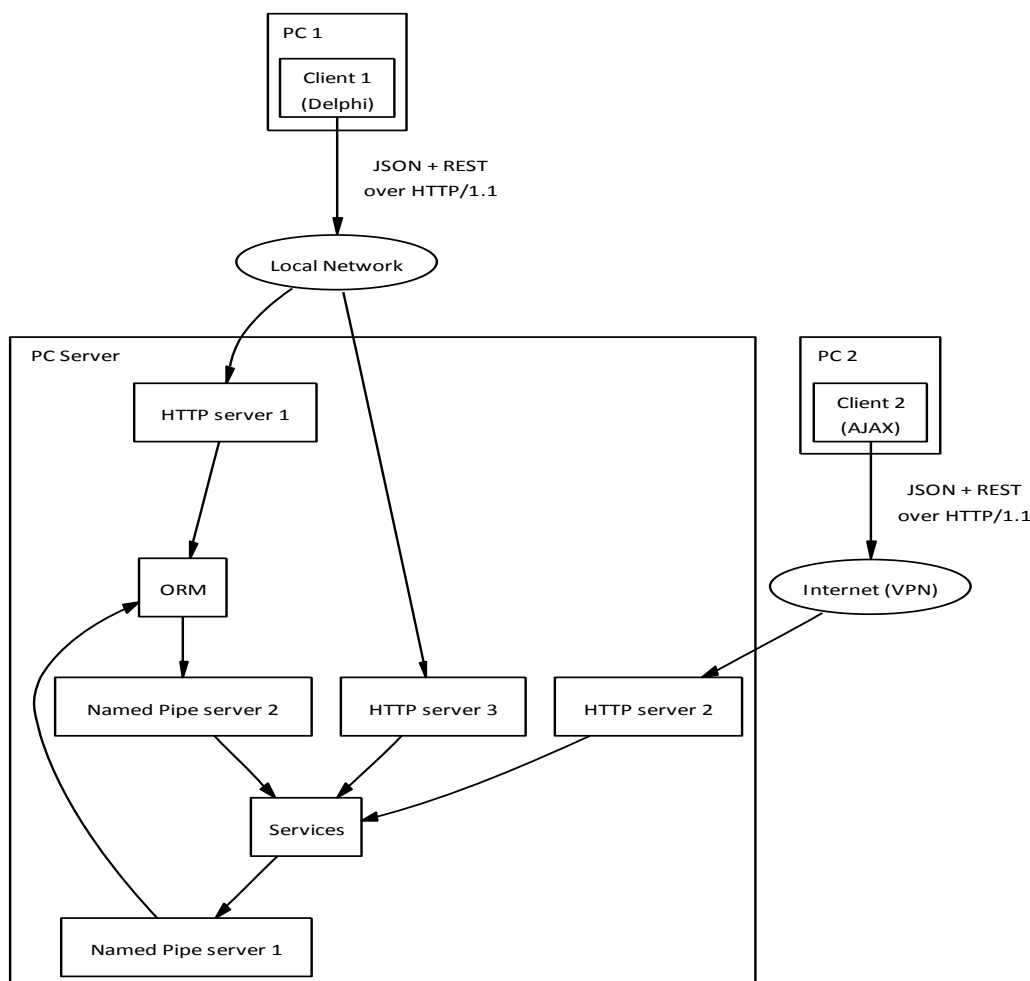

Service Hosting on mORMot - two servers

Of course, the database will be located on "PC Server internal", i.e. the one hosting the ORM, and the Services will be one regular client: so we may use *CRUD level cache* (page 360) on purpose to enhance performance. In order to access the remote ORM features, and provide a communication endpoint to the embedded services, a `TSQLRestServerRemoteDB` kind of server class can be used.

20.2.3. Two instances on the same server

This is the most complex configuration. In this case, only one physical server is deployed:

- A dedicated "HTTP server 2" instance will serve service content over the Internet (via a DMZ configuration of the associated network card);
- "PC Client 1" will access to the ORM via "HTTP server 1", or to services via "HTTP server 3";
- For performance reasons, since ORM and Services are on the same computer, using named pipes (or even local Windows Messages) instead of slower HTTP-TCP/IP is a good idea: in such case, ORM will access services via "Named Pipe server 2", whereas Services will serve their content to the ORM via "Named Pipe server 1".

Service Hosting on mORMot - one server, two instances

Of course, you can make any combination of the protocols and servers, to tune hosting for a particular purpose. You can even create several ORM servers or Services servers (grouped per features family or per product), which will cooperate for better scaling and performance.

If you consider implementing a stand-alone application for hosting your services, and has therefore basic ORM needs (e.g. you may need only CRUD statements for handling authentication), you may use the lighter `TSQLRestServerFullMemory` kind of server instead of a full `TSQLRestServerDB`, which will embed a `SQLite3` database engine, perhaps not worth it in this case.

Our beloved stateless *REST* (page 312) model, in conjunction with *Browser speed-up for unmodified requests* (page 380) will enable several levels of caching, from a local proxy cache - see e.g. <http://www.squid-cache.org..> or <http://www.varnish-cache.org..> - or an external *Content Delivery Network* (CDN) service - e.g. <http://www.cloudflare.com..>

```
graph TD; subgraph Office_B [Office B]; B2[Client B2 (Delphi)] --> LB[Local Network B]; B1[Client B1 (Delphi)] --> LB; end; subgraph Mobile; C[Client C (Mobile AJAX)] --> N[3G/4G Network]; end; subgraph Office_A [Office A]; A3[Client A3 (AJAX)] --> LA[Local Network A]; A2[Client A2 (Delphi)] --> LA; A1[Client A1 (Delphi)] --> LA; end; LB --> I((Internet)); N --> I; LA --> I; I --> US[US]; I --> UK[UK]; I --> DC[Data Center]; subgraph US_Box [US]; US --> CDN_US[CDN US]; CDN_US --> Cache_US[Cache]; end; subgraph UK_Box [UK]; UK --> CDN_UK[CDN UK]; CDN_UK --> Cache_UK[Cache]; end; subgraph DC_Box [Data Center]; DC --> mORMot[mORMot Server]; mORMot --> DB[(Database)]; end; Cache_US --> mORMot; Cache_UK --> mORMot;
```

In practice, static content - see *Returning file content* (page 380) - or some simple JSON requests - returned via `Ctxt.Results()` or an interface-based service - will benefit of using such a CDN.

Then each CDN will check if the requested URI is already in its cache, according to its settings, and the expiration parameters which may be set within the HTTP headers of the cache header. If the resource is in local cache, it will be returned to the client immediately. If the resource is not in its cache, the CDN node will ask the *mORMot* server, cache the returned content, then return this content to the client. Any further attempt to this URI, compatible with the expiration parameters, won't trigger any request to the *mORMot* server.

Page 544 of 2562

The per-session signature appended at each URI will indeed void any attempt of third-party cache.

If your project starts to have success, using a CDN is an easy and cheap way of increasing your number of clients. Your *mORMot* server will focus on its own purpose, which may be safe storage, authentication and high-level SOA, then let the remaining content be served by such a third-party caching system.

21. Security

Adopt a mORMot

The framework tries to implement security via:

- Process safety;
- Authentication;
- Authorization.

Process safety is implemented at every *Multi-tier architecture* (page 88) level:

- Strong encryption to keep information private - see *AES encryption over HTTP* (page 334) and below (page 572);
- Atomicity of the *SQLite3* database - see *ACID and speed* (page 222);
- *Stateless ORM* (page 315) architecture to avoid most synchronization issues;
- *Object-Relational Mapping (ORM)* (page 92) associated to the Object pascal strong type syntax;
- Extended test coverage - see below (page 627) - of the framework core.

Authentication allows user identification:

- Build-in optional authentication mechanism, implementing both *per-user sessions* and individual *REST Query Authentication*;
- *Authentication groups* are used for proper authorization;
- Several authentication schemes, from very secure HMAC-SHA256 based challenging to weak but simple authentication;
- Class-based architecture, allowing custom extension.

Authorization of a given process is based on the group policy, after proper authentication:

- *Per-table access right* functionalities built-in at lowest level of the framework;
- Per-method execution policy for interface-based services;

- General high-level security attributes, for SQL or Service remote execution.

Process safety has already been documented (see links above).

We will now give general information about both authentication and authorization in the framework.

21.1. Authentication

Extracted from *Wikipedia*:

Authentication (from Greek: "real" or "genuine", from "author") is the act of confirming the truth of an attribute of a datum or entity. This might involve confirming the identity of a person or software program, tracing the origins of an artifact, or ensuring that a product is what its packaging and labeling claims to be. Authentication often involves verifying the validity of at least one form of identification.

21.1.1. Principles

How to handle authentication in a RESTful Client-Server architecture is a matter of debate.

Commonly, it can be achieved, in the SOA over HTTP world via:

- HTTP *basic auth* over HTTPS;
- *Cookies* and session management;
- *Query Authentication* with additional signature parameters.

We'll have to adapt, or even better mix those techniques, to match our framework architecture at best.

Each authentication scheme has its own PROs and CONS, depending on the purpose of your security policy and software architecture:

Criteria	HTTPS <i>basic auth</i>	Cookies+Session	Query Auth.
Browser integration	Native	Native	Via <i>JavaScript</i>
User Interaction	Rude	Custom	Custom
Web Service use (rough estimation)	95%	4%	1%
Session handling	Yes	Yes	No
Session managed by	Client	Server	N/A
Password on Server	Yes	Yes/No	N/A
Truly Stateless	Yes	No	Yes
Truly RESTful	No	No	Yes
HTTP-free	No	No	Yes

21.1.1.1. HTTP basic auth over HTTPS

This first solution, based on the standard HTTPS protocol, is used by most web services. It's easy to implement, available by default on all browsers, but has some known draw-backs, like the awful authentication window displayed on the Browser, which will persist (there is no *LogOut*-like feature here), some server-side additional CPU consumption, and the fact that the user-name and password are transmitted (over HTTPS) into the Server (it should be more secure to let the password stay only on the client side, during keyboard entry, and be stored as secure hash on the Server).

The supplied `TSQLHttpClientWinHTTP` and `TSQLHttpClientWinINet` clients classes are able to connect using HTTPS, and the `THttpApiServer` server class can send compatible content.

21.1.1.2. Session via Cookies

To be honest, a session managed on the Server is not truly Stateless. One possibility could be to maintain all data within the cookie content. And, by design, the cookie is handled on the Server side (Client in fact don't even try to interpret this cookie data: it just hands it back to the server on each successive request). But this cookie data is application state data, so the client should manage it, not the server, in a pure Stateless world.

The cookie technique itself is HTTP-linked, so it's not truly RESTful, which should be protocol-independent. Since our framework does not provide only HTTP protocol, but offers other ways of transmission, Cookies were left at the baker's home.

21.1.1.3. Query Authentication

Query Authentication consists in signing each RESTful request via some additional parameters on the URI. See <http://broadcast.oreilly.com/2009/12/principles-for-standardized-rest-authentication.html> about this technique. It was defined as such in this article:

All REST queries must be authenticated by signing the query parameters sorted in lower-case, alphabetical order using the private credential as the signing token. Signing should occur before URI encoding the query string.

For instance, here is a generic URI sample from the link above:

```
GET /object?apiKey=Qwerty2010
```

should be transmitted as such:

```
GET /object?timestamp=1261496500&apiKey=Qwerty2010&signature=abcdef0123456789
```

The string being signed is `"/object?apikey=Qwerty2010×tamp=1261496500"` and the signature is the *SHA256* hash of that string using the private component of the API key.

This technique is perhaps the more compatible with a Stateless architecture, and can also been implemented with a light session management.

Server-side data caching is always available. In our framework, we cache the responses at the SQL level, not at the URI level (thanks to our optimized implementation of `GetJsonObjectAsSQL`, the URI to SQL conversion is very fast). So adding this extra parameter doesn't break the cache mechanism.

21.1.2. Framework authentication

Even if, theoretically speaking, *Query Authentication* sounds to be the better for implementing a truly RESTful architecture, our framework tries to implement a Client-Server design.

In practice, we may consider two way of using it:

- With no authentication nor user right management (e.g. for local access of data, or framework use over a secured network);
- With per-user authentication and right management via defined *security groups*, and a per-query authentication, following several protocols (a set of *mORMot* flavors, Windows NTLM/Kerberos, or any custom scheme).

According to RESTful principle, handling per-session data is not to be implemented in such

architecture. A minimal "session-like" feature was introduced only to handle user authentication with very low overhead on both Client and Server side. The main technique used for our security is therefore *Query Authentication*, i.e. a per-URI signature.

If the `aHandleUserAuthentication` parameter is left to its default `false` value for the `TSQLRestServer`. Create constructor, no authentication is performed. All tables will be accessible by any client, as stated in below (page 560). As stated above, for security reasons, the ability to execute `INSERT` / `UPDATE` / `DELETE` SQL statement via a RESTful `POST` command is never allowed by default with remote connections: only `SELECT` can be executed via this `POST` verb.

If authentication is enabled for the Client-Server process (i.e. if the `aHandleUserAuthentication` parameter is set to `true` at the `TSQLRestServer` instance construction), the following security features will be added:

- On the Server side, a dedicated service, accessible via the `ModelRoot/Auth` URI is to be called to register an User, and create an in-memory session;
- Client *should* open a session to access to the Server, and after authentication validation (e.g. via `UserName` / `Password` pair, or Windows credentials);
- Each CRUD statement is checked against the authenticated User security group, via the `AccessRights` column and its `GET` / `POST` / `PUT` / `DELETE` per-table bit sets;
- Thanks to *Per-User* authentication, any SQL statement commands may be available via the RESTful `POST` verb for an user with its `AccessRights` group field containing a `reSQL` flag in its `AllowRemoteExecute`;
- Each REST request will expect an additional parameter, named `session_signature`, to every URL. Using the URI instead of *cookies* allows the signature process to work with all communication protocols, not only HTTP;
- Of course, you have the opportunity to tune or even by-pass the security for a given service (method-based or interface-based), on need: e.g. to allow some methods only to your system administrators, or to serve public HTML content.

21.1.2.1. Per-User authentication

On the Server side, two tables, defined by the `TSQLAuthGroup` and `TSQLAuthUser` classes, will handle respectively per-group access rights (authorization), and user validation (authentication). In the database, they will be persisted as `AuthGroup` and `AuthUser` tables.

The Server will search for any class inheriting from `TSQLAuthGroup` and `TSQLAuthUser` in its Model. By default, you can use plain `TSQLAuthGroup` and `TSQLAuthUser` classes - and if none is defined in the model, and authentication is enabled, those mandatory classes will be added. But you can inherit from `TSQLAuthGroup` and `TSQLAuthUser`, and define e.g. your own fields, for any custom purpose at *Group* or *User* level. The exact class types are available from `SQLAuthUserClass` and `SQLAuthGroupClass` properties of `TSQLRestServer`.

Since the whole records will be loaded and persisted in memory at every authentication, do not store too much data in those tables: for instance, do not put historical data (like previous client activity), or huge BLOBs (like detailed pictures) - a dedicated table or set of tables will be a better idea.

Here is the layout of the default `AuthGroup` table, as defined by the `TSQLAuthGroup` class type:

ID : TID
AccessRights : RawUTF8
Ident : RawUTF8
SessionTimeout : integer

AuthGroup Record Layout

The `AccessRights` column is a textual CSV serialization of the `TSQLAccessRights` record content, as expected by the `TSQLRestServer.URI` method. Using a CSV serialization, instead of a binary serialization, will allow the change of the `MAX_SQLTABLES` constant value.

The `AuthUser` table, as defined by the `TSQLAuthUser` class type, is defined as such:

AuthUser Record Layout

Each user has therefore its own associated `AuthGroup` table, a name to be entered at login, a name to be displayed on screen or reports, and a SHA256 hash of its registered password (with optional PBKDF2_HMAC_SHA256 derivation). A custom Data BLOB field is specified for your own application use, but not accessed by the framework.

By default, the following security groups are created on a void database:

Group	POST SQL	SELECT SQL	Auth R	Auth W	Tables R	Tables W	Services
Admin	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Supervisor	No	Yes	Yes	No	Yes	Yes	Yes
User	No	No	No	No	Yes	Yes	Yes
Guest	No	No	No	No	Yes	No	No

'Admin' will be the only able to execute remote not SELECT SQL statements for POST commands (reSQL flag in `TSQLAccessRights`. `AllowRemoteExecute`) and modify the Auth* tables (i.e. `AuthUser` and `AuthGroup`).

'Admin' and 'Supervisor' will allow any SELECT SQL statements to be executed, even if the table can't be retrieved and checked (corresponding to the `reSQLSelectWithoutTable` flag).

'User' won't have the `reSQLSelectWithoutTable` flag, nor the right to retrieve the Auth* tables data for other users.

'Guest' won't have access to the interface-based remote JSON-RPC service (no `reService` flag), nor perform any modification to a table: in short, this is an ORM read-only limited user.

Please see below (page 560) and the `TSQLAccessRights` documentation for all available options and use cases.

Then the corresponding 'Admin', 'Supervisor' and 'User' `AuthUser` accounts are created, with the default 'synapse' password.

You MUST override those default 'synapse' passwords for each `AuthUser` record to a custom genuine value.

A typical JSON representation of the default security user/group definitions are the following:

```
[{"AuthUser": [
{"RowID":1, "LogonName":"Admin", "DisplayName":"Admin",
```

```
"PasswordHashHexa": "67aeaa294e1cb515236fd7829c55ec820ef888e8e221814d24d83b3dc4d825dd",
"GroupRights": 1, "Data": null},
{"RowID": 2, "LogonName": "Supervisor", "DisplayName": "Supervisor",
"PasswordHashHexa": "67aeaa294e1cb515236fd7829c55ec820ef888e8e221814d24d83b3dc4d825dd",
"GroupRights": 2, "Data": null},
{"RowID": 3, "LogonName": "User", "DisplayName": "User",
"PasswordHashHexa": "67aeaa294e1cb515236fd7829c55ec820ef888e8e221814d24d83b3dc4d825dd",
"GroupRights": 3, "Data": null}]],
{"AuthGroup": [
{"RowID": 1, "Ident": "Admin", "SessionTimeout": 10,
"AccessRights": "11,1-256,0,1-256,0,1-256,0,1-256,0"},
{"RowID": 2, "Ident": "Supervisor", "SessionTimeout": 60,
"AccessRights": "10,1-256,0,3-256,0,3-256,0,3-256,0"},
{"RowID": 3, "Ident": "User", "SessionTimeout": 60,
"AccessRights": "10,3-256,0,3-256,0,3-256,0,3-256,0"},
{"RowID": 4, "Ident": "Guest", "SessionTimeout": 60, "AccessRights": "0,3-256,0,0,0,0"}]]]
```

Of course, you can change AuthUser and AuthGroup table content, to match your security requirements, and application specifications. You can specify a per-table CRUD access, via the AccessRights column, as we stated above, speaking about the TSQLAccessRights record layout.

This will implement both *Query Authentication* together with a group-defined *per-user right* management.

21.1.2.2. Session handling

A dedicated RESTful service, available from the ModelRoot/Auth URI, is to be used for user authentication, handling so called sessions.

In *mORMot*, a very light in-memory set of sessions is implemented:

- The unique ModelRoot/Auth URI end-point will create a session after proper authorization;
- *In-memory* session allows very fast process and reactivity, on Server side;
- Sessions could be optionally persisted on disk at server shutdown, to avoid breaking existing client connections;
- An integer *session identifier* is used for all authorization process, independently from the underlying authentication scheme (i.e. *mORMot* is not tied to cookies, and its session process is much more generic).

Those sessions are in-memory TAuthSession class instances. Note that this class does not inherit from a TSQLRecord table so won't be remotely accessible, for performance and security reasons.

The server methods should not have to access those TAuthSession instances directly, but rely on the SessionID identifier. But you can still access the current session properties, e.g. the remote user, thanks to methods like TSQLRestServer.SessionGetUser(): TSQLAuthUser.

When the Client is about to close (typically in TSQLRestClientURI.Destroy), a GET ModelRoot/auth?UserName=...&Session=... request is sent to the remote server, in order to explicitly close the corresponding session in the server memory (avoiding most *re-play* attacks).

Note that each opened session has an internal *TimeOut* parameter (retrieved from the associated TSQLAuthGroup table content): after some time of inactivity, sessions are closed on the Server Side.

In addition, sessions are used to manage safe cross-client transactions:

- When a transaction is initiated by a client, it will store the corresponding client Session ID, and use it to allow client-safe writing;
- Any further write to the DB (Add/Update/Delete) will be accessible only from this Session ID, until the transaction is released (via commit or rollback);
- If a transaction began and another client session try to write on the DB, it will wait until the current

- transaction is released - a timeout may occur if the server is not able to acquire the write status within some time;
- This global write locking is defined by the `TSQLRest.AcquireWriteMode / AcquireWriteTimeOut` properties, and used on the Server-Side by `TSQLRestServer.URI` - you can change this behavior by setting e.g. `AcquireWriteMode := amBackgroundThread` which will lock any write process to be executed in a dedicated thread: this may be mandatory if your database client expects the transaction process to take place in the same thread (e.g. MS SQL);
 - If the server do not handle Session/Authentication, transactions can be unsafe, in a multi-client concurrent architecture.

For performance reasons in a multi-client environment, it's mandatory to release a transaction (via commit or rollback) as soon as possible, using e.g. *BATCH sequences for adding/updating/deleting records* (page 351), or - even better - write dedicated *Client-Server services via interfaces* (page 420) which will process the whole transaction in one step, following the *Unit Of Work pattern* (page 354).

You can specify an optional file name parameter to the `TSQLRestServer.Shutdown()` method, which will save the current server state into a local file. Then, if you restart the server in a short time, you may be able to restore all session information by using `TSQLRestServer.SessionsLoadFromFile()`. This feature will enable e.g. a quick and transparent ORM Server executable upgrade, in production. But note that even if sessions are persisted and able to be restored, any session-dependent complex data - like server-side temporary *Instances life time implementation* (page 430) as generated by interface-based services - won't be available. This session temporary backup/restore will make sense only when the server is in ORM mode, *not* when used as SOA.

21.1.3. Authentication schemes

21.1.3.1. Class-driven authentication

Authentication is implemented in *mORMot* via the following classes:

TSQLRestServerAuthentication classes hierarchy

In fact, you can use one of the following RESTful authentication schemes:

class	Scheme
<code>TSQLRestServerAuthenticationDefault</code>	<i>mORMot</i> secure authentication, as a proprietary dual-pass challenge and SHA256/PBKDF2_HMAC_SHA256 hashing
<code>TSQLRestServerAuthenticationSSPI</code>	Windows authentication, via the logged user

TSQLEstServerAuthenticationNone	Weak but simple authentication, based on user name
TSQLEstServerAuthenticationHttpBasic	HTTP Basic authentication Warning: password is not encrypted

All those classes will identify a `TSQLEstUser` record from a user name. The associated `TSQLEstGroup` is then used later for authorization.

You can add you own custom authentication scheme by defining your own class, inheriting from `TSQLEstServerAuthentication`.

By default, no authentication is performed.

If you set the `aHandleUserAuthentication` parameter to `true` when calling the constructor `TSQLEstServer.Create()`, both default secure *mORMot* authentication and Windows authentication are available. In fact, the constructor executes the following:

```
constructor TSQLEstServer.Create(aModel: TSQLEstModel; aHandleUserAuthentication: boolean);
(...)
if aHandleUserAuthentication then
  // default mORMot authentication schemes
  AuthenticationRegister([
    TSQLEstServerAuthenticationDefault,TSQLEstServerAuthenticationSSPI]);
(...)
```

In order to define one or several authentication scheme, you can call the `AuthenticationRegister()` and `AuthenticationUnregister()` methods of `TSQLEstServer`.

21.1.3.2. mORMot secure RESTful authentication

The `TSQLEstServerAuthenticationDefault` class implements a proprietary but secure RESTful *Authentication* (page 547).

As stated in *Enhanced sample: remote SQL access* (page 440), typical client-side authentication is performed using the following command:

```
MyClient.SetUser('User','synapse'); // default user for Security tests
```

Here are the typical steps to be followed in order to create a new user session via *mORMot* authentication scheme:

- Client sends a GET `ModelRoot/auth?UserName=...` request to the remote server - with the above command, it will be GET `ModelRoot/auth?UserName=User`;
- Server answers with a hexadecimal *nonce* contents (valid for about 5 minutes), encoded as JSON result object;
- Client sends a GET `ModelRoot/auth?UserName=...&PassWord=...&ClientNonce=...` request to the remote server, in which `ClientNonce` is a random value used as Client *nonce*, and `PassWord` is computed from the log-on and password entered by the User, using both Server and Client *nonce* as salt;
- Server checks that the transmitted password is valid, i.e. that its matches the hashed password stored in its database and a time-valid Server *nonce* - if the value is not correct, authentication fails;
- On success, Server will create a new in-memory session and return the session number and a private key to be used during the session (encoded as JSON result object);
- On any further access to the Server, a `&session_signature=` parameter is added to the URL, and will be checked against the valid sessions in order to validate the request.

Query Authentication is handled at the Client side in `TSQLEstClientURI.SessionSign` method, by

computing the `session_signature` parameter for a given URL, according to the `TSQLRestServerAuthentication` class used.

In order to enhance security, the `session_signature` parameter will contain, encoded as 3 hexadecimal 32-bit cardinals:

- The Session ID (to retrieve the private key used for the signature);
- A Client Time Stamp (in 256 ms resolution) which must be greater or equal than the previous time stamp received;
- The URI signature, using the session private key, the user hashed password, and the supplied Client Time Stamp as source for its `crc32` hashing algorithm.

Such a classical 3 points signature will avoid most *man-in-the-middle* (MITM) or *re-play* attacks.

Here is typical signature to access the root URL

```
root?session_signature=0000004C000F6BE365D8D454
```

In this case, `0000004C` is the Session ID, `000F6BE3` is the client time stamp (aka nonce), and `65D8D454` is the signature, computed by the following *Delphi* expression:

```
(crc32(crc32(fPrivateSaltHash,PTimestamp,8),pointer(aURL),aURLlength)=aSignature);
```

For instance, a RESTful GET of the `TSQLRecordPeople` table with `RowID=6` will have the following URI:

```
root/People/6?session_signature=0000004C000F6DD02E24541C
```

For better Server-side performance, the URI signature will use fast `crc32` hashing method, and not the more secure (but much slower) `SHA256`. Since our security model is not officially validated as a standard method (there is no standard for per URI authentication of RESTful applications), the better security will be handled by encrypting the whole transmission channel, using standard `HTTPS` with certificates signed by a trusted CA, validated for both client and server side. The security involved by using `crc32` will be enough for most common use. Note that the password hashing and the session opening will use `SHA256` or `PBKDF2_HMAC_SHA256`, to enhance security with no performance penalty.

In our implementation, for better Server-side reaction, the `session_signature` parameter is appended at the end of the URI, and the URI parameters are not sorted alphabetically, as suggested by the reference article quoted above. This should not be a problem, either from a *Delphi* Client or from a *AJAX / JavaScript* client.

On practice, this scheme is secure and very fast, perfect for a *Delphi* client, or an *AJAX* application. If you expect a higher level of security for the URI signature, you may consider setting a cryptographic-level `MD5/SHA1/SHA256/SHA512` hash, by selecting a given `TSQLRestServerAuthenticationSignedURIAlgo` on server side.

21.1.3.3. Authentication using Windows credentials

21.1.3.3.1. Windows Authentication

By default, the *hash* of the user password is stored safely on the server side. This may be an issue for corporate applications, since a new user name / password pair is to be defined by each client, which may be annoying.

Since revision 1.18 of the framework, *mORMot* is able to use *Windows Authentication* to identify any user. That is, the user does not need to enter any name nor password, but her/his Windows credentials, as entered at Windows session startup, will be used.

If the `SSPIAUTH` conditional is defined (which is the default), any call to `TSQLRestClientURI.SetUser()` method with a void `aUserName` parameter will try to use current logged name and password to perform a secure Client-Server authentication. It will in fact call the class function `TSQLRestServerAuthenticationSSPI.ClientSetUser()` method.

In this case, the `aPassword` parameter will identify if either *NTLM* or *Kerberos* authentication scheme is to be used: it may contain the SPN domain name to enabled *Kerberos* - see next section. This will be transparent to the framework, and a regular session will be created on success.

Only prerequisite is that the `TSQLAuthUser` table shall contain a corresponding entry, with its `LogonName` column equals to '*DomainName*' value. This data row won't be created automatically, since it is up to the application to allow or disallow access from an authenticated user: you can be member of the domain, but not eligible to the application.

21.1.3.3.2. Using NTLM or Kerberos

Kerberos is the preferred authentication protocol for Windows Server 2003 and subsequent Active Directory domains.

Kerberos authentication offers the following advantages over *NTLM* authentication:

- Mutual authentication.
When a client uses the *Kerberos* protocol for authentication with a particular service on a particular server, *Kerberos* provides the client with an assurance that the service is not being impersonated by malicious code on the network.
- Simplified trust management.
Networks with multiple domains no longer require a complex set of explicit, point-to-point trust relationships.
- Enhanced security.
The old *NTLM* protocol suffers from several weaknesses, which have been fixed by *Kerberos*.
- Performance.
Offers improved performance, mostly for server applications.

Requirements for *Kerberos* authentication are the following:

- Client and Server must join a domain, and the trusted third party must exist; if client and server are in different domain, these two domains must be configured as two-way trust.
- SPN must have been registered properly. *Service Principal Name* (SPNs) are unique identifiers for services running on servers. Each service that will use *Kerberos* authentication needs to have an SPN set for it so that clients can identify the service on the network. It is registered in *Active Directory* under either a computer account or a user account. See below for corresponding instructions.

Typical use case of either *Kerberos* or *NTLM* are defined by the `aPassword` parameter:

- *Kerberos* is used for a remote connection over a network and if `aPassword` is set to the expected SPN domain;
- *NTLM* is used over network connection if `aPassword` is empty;
- *NTLM* is used when making local connection.

Note that *Kerberos* is used only when making remote connection over a network; *NTLM* is used when making local connection..

To enable *Kerberos* authentication in *mORMot*, you need to register SPN for your service.

The format of an SPN is `ServiceClass/Host:Port/ServiceName`. Typically, SPN for your service,

developed with *mORMot*, looks like `mymormotservice/myserver.mydomain.tld` or `http/myserver.mydomain.tld`.

To list SPNs of a computer named MYSERVER, at the command prompt, type:

```
setspn -l myserver
```

Typically, you can see the following output:

```
Registered ServicePrincipalNames for CN=MYSERVER,OU=Computers,DC=domain,DC=tld:  
HOST/MYSERVER.domain.tld  
HOST/MYSERVER
```

If your service runs under SYSTEM or Network Service machine accounts, you can test *Kerberos* authentication by setting the `aPassword` parameter to value 'HOST/MYSERVER.domain.tld' in the client code and run the application.

To register SPN for your service, at the command prompt, type:

- If your service run under SYSTEM or Network Service machine accounts:

```
setspn -a mymormotservice/myserver.mydomain.tld myserver
```

- If your service run under another domain account:

```
setspn -a mymormotservice/myserver.mydomain.tld myserviceaccount
```

Membership in *Domain Admins* group, or equivalent, is the minimum required to complete this procedure.

See <http://technet.microsoft.com/en-us/library/cc731241.aspx..> for more details.

After registration, you can connect to the server as such:

```
MyClient.SetUser('', 'mymormotservice/myserver.mydomain.tld'); // will use Kerberos
```

For good old NTLM, you can run:

```
MyClient.SetUser('', ''); // will use NTLM
```

Or directly call the `TSQLRestServerAuthenticationSSPI.ClientSetUser()` method.

The authentication mode used will appear in the log file, if you define `WITHLOG` conditional when building the service application and if `s11UserAuth` is in `TSQLLog.Family.Level` set.

Messages will be as follows:

```
NTLM Authentication success for domain\myuser  
Kerberos Authentication success for domain\myuser
```

The framework authorization will then be processed as usual, for all features like RESTful ORM process and remote services.

21.1.3.4. Weak authentication

The `TSQLRestServerAuthenticationNone` class can be used if you trust your client (e.g. via a https connection). It will implement a weak but simple authentication scheme.

Here are the typical steps to be followed in order to create a new user session via this authentication scheme:

- Client sends a GET `ModelRoot/auth?UserName=...` request to the remote server;
- Server checks that the transmitted user name is valid, i.e. that it is available in the `TSQLAuthGroup` table - if the value is not correct, authentication fails
- On success, Server will create a new in-memory session and returns the associated session number

- (encoded as decimal in the JSON result object);
- On any further access to the Server, a `&session_signature=` parameter is to be added to the URL with the correct session ID (encoded as hexadecimal), and will be checked against the valid sessions in order to validate the request.

For instance, a RESTful GET of the `TSQLRecordPeople` table with `RowID=6` will have the following URI:

```
root/People/6?session_signature=0000004C
```

Here is some sample code about how to define this authentication scheme:

```
// on the Server side:
Server.AuthenticationRegister(TSQLRestServerAuthenticationNone);
...
// on the Client side:
TSQLRestServerAuthenticationNone.ClientSetUser(Client, 'User');
```

The performance benefit is very small in comparison to `TSQLRestServerAuthenticationDefault`, so should not be used for *Delphi* clients.

21.1.3.5. HTTP Basic authentication

The *Basic Authentication* mechanism provides no confidentiality protection for the transmitted credentials. They are merely encoded with *Base64* in transit, but not encrypted or hashed in any way. *Basic Authentication* is, therefore, typically used over HTTPS.

The `TSQLRestServerAuthenticationHttpBasic` class can be used to enable HTTP Basic authentication.

This class is not to be used with a *mORMot* client, since `TSQLRestServerAuthenticationDefault` provides a much better scheme, both safer and faster, but could be used in conjunction with some browser clients, over HTTPS.

21.1.4. Clients authentication

21.1.4.1. Client interactivity

Note that with this design, it's up to the Client to react to an authentication error during any request, and ask again for the User pseudo and password at any time to create a new session. For multiple reasons (server restart, session timeout...) the session can be closed by the Server without previous notice.

In fact, the Client should just use create one instance of the `TSQLRestClientURI` classes as presented in *JSON RESTful Client-Server* (page 296), then call the `SetUser` method as such:

```
Check(Client.SetUser('User', 'synapse')); // use default user
```

Then an event handled can be associated to the `TSQLRestClientURI`. `OnAuthenticationFailed` property, in order to ask the user to enter its login name and password:

```
TOnAuthenticationFailed = function(Retry: integer;
  var aUserName, aPassword: string): boolean;
```

Of course, if *Windows Authentication* is defined (see above), this event handler shall be adapted as expected. For instance, you may add a custom notification to register the corresponding user to the `TSQLAuthUser` table.

21.1.4.2. Authentication using AJAX

Smart Mobile Studio support (page 487) can generate *JavaScript* code from its IDE. Our

template-based code generation make this solution perfectly integrated with our *mORMot* server, especially about authentication: you will find the same *TSQLRestServerAuthenticationDefault* and *TSQLRestServerAuthenticationNone* classes in our *SynCrossPlatformREST.pas* unit, ready to authenticate to the server.

In fact, there is also a command-line compiler available (named *smc.exe*) which can create a *.js* file from *SmartPascal* code: you may use it to integrate the generated client to a regular HTML5 application (using e.g. *jQuery* or *AngularJS*).

Some stand-alone working *JavaScript* code has been published in our forum by a framework user (thanks, "RangerX"), which implements the authentication schema as detailed above. It uses *jQuery*, and HTML 5 *LocalStorage*, not cookies, for storing session information on the Client side.

See <https://synapse.info/forum/viewtopic.php?pid=2995#p2995..>

21.1.5. JWT Authentication

As an alternative, you may use *JSON Web Tokens (JWT)* (page 380) for authentication.

On server side, you can assign a *TJWTAbstract* inherited instance to *TSQLRestServer.JWTForUnauthenticatedRequest* so that any client providing a valid JWT would be allowed to execute some requests.

```
aJWTEngine := TJWTS3256.Create(aSecretKey, 60000, [jrcIssuer, jrcExpirationTime], [],  
aExpireMinutes);  
aRestServer.JWTForUnauthenticatedRequest := aJWTEngine; // will be owned by aRestServer
```

On *mORMot* client side, you can provide a valid JWT via:

```
aRestClientURI.SessionHTTPHeader := AuthorizationBearer(aJWT);
```

Any kind of JSON/HTTPS client could easily connect to such a service, by providing a valid JWT as 'Authorization: Bearer #####' HTTP header. A dedicated authentication service may be used to return some JWT in exchange from some credential (typically a user-name/password) for your application.

In practice, for your internal *MicroServices* communication, you could therefore use regular *mORMot* secure *RESTful* authentication (page 553) over a *WebSockets* support (page 445), which are pretty stable and efficient. Then for a public API, you could use a regular *TSQLHttpServer* - see *Network and Internet access via HTTP* (page 326) - perhaps over a *nginx* reverse proxy (e.g. for *Let's Encrypt* HTTPS certification). Since the *mORMot* authentication is proprietary, using a JWT may sound more natural for a public API service, with a more relaxed JSON encoding and no contract. That is, on the server side, you define: *ServiceDefine(...).ResultAsJSONObjectWithoutResult := true*; and on the client side, you call the *TSQLRestClientURI.ServiceDefineSharedAPI()* method to follow a similar more standard JSON layout (i.e. JSON objects as input/output and not a JSON array without any contract negotiation).

By design, such clients won't be tied to any associated *mORMot* session or user. So *Client-Server services via interfaces* (page 420) should be only of *sicSingle*, *sicShared* or *sicPerThread* kind - see *Instances life time implementation* (page 430).

See also *TSQLRestServer.JWTForUnauthenticatedRequestWhiteIP* for additional security, to require the client to connect from a finite set of allowed IP addresses.

21.2. Authorization

By authorization, we mean the action to define an access policy to the RESTful resources, for an authenticated user. Even if this user may be a guest user (with no specific access credential), it should be identified as such, e.g. to serve public content.

The main principle is the *principle of least privilege* (also known as the *principle of minimal privilege* or the *principle of least authority*): in a particular abstraction layer of a computing environment, every module (such as a process, a user or a program depending on the subject) must be able to access only the information and resources that are necessary for its legitimate purpose.

It is most of the time implemented e.g. via *Access Control Lists* (ACL), set of capabilities or user groups. In *mORMot*, we defined user groups, associated to *TSQLAuthGroup* ORM class.

Today, authorization is part of a trust chain:

- In corporate networks, the *Active Directory* service gives a token for an already signed user, or LDAP allows access to resources;
- In social networks, protocols like *OAuth* allows to trust an user between services.

This allows the very convenient feature of *single sign-on*: the user can authenticate only once (e.g. at Windows logon), then he/she will be authenticated for its whole session, and each authorization will provide the appropriate rights. Our framework e.g. features NTLM / Kerberos authentication, as we just saw.

21.2.1. Per-table access rights

Even if authentication is disabled, a pointer to a *TSQLAccessRights* record, and its GET / POST / PUT / DELETE fields, is sent as a member of the parameter to the unique access point of the server class:

```
procedure TSQLRestServer.URI(var Call: TSQLRestServerURIParams);
```

This will allow checking of access right for all CRUD operations, according to the table invoked. For instance, if the table *TSQLRecordPeople* has 2 as index in *TSQLModel.Tables[]*, any incoming POST command for *TSQLRecordPeople* will be allowed only if the 2nd bit in *RestAccessRights^.POST* field is set, as such:

```
case URI.Method of
mPOST: begin // POST=ADD=INSERT
  if URI.Table=nil then begin
    (...)
  end else
    // here, Table<>nil and TableIndex in [0..MAX_SQLTABLES-1]
    if not (URI.TableIndex in Call.RestAccessRights^.POST) then // check User
      Call.OutStatus := HTTP_FORBIDDEN else
    (...)
end;
```

Making access rights a parameter allows this method to be handled as pure stateless, thread-safe and session-free, from the bottom-most level of the framework.

On the other hand, the security policy defined by this global parameter does not allow tuned per-user authorization. In the current implementation, the *SUPERVISOR_ACCESS_RIGHTS* constant is transmitted for all handled communication protocols (direct access, Windows Messages, named pipe or HTTP). Only direct access via *TSQLRestClientDB* will use *FULL_ACCESS_RIGHTS*, i.e. will have *AllowRemoteExecute* parameter set to all possible flags.

The light session process, as implemented by *Authentication* (page 547), is used to override the access rights with the one defined in the *TSQLAuthGroup.AccessRights* field.

Be aware that this per-table access rights depend on the table order as defined in the associated `TSQLModel`. So if you add some tables to your database model, please take care to add the new tables *after* the existing. If you insert the new tables within current tables, you will need to update the access rights values.

21.2.2. Additional safety

A `AllowRemoteExecute`: `TSQLAllowRemoteExecute` field has been made available in the `TSQLAccessRights` record to tune remote execution, depending on the authenticated user, and the group he/she is part of.

This field adds some flags to tune the security policy, for both SQL or SOA dimensions.

21.2.2.1. SQL remote execution

In our RESTful implementation, the POST command with no table associated in the URI allows to execute any SQL statement directly. A GET command could also be used, either with the SQL statement transmitted as body (which is convenient, but not supported by all HTTP clients, since it is not standard), or inlined at URI level.

These special commands should be carefully tested before execution, since SQL misuses could lead into major security issues. Such execution on any remote connection, if the SQL statement is not a SELECT, is unsafe. In fact, it may affect the data content.

By default, for security reasons, the `AllowRemoteExecute` field value in `SUPERVISOR_ACCESS_RIGHTS` constant does not include the `reSQL` flag. It means that no remote call will be allowed but for safe read-only SELECT statements.

When SELECT statements are sent, the server will always check for the table name specified in their FROM clause. If there is a single table appearing, its security policy will be checked against the `GET[]` flags of the corresponding table. If the SELECT statement is more complex (e.g. is a JOINed statement), then the `reSQLSelectWithoutTable` will be checked to ensure that the user has the right to execute such statements.

Another possibility of SQL remote execution is to add a `sql=...` inline parameter to a GET request (with optional paging). The `reUrlEncodedSQL` flag is used to enable or disable this feature.

Last but not least, a `WhereClause=...` inline parameter can be added to a DELETE request. The `reUrlEncodedDelete` option is used to enable or disable this feature.

You can change the default safe policy by including or excluding `reSQL`, `reSQLSelectWithoutTable`, `reUrlEncodedSQL` or `reUrlEncodedDelete` flags in the `TSQLAuthGroup`. `AccessRights.AllowRemoteExecute` field of an authentication user session.

If security is a real concern, you should enable *mORMot secure RESTful authentication* (page 553) and URI signature on your server, so that only trusted clients may access to the server. This is the main security rule of the framework - in practice, those *per table* access right or *SQL remote execution flags* are more a design rule than a strong security feature. Since remote execution of any SQL statements can be unsafe, we recommend to write a dedicated server-side service (method-based or interface-based) to execute such statements instead, and disallow remote SQL execution; then clients can safely use those dedicated safe services, and/or ORM CRUD operations for simple data requests. It will also help your project to be not tied to SQL, so that a switch to a *NoSQL* persistence engine will still be possible, without changing the client code.

21.2.2.2. Service execution

The `reService` flag of `AllowRemoteExecute`: `TSQLAllowRemoteExecute` can be used to enable or unblock the *Client-Server services via interfaces* (page 420) feature of *mORMot*.

In addition to this global parameter, you can set per-service and per-method *Security* (page 460).

For *Client-Server services via methods* (page 374), if authentication is enabled, any method execution will be processed only from a signed URI.

You can use `TSQLRestServer.ServiceMethodByPassAuthentication()` to disable the need of a signature for a given service method - e.g. it is the case for `Auth` and `Timestamp` standard method services.

For *Client-Server services via interfaces* (page 420), if authentication is enabled, any service execution will be processed only from a signed URI.

You can use the `TServiceFactoryServer.ByPassAuthentication` property, to let a given service URI not be signed.

Do not forget to remove authentication for the services for which you want to enable *Scaling via CDN* (page 543). In fact, such world-wide CDN caching services expect the URI to be generic, and not tied to a particular client session.

22. Scripting Engine

Adopt a mORMot

22.1. Scripting abilities

As a *Delphi* framework, *mORMot* premium language support is for the *object pascal* language. But it could be convenient to have some part of your software not fixed within the executable. In fact, once the application is compiled, execution flow is written in stone: you can't change it, unless you modify the *Delphi* source and compile it again. Since *mORMot* is *Open Source*, you can ship the whole source code to your customers or services with no restriction, and diffuse your own code as pre-compiled .dcu files, but your end-user will need to have a *Delphi* IDE installed (and paid), and know the *Delphi* language.

This is when scripting does come on the scene.

For instance, scripting may allow to customize an application behavior for an end-user (i.e. for reporting), or let a domain expert define evolving appropriate business rules - following *Domain-Driven Design* (page 99).

If your business model is to publish a core domain expertise (e.g. accounting, peripheral driving, database model, domain objects, communication, AJAX clients...) among several clients, you will sooner or later need to adapt your application to one or several of your customers. There is no "one exe to rule them all". Maintaining several executables could become a "branch-hell". Scripting is welcome here: speed and memory critical functionality (in which *mORMot* excels) will be hard-coded within the main executable, then everything else could be defined in script.

There are plenty of script languages available.

We considered <http://code.google.com/p/dwscript..> which is well maintained and expressive (it is the

code of our beloved *Smart Mobile Studio*), but is not very commonly used. We still want to include it in the close future.

Then <http://www.lua.org..> defines a light and versatile general-purpose language, dedicated to be embedded in any application. Sounds like a viable solution: if you can help with it, your contribution is welcome!

We did also take into consideration <http://www.python.org..> and <http://www.ruby-lang.org..> but both are now far from light, and are not meant to be embedded, since they are general-purpose languages, with a huge set of full-featured packages.

Then, there is *JavaScript*:

- This is the *World Wide Web* assembler. Every programmer in one way or another knows *JavaScript*;
- *JavaScript* can be a very powerful language - see Crockford's book "*JavaScript - The Good Parts*";
- There are a huge number of libraries written in *JavaScript*: template engines (jade, mustache...), SOAP and LDAP clients, and many others (including all `node.js` libraries of course);
- It was the base for some strongly-typed syntax extensions, like *CoffeScript*, *TypeScript*, *Dart*;
- In case of *AJAX / Rich Internet Application* we can directly share part of logic between client and server (validation, template rendering...) without any middle-ware;
- One long time *mORMot*'s user (Pavel, aka *mpv*) already integrated *SpiderMonkey* to *mORMot*'s core. His solution is used on production to serve billion of requests per day, with success. We officially integrated his units. Thanks Pavel!

As a consequence, *mORMot* introduced direct *JavaScript* support via *SpiderMonkey*.

It allows to:

- Execute *Delphi* code from *JavaScript* - including our *Object-Relational Mapping (ORM)* (page 92)/ *Service-Oriented Architecture (SOA)* (page 90) methods, or even reporting;
- Consume *JavaScript* code from *Delphi* (e.g. to define and customize any service or rule, or use some existing `.js` library);
- Expose *JavaScript* objects and functions via a *TSMVariant* custom variant type: it allows to access any *JavaScript* object properties or call any of its functions via late-binding, from your *Delphi* code, just as if it was written in native Object-Pascal;
- Follow a classic synchronous blocking pattern, rooted on *mORMot*'s multi-thread efficient model, easy to write and maintain;
- Handle *JavaScript* or *Delphi* objects as *Unicode and UTF-8* (page 105) *JSON* (page 296), ready to be published or consumed via *JSON RESTful Client-Server* (page 296) remote access.

22.2. SpiderMonkey integration

22.2.1. A powerful JavaScript engine

SpiderMonkey, the Mozilla *JavaScript* engine, can be embedded in your *mORMot* application. It could be used on client side, within a *Delphi* application (e.g. for reporting), but the main interest of it may be on the server side.

The word *JavaScript* may bring to mind features such as event handlers (like `onclick`), DOM objects, `window.open`, and `XMLHttpRequest`.

But all of these features are actually not provided by the *SpiderMonkey* engine itself.

SpiderMonkey provides a few core *JavaScript* data types—numbers, strings, Arrays, Objects, and so on—and a few methods, such as `Array.push`. It also makes it easy for each application to expose some of its own objects and functions to *JavaScript* code. Browsers expose DOM objects. Your application will expose objects that are relevant for the kind of scripts you want to write. It is up to the

application developer to decide what objects and methods are exposed to scripts.

22.2.2. Direct access to the SpiderMonkey API

The `SynSMAPI.pas` unit is a tuned conversion of the *SpiderMonkey* API, providing full *ECMAScript 5* support and *JIT*. The *SpiderMonkey* revision 24 engine is included, with a custom C wrapper around the original C++ code.

You could take a look at <http://developer.mozilla.org/en-US/docs/Mozilla/Projects/SpiderMonkey..> for a full description of this low-level API, and find our patched version of the library, modified to be published from C instead of C++, in the `synsm-mozjs` folder of the *mORMot* source code repository.

But the `SynSM.pas` unit will encapsulate most of it into higher level *Delphi* classes and structures (including a custom variant type), so you probably won't need to use `SynSMAPI.pas` directly in your code:

Type	Description
<code>TSMEngineManager</code>	main access point to the <i>SpiderMonkey</i> per-thread scripting engines
<code>TSMEngine</code>	implements a Thread-Safe <i>JavaScript</i> engine instance
<code>TSMObject</code>	wrap a <i>JavaScript</i> object and its execution context
<code>TSMValue</code>	wrap a <i>JavaScript</i> value, and interfaces it with <i>Delphi</i> types
<code>TSMVariant / TSMVariantData</code>	define a custom variant type, for direct access to any <i>JavaScript</i> object, with late-binding

We will see how to work with all those classes.

22.2.3. Execution scheme

The *SpiderMonkey JavaScript engine* compiles and executes scripts containing *JavaScript* statements and functions. The engine handles memory allocation for the objects needed to execute scripts, and it cleans up—garbage collects—objects it no longer needs.

In order to run any *JavaScript* code in *SpiderMonkey*, an application must have three key elements:

- A *JSRuntime*,
- A *JSContext*,
- And a *global JSObject*.

A *JSRuntime*, or runtime, is the space in which the *JavaScript* variables, objects, scripts, and contexts used by your application are allocated. Every *JSContext* and every object in an application lives within a *JSRuntime*. They cannot travel to other runtimes or be shared across runtimes.

A *JSContext*, or context, is like a little machine that can do many things involving *JavaScript* code and objects. It can compile and execute scripts, get and set object properties, call *JavaScript* functions, convert *JavaScript* data from one type to another, create objects, and so on.

Lastly, the *global JSObject* is a *JavaScript* object which contains all the classes, functions, and variables that are available for *JavaScript* code to use. Whenever a web browser code does something like `window.open("http://www.mozilla.org/")`, it is accessing a global property, in this case `window`. *SpiderMonkey* applications have full control over what global properties scripts can see.

Every *SpiderMonkey* instance starts out every execution context by creating its *JSRunTime*, *JSContext*

instances, and a global JSObject. It populates this global object with the standard *JavaScript* classes, like *Array* and *Object*. Then application initialization code will add whatever custom classes, functions, and variables (like *window*) the application wants to provide; it may be, for a *mORMot* server application, ORM access or SOA services consumption and/or implementation.

Each time the application runs a *JavaScript* script (using, for example, *JS_EvaluateScript*), it provides the global object for that script to use. As the script runs, it can create global functions and variables of its own. All of these functions, classes, and variables are stored as properties of the global object.

22.2.4. Creating your execution context

The main point about those three key elements is that, in the current implementation pattern of *SpiderMonkey*, runtime, context or global objects are *not thread-safe*.

Therefore, in the *mORMot*'s use of this library, each thread will have its own instance of each.

In the *SynSM.pas* unit, a *TSMEngine* class has been defined to give access to all those linked elements:

```
TSMEngine = class
...
  /// access to the associated global object as a TSMVariant custom variant
  /// - allows direct property and method executions in Delphi code, via
  /// late-binding
  property Global: variant read FGlobal;
  /// access to the associated global object as a TSMObject wrapper
  /// - you can use it to register a method
  property GlobalObject: TSMObject read FGlobalObject;
  /// access to the associated global object as low-level PJSObject
  property GlobalObj: PJSObject read FGlobalObject.fobj;
  /// access to the associated execution context
  property cx: PJSContext read fCx;
  /// access to the associated execution runtime
  property rt: PJSRuntime read frt;
...
```

Our implementation will define one Runtime, one Context, and one global object per thread, i.e. one *TSMEngine* class instance per thread.

A JSRuntime, or runtime, is created for each *TSMEngine* instance. In practice, you won't need access to this value, but rely either on a JSContext or directly a *TSMEngine*.

A JSContext, or context, will be the main entry point of all *SpiderMonkey* API, which expect this context to be supplied as parameter. In *mORMot*, you can retrieve the running *TSMEngine* from its context by using the function *TSMObject.Engine: TSMEngine* - in fact, the engine instance is stored in the *private data* slot of each JSContext.

Lastly, the *TSMEngine*'s *global object* contains all the classes, functions, and variables that are available for JavaScript code to use. For a *mORMot* server application, ORM access or SOA services consumption and/or implementation, as stated above.

You can note that there are several ways to access this global object instance, from high-level to low-level *JavaScript* object types. The *TSMEngine.Global* property above is in fact a variant. Our *SynSM.pas* unit defines in fact a custom variant type, identified as the *TSMVariant* class, able to access any JavaScript object via late-binding, for both variables and functions:

```
engine.Global.MyVariable := 1.0594631;
engine.Global.MyFunction(1, 'text');
```

Most web applications only need one runtime, since they are running in a single thread - and (ab)use

of callbacks for non-blocking execution. But in *mORMot*, you will have one *TMSEngine* instance per thread, using the *TSEngineManager.ThreadSafeEngine* method. Then all execution may be blocking, without any noticeable performance issue, since the whole *mORMot* threading design was defined to maximize execution resources.

22.2.5. Blocking threading model

This threading model is the big difference with other server-side scripting implementation schemes, e.g. the well-known *node.js* solution.

Multi-threading is not evil, when properly used. And thanks to the *mORMot*'s design, you won't be afraid of writing *blocking* JavaScript code, without any callbacks. In practice, those callbacks are what makes most *JavaScript* code difficult to maintain.

On the client side, i.e. in a web browser, the *JavaScript* engine only uses one thread per web page, then uses callbacks to defer execution of long-running methods (like a remote HTTP request).

If fact, this is one well identified performance issue of modern AJAX applications. For instance, it is not possible to perform some intensive calculation in *JavaScript*, without breaking the web application responsiveness: you have to split your computation task in small tasks, then let the *JavaScript* code pause, until a next piece of computation could be triggered... On server side, *node.js* allows to define *Fibers* and *Futures* - see <http://github.com/laverdet/node-fibers..> - but this is not available on web clients. Some browsers did only start to uncouple the *JavaScript* execution thread from the HTML rendering thread - and even this is hard to implement... we reached here the limit of a technology rooted in the 80's...

On the server side, *node.js* did follow this pattern, which did make sense (it allows to share code with the client side, with some name-space tricks), but it is also a big waste of resources. Why should we stick to an implementation pattern inherited from the 80's computing model, when all CPUs were mono core, and threads were not available?

The main problem when working with one single thread, is that your code shall be asynchronous. Soon or later, you will face a syndrome known as "*Callback Hell*". In short, you are nesting anonymous functions, and define callbacks. The main issue, in addition to lower readability and being potentially sunk into *function()* nesting, is that you just lost the *JavaScript* exception model. In fact, each callback function has to explicitly check for the error (returned as a parameter in the callback function), and handle it.

Of course, you can use so-called *Promises* and some nice libraries - mainly *async.js*.

But even those libraries add complexity, and make code more difficult to write. For instance, consider the following non-blocking/asynchronous code:

```
getTweetsFor("domenic") // promise-returning function
  .then(function (tweets) {
    var shortUrls = parseTweetsForUrls(tweets);
    var mostRecentShortUrl = shortUrls[0];
    return expandUrlUsingTwitterApi(mostRecentShortUrl); // promise-returning function
  })
  .then(httpGet) // promise-returning function
  .then(
    function (responseBody) {
      console.log("Most recent link text:", responseBody);
    },
    function (error) {
      console.error("Error with the twitterverse:", error);
    }
  )
  );
```

Taken from <https://blog.domenic.me/youre-missing-the-point-of-promises/>..

This kind of code will be perfectly readable for a *JavaScript* daily user, or someone fluent with functional languages.

But the following blocking/synchronous code may sound much more familiar, safer and less verbose, to most *Delphi* / *Java* / *C#* programmer:

```
try {  
  var tweets = getTweetsFor("domenic"); // blocking  
  var shortUrls = parseTweetsForUrls(tweets);  
  var mostRecentShortUrl = shortUrls[0];  
  var responseBody = httpGet(expandUrlUsingTwitterApi(mostRecentShortUrl)); // blocking x 2  
  console.log("Most recent link text:", responseBody);  
} catch (error) {  
  console.error("Error with the twitterverse: ", error);  
}
```

Thanks to the blocking pattern, it becomes obvious that code readability and maintainability is as high as possible, and error detection is handled nicely via *JavaScript* exceptions, and a global `try .. catch`.

Last but not least, debugging blocking code is easy and straightforward, since the execution will be linear, following the code flow.

Upcoming ECMAScript 6 should go even further thanks to the `yield` keyword and some task generators - see <http://taskjs.org..> - so that asynchronous code may become closer to the synchronous pattern. But even with `yield`, your code won't be as clean as with plain blocking style.

In *mORMot*, we did choose to follow an alternate path, i.e. write blocking synchronous code. Sample above shows how easier it is to work with. If you use it to define some huge business logic, or let a domain expert write the code, blocking syntax is much more straightforward.

Of course, *mORMot* allows you to use callbacks and functional programming pattern in your *JavaScript* code, if needed. But by default, you are allowed to write KISS blocking code.

22.3. Interaction with existing code

Within *mORMot* units, you can mix *Delphi* and *JavaScript* code by two ways:

- Either define your own functions in *Delphi* code, and execute them from *JavaScript*;
- Or define your own functions in *JavaScript* code (including any third-party library), and execute them from *Delphi*.

Like for other part of our framework, performance and integration has been tuned, to follow our KISS way.

You can take a look at "22 - JavaScript HTTPApi web server\JSHttpApiServer.dpr" sample for reference code.

22.3.1. Proper engine initialization

As was previously stated, the main point to interface the *JavaScript* engine is to *register* all methods when the *TSMEngine* instance is initialized.

For this, you set the corresponding `OnNewEngine` callback event to the main *TSMEngineManager* instance.

See for instance, in the sample code:

```
constructor TTestServer.Create(const Path: TFileName);
```

```
begin
...
fSMMManager := TSMEngineManager.Create;
fSMMManager.OnNewEngine := DoOnNewEngine;
...
```

In `DoOnNewEngine`, you will initialize every newly created `TSMEngine` instance, to register all needed *Delphi* methods and prepare access to *JavaScript* via the runtime's global `JSObject`.

Then each time you want to access the *JavaScript* engine, you will write for instance:

```
function TTestServer.Process(Ctxt: THttpRequest): cardinal;
var engine: TSMEngine;
...
engine := fSMMManager.ThreadSafeEngine;
... // now you can use engine, e.g. engine.Global.someMethod()
```

Each thread of the HTTP server thread-pool will be initialized on the fly if needed, or the previously initialized instance will be quickly returned otherwise.

Once you have the `TSMEngine` instance corresponding to the current thread, you can launch actions on its global object, or tune its execution.

For instance, it could be a good idea to check for the *JavaScript* VM's garbage collector:

```
function TTestServer.Process(Ctxt: THttpRequest): cardinal;
...
engine := fSMMManager.ThreadSafeEngine;
engine.MaybeGarbageCollect; // perform garbage collection if needed
...
```

We will now find out how to interact between *JavaScript* and *Delphi* code.

22.3.2. Calling Delphi code from JavaScript

In order to call some *Delphi* method from *JavaScript*, you will have to register the method.

As just stated, it is done by setting a callback within `TSMEngineManager.OnNewEngine` initialization code. For instance:

```
procedure TTestServer.DoOnNewEngine(const Engine: TSMEngine);
...
// add native function to the engine
Engine.RegisterMethod(Engine.GlobalObj, 'loadFile', LoadFile, 1);
end;
```

Here, the local `LoadFile()` method is implemented as such in native code:

```
function TTestServer.LoadFile(const This: variant; const Args: array of variant): variant;
begin
if length(Args)<>1 then
raise Exception.Create('Invalid number of args for loadFile(): required 1 (file path)');
result := AnyTextFileToSynUnicode(Args[0]);
end;
```

As you can see, this is perfectly easy to follow.

Its purpose is to load a file content from *JavaScript*, by defining a new global function named `loadFile()`.

Remember that the *SpiderMonkey* engine, by itself, does not know anything about file system, database or even DOM. Only basic objects were registered, like arrays. We have to explicitly register the functions needed by the *JavaScript* code.

In the above code snippet, we used the `TSMEngineMethodEventVariant` callback signature, marshalling variant values as parameters. This is the easiest method, with only a slight performance impact.

Such methods have the following features:

- Arguments will be transmitted from *JavaScript* values as simple *Delphi* types (for numbers or text), or as our custom *TSMVariant* type for *JavaScript* objects, which allows late-binding;
- The *This*: variant first parameter map the "callee" *JavaScript* object as a *TSMVariant* custom instance, so that you will be able to access the other object's methods or properties directly via late-binding;
- You can benefit of the *JavaScript* feature of variable number of arguments when calling a function, since the input arguments is a dynamic array of variant;
- All those registered methods are registered in a list maintained in the *TSMEngine* instance, so it could be pretty convenient to work with, in some cases;
- You can still access to the low-level *JObject* values of any the argument, if needed, since they can be trans-typed to a *TSMVariantData* instance (see below) - so you do not loose any information;
- The *Delphi* native method will be protected by the *mORMot* wrapper, so that any exception raised within the process will be catch and transmitted as a *JavaScript* exception to the runtime;
- There is also an hidden set of the FPU exception mask during execution of native code (more on it later on) - you should not bother on it here.

Now consider how you should have written the same `loadFile()` function via low-level API calls.

First, we register the callback:

```
procedure TTestServer.DoOnNewEngine(const Engine: TSMEngine);
...
// add native function to the engine
Engine.GlobalObject.DefineNativeMethod('loadFile', nsm_loadFile, 1);
end;
```

Then its implementation:

```
function nsm_loadFile(cx: PJSCContext; argc: uintN; vp: Pjsval): JSBool; cdecl;
var in_argv: PjsvalVector;
    filePath: TFileName;
begin
  TSynFPUException.ForDelphiCode;
  try
    if argc <> 1 then
      raise Exception.Create('Invalid number of args for loadFile(): required 1 (file path)');
    in_argv := JS_ARGV(cx, vp);
    filePath := JSVAL_TO_STRING(in_argv[0]).ToString(cx);
    JS_SET_RVAL(cx, vp, cx^.NewJSSString(AnyTextFileToSynUnicode(filePath)).ToJSVal);
    Result := JS_TRUE;
  except
    on E: Exception do begin // all exceptions MUST be caught on Delphi side
      JS_SET_RVAL(cx, vp, JSVAL_VOID);
      JS_Error(cx, E);
      Result := JS_FALSE;
    end;
  end;
end;
```

As you can see, this `nsm_loadFile()` function is much more difficult to follow:

- Your code shall begin with a cryptic `TSynFPUException.ForDelphiCode` instruction, to protect the FPU exception flag during execution of native code (*Delphi* RTL expects its own set of FPU exception mask during execution, which does not match the FPU exception mask expected by *SpiderMonkey*);
- You have to explicitly catch any *Delphi* exception which may raise, with a `try...finally` block, and marshal them back as *JavaScript* errors;
- You need to do a lot of manual low-level conversions - via `JS_ARGV()` then e.g. `JSVAL_TO_STRING()` macros - to retrieve the actual values of the arguments;
- And the returning function is to be marshaled by hand - see the `JS_SET_RVAL()` line.

Since the variant-based callback has only a slight performance impact (nothing measurable, when compared to the *SpiderMonkey* engine performance itself), and still have access to all the transmitted information, we strongly encourage you to use this safer and cleaner pattern, and do not define any native function via low-level API.

Note that there is an alternate JSON-based callback, which is not to be used in your end-user code, but will be used when marshalling to JSON is needed, e.g. when working with *mORMot*'s ORM or SOA features.

22.3.3. TSMVariant custom type

As stated above, the *SynSM.pas* unit defines a *TSMVariant* custom variant type. It will be used by the unit to marshal any *JSObject* instance as variant.

Via the magic of late-binding, it will allow access of any *JavaScript* object property, or execute any of its functions. Only with a slightly performance penalty, but with much better code readability than with low-level access of the *SpiderMonkey* API.

The *TSMVariantData* memory structure can be used to map such a *TSMVariant* variant instance. In fact, the custom variant type will store not only the *JSObject* value, but also its execution context - i.e. *JSContext* - so is pretty convenient to work with.

For instance, you may be able to write code as such:

```
function TMyClass.MyFunction(const This: variant; const Args: array of variant): variant;
var global: variant;
begin
  TSMVariantData(This).GetGlobal(global);
  global.anotherFunction(Args[0],Args[1],'test');
  // same as:
  global := TSMVariantData(This).SMObject.Engine.Global;
  global.anotherFunction(Args[0],Args[1],'test');
  // but you may also write directly:
  with TSMVariantData(This).SMObject.Engine do
    Global.anotherFunction(Args[0],Args[1],'test');
  result := AnyTextFileToSynUnicode(Args[0]);
end;
```

Here, the *This* custom variant instance is trans-typed via *TSMVariantData(This)* to access its internal properties.

22.3.4. Calling JavaScript code from Delphi

In order to execute some *JavaScript* code from *Delphi*, you should first define the *JavaScript* functions to be executed.

This shall take place within *TSMEngineManager.OnNewEngine* initialization code:

```
procedure TTestServer.DoOnNewEngine(const Engine: TSMEngine);
var showDownRunner: SynUnicode;
begin
  // add external JavaScript library to engine (port of the Markdown Library)
  Engine.Evaluate(fShowDownLib, 'showdown.js');
  // add the bootstrap function calling Loadfile() then showdown's makeHtml()
  showDownRunner := AnyTextFileToSynUnicode(ExeVersion.ProgramFilePath+'showDownRunner.js');
  Engine.Evaluate(showDownRunner, 'showDownRunner.js');
  ...
end;
```

This code first *evaluates* (i.e. "executes") a general-purpose *JavaScript* library contained in the *showdown.js* file, available in the sample executable folder. This is an open source library able to convert any *Markdown* markup into HTML. Plain standard *JavaScript* code.

Then we *evaluate* (i.e. "execute") a small piece of *JavaScript* code, to link the `makeHtml()` function of the just defined library with our `loadFile()` native function:

```
function showDownRunner(pathToFile){  
  var src = loadFile(pathToFile);           // call Delphi native code  
  var converter = new Showdown.converter(); // get the Showdown converted  
  return converter.makeHtml(src);           // convert .md content into HTML via showdown.js  
}
```

Now we have a new global function `showDownRunner(pathToFile)` at hand, ready to be executed by our *Delphi* code:

```
function TTestServer.Process(Ctxt: THttpRequest): cardinal;  
var content: variant;  
    FileName, FileExt: TFileName;  
    engine: TSMEngine;  
...  
if FileExt='.md' then begin  
...  
    engine := fSMManager.ThreadSafeEngine;  
...  
    content := engine.Global.showDownRunner(FileName);  
...  
end;
```

As you can see, we access the function via late-binding. Above code is perfectly readable, and we call here a *JavaScript* function and a whole library as natural as if it was native code.

Without late-binding, we may have written, accessing not the `Global` `TSMVariant` instance, but the lower level `GlobalObject`: `TSMObject` property:

```
...  
    content := engine.GlobalObject.Run('showDownRunner',[SynUnicode(FileName)]);  
...
```

It is up to you to choose which kind of code you prefer, but late-binding is worth considering.

23. Asymmetric Encryption

Adopt a mORMot

As we have seen when dealing about *Security* (page 545), the framework offers built-in encryption of the content transmitted between its REST client and server sides, especially via *Custom Encodings* (page 334), or HTTPS. The later, when using TLS 1.2 and proven patterns, implements state-of-the-art security. But default *mORMot* encryption, even if using proven algorithms like AES256-CFB and SHA256, uses symmetric keys, that is the same secret key is shared on both client and server sides.

Asymmetric encryption, also known as public-key cryptography, uses pairs of keys:

- *Public* keys that may be disseminated widely;
- Paired with *private* keys which are known only to the owner.

The framework features a full asymmetric encryption system, based on *Elliptic curve cryptography* (ECC), which may be used at application level (i.e. to protect your application data), or at transmission level (to enhance communication safety).

23.1. Public-key Cryptography

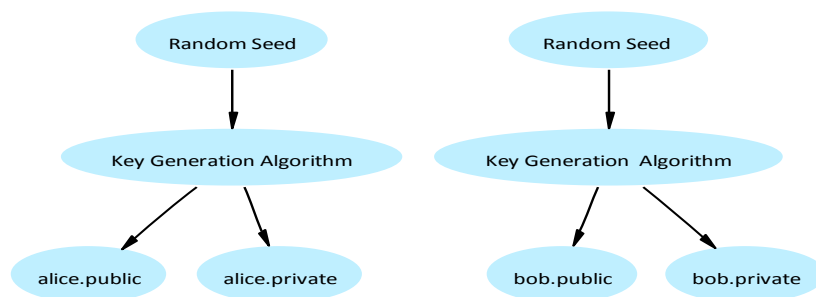

Once you have *generated* a public/private pairs of keys, you can perform two functions:

- *Authenticate* a message originated with a holder of the private key; a *certification* system should be used to maintain a trust chain of authority;
- *Encrypt* a message with a public key to ensure that only the holder of the paired private key can decrypt it.

23.1.1. Keys Generation and Distribution

First process is to generate a pair of public/private keys. Some random number generator, probably based on an external entropy source, will gather unpredictable numbers, which will be consumed by a public-key algorithm to generate the actual set of keys. This step usually requires some computing powers, due to the complexity of the algorithms involved, and the encryption needed for storing the private key in secret.

Let's explain how it works for the classic Alice/Bob scheme:

Asymmetric Key Generation

Now we have two pairs of keys:

- `alice.public` and `alice.private` for Alice;
- `bob.public` and `bob.private` for Bob.

By design, *public* keys (`alice.public` and `bob.public`) can be published, via mail, in application settings, as unprotected file, or even on a public server. On the contrary, *private* keys (`alice.private` or `bob.private`) should remain as secret as possible, and are usually encrypted, then stored in password-protected files, in some safe place of the operating system, or even dedicated hardware.

In practice, Alice will send her `alice.public` key to Bob, so that:

- Bob can verify the digital signature of a message sent by Alice, who signed it with her `alice.private` key;
- Bob can encrypt some information with the known `alice.public` key, then send it to Alice - and that only Alice could decrypt it using her `alice.private` key.

Of course, since Bob has his own set of keys, he also publishes his `bob.public` key, so that:

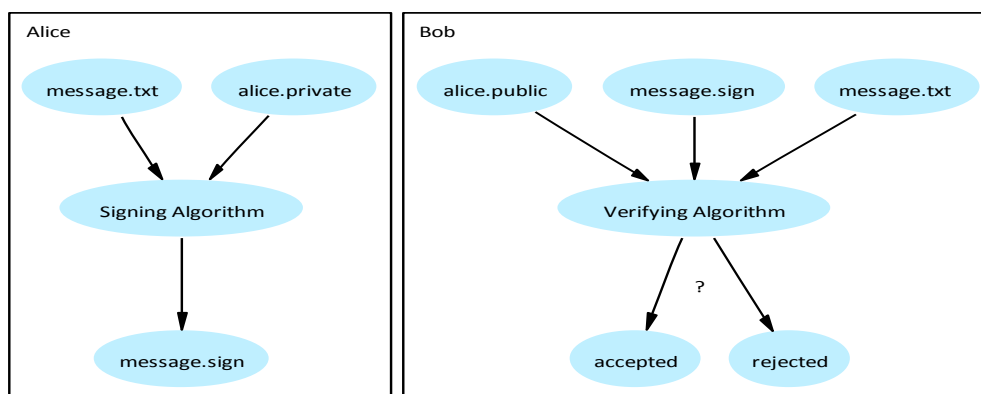

- Alice can verify the digital signature of a message sent by Bob, who signed it with his `bob.private` key;
- Alice can encrypt some information with the known `bob.public` key, then send it to Bob - and that only Bob could decrypt it using his `bob.private` key.

Key distribution is an important part of any asymmetric encryption scheme. The whole security chain

is as secure as its weakest link, so the secrecy of the private keys requires as most attention as possible. Every software solution using security will probably require external audits, at least peer review, to validate each implementation.

23.1.2. Message Authentication

Any kind of message (most probably a file or a memory buffer) can be authenticated using *digital signatures*, using the private key of the sender. Then, on the other side, the receiver can verify the message signature, using the public key of the sender.

Asymmetric Digital Signature

As you can see, if Bob believes that the `alice.public` file comes from Alice, he can assume that the `message.txt` content has really been sent by Alice. Most of the time, in such simple scenarios, Alice probably gave directly her `alice.public` file to Bob, for instance via an email. But for most complex scenarios, like the Client/Server solutions which can be built using the *mORMot* framework, the multiplicity of nodes, and therefore keys, induces a potential risk.

23.1.3. Certificates and Public Key Infrastructure

A central problem with the use of public-key cryptography is confidence that a particular public key is authentic, in that it belongs to the person or entity claimed, and has not been tampered with or replaced by a malicious third party. Digital signature is more than just creating a hash of some content, or applying some kind of "seal" on it: validation should be done against some reference public keys, which are hosted into a *public-key infrastructure* (PKI). One or more third-parties, aka certification authorities (CA), certify ownership of key pairs, by supplying some online service and/or local safe storage of reference public keys, but keeping their own private keys secret. Any certificate authority could sign a message with his private key, or even delegate his own authority to another certification instance, by signing the intermediate authority with his private key. If one certificate is compromised - i.e. if its private key has been released - the whole chain of trust is broken, and all dependent certificates should be immediately revoked.

In practice, when a public certificate key is generated in such a trusted PKI system, it will contain:

- The genuine public key material, depending on the underlying algorithm used;
- Some ownership information (i.e. who emitted it);
- The scope of the certification (may apply to a user, a company, a web site, an application...);
- A certified link to one or several other certificates, signed with their private key to prove their authenticity using the known public key of the CA chain;
- Optional validity and revocation dates - since it is a good practice to renew certificates on a regular

basis.

The private key store may also contain the very same set of information, added to its private key material. It will enforce consistency between public and private keys - for instance, you won't be fooled by using a private key after its associated public certificates expired.

Certification authorities create a chain of trust, used as reference to authenticate public keys. Every Operating System, or Internet browser do contain some root certificates, and the whole Internet security (HTTPS/TLS) is governed by such a PKI. Of course, for your own set of applications or products, you can create your own key chain, keeping the same principles - mainly private key secrecy and trust chain management.

23.1.4. Message encryption

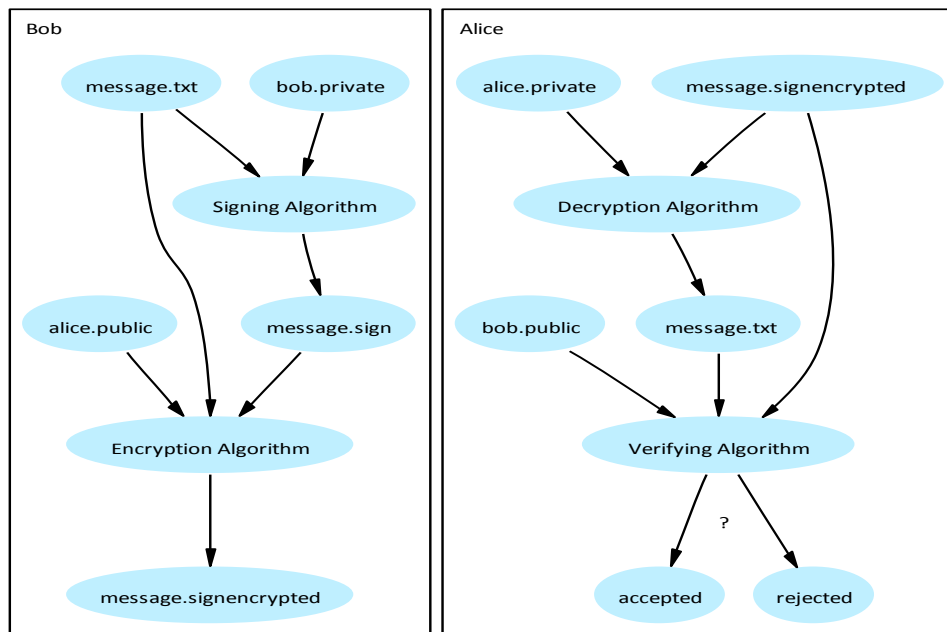

A naive approach of hiding a message content is by using a secret key or pattern, then apply it on the message. It has been done since ages, and will be safe as much as the symmetric key is safe. As a side effect, you have to trust the receiver not to spread the key to the public - and in fact, you shouldn't: don't trust anyone, even not you!

Public-key cryptography solves this problem by using a public key to encrypt a message, which will therefore only be decryptable by someone knowing the corresponding secret key.

Asymmetric Encryption Scheme

Of course, you can not only encrypt the message, but also sign it, using the other end public key. Here is how a sign-then-encrypt pattern can be implemented:

Asymmetric Sign-Then-Encrypt Scheme

As always, the `alice.public` and `bob.public` keys are validated against the trust chain of certificates of a *public-key infrastructure* (PKI).

With all this elements, we can now apply them to our *mORMot* applications.

23.2. Elliptic Curve Cryptography

The framework features an implementation of *Elliptic Curve Cryptography* (ECC), based on the mathematical structure of the "elliptic curve discrete logarithm problem". The mathematical community has not made any major progress in improving algorithms to solve this problem since it was independently introduced by Koblitz and Miller in 1985. In short, the public key is an equation for an elliptic curve and a point that lies on that curve. The private key is a number. Thanks to the symmetry of the elliptic curve, there is some kind of symmetry also between ECC public and private key values, and ECDSA and ECDH algorithms capitalize on this characteristic to compute a digital signature or a shared secret.

In comparison to the RSA algorithm, ECC has some advantages:

- Smaller key size, for the same level of safety (a 256-bit elliptic curve key is comparable to a 3072-bit RSA key);
- Well endorsed by most certification authorities (NIST/NSA);
- Faster performance, especially when the key size increases;
- Offers perfect forward secrecy, since a fresh key is created for every encryption;
- Potentially less patents infringement, in all its practical appliances;
- Last but not least, it is one the strongest algorithms for the future of web.

There will no doubt be criticism of our decision to re-implement a whole public-key cryptography stack from scratch, with its own small choice of algorithms, instead of using an existing library (like OpenSSL), and established standards (like X509).

To be fair, such libraries are complex and confusing, whereas we selected a set of future-proof algorithms (AES256 excluding ECB, HMAC-SHA256, PBKDF2_HMAC_SHA256, ECDSA, ECIES...) to follow *mORMot*'s KISS and DRY principles, keep code maintainable and readable, and reduce risk assessment scope. We followed all identified best practices, and tried to avoid, from the beginning, buffer overflows, weak protocols, low entropy, low default values, serial collision, forensic vulnerabilities, hidden memory copies, evil optimizations. The last thing we want to do is to start mandating DLLs, which are perhaps deprecated/unsafe if part of the OS. Last but not least, it was fun, we learned a lot, and we hope you will enjoy using it, and contribute to it!

23.2.1. Introducing SynEcc

The *mORMot*'s SynEcc.pas unit implements full ECC computation, using secp256r1 curve, i.e. NIST P-256, or OpenSSL's prime256v1. The low-level computation is done in optimized C code - from the <https://github.com/esxgx/easy-ecc..> Open Source project - and is statically linked in your Windows or Linux executable: i.e. no external .dll/.so library is needed. On targets (e.g. BSD/MacOSX or ARM) where we didn't provide the static .o files, there is an optimized pascal version available. Then we defined a feature-rich set of object pascal classes on top of this solid ECC ground, to include certificates, safe storage of private keys, JSON publication of public keys, as an integrated toolset.

All needed low-level asymmetric cryptography is available:

- ECC key generation, using SynCrypto.pas's secure TAESPRNG as random seed;
- ECDSA signature and verification of 256-bit hashes;
- ECDH shared secret computation - suitable for ECIES encryption, after PBKDF2_HMAC_SHA256 derivation.

The very same SynEcc.pas unit defines some high-level classes and structures, ready to implement:

- Authority certificates - via public TECCCertificate and private TECCCertificateSecret classes, and full PKI chaining - see TECCCertificateChain;

- Digital signature of files or memory buffers - via `TECCSignatureCertified`;
- Encryption of files or memory buffers - calling `TECCCertificate.Encrypt` and `TECCCertificateSecret.Decrypt` methods;
- Innovative `.cheat` files generation, for safe storage of private keys passwords, encrypted from a master `cheat.public` key and its master password.

You are free to use those classes, in your programs, whenever some advanced cryptography is needed - and it will eventually be the case, trust me! A command-line ECC tool has also been developed, for convenient operation on files.

23.2.2. ECC command line tool

You will find in the `SQLite3\Samples\33 - ECC` folder the source code of the `ECC.dpr` console project. Just compile it into an executable, accessible from your command line prompt. Or download an already compiled version from <https://synopse.info/files/ecc.7z..>

It works with no problem under Windows, or Linux, with no external dependency (e.g. no *OpenSSL* needed), so could be used in an automated server infrastructure. No need to deploy a complex PKI system, just manage your certificates, encryption and signature details, via a single command line tool.

If you run it without argument, you will get simple help information (here is the list at the time of this writing, your own version may differ):

```
>ecc

Synopsis ECC certificate-based public-key cryptography
-----
Using mORMot's SynECC rev. 1.18.3112

ECC help
ECC new -auth key.private -authpass authP@ssw0rd -authrounds 60000
        -issuer toto@toto.com -start 2016-10-30 -days 30

ECC cheat -auth key.private -authpass MasterP@ssw0RD@ -authrounds 100000
```

Note that you can add the `-noprompt` switch for no console interactivity.

As you can see, the action is defined by a keyword, at first place (`new sign verify source...`). Then some optional parameters, in form of `-key value` pairs, can be supplied. If no parameter is specified, the ECC console application will prompt for input, with user-friendly questions, and adequate default values.

You can define the `-noprompt` switch to force no console interaction at all, therefore allowing

automated use from another process, or batch file. The `ECCProcess.pas` unit publishes all high-level commands of the ECC tool, so could be reused in your own setup or maintenance projects.

We will now use this ECC tool to show most common features of the `SynEcc` unit, but also showing the code corresponding to each action.

23.2.3. Keys and Certificates Generation

The first step is to create a new key pair, which will contain their own certification information:

```
>ecc new
Enter the first chars of the .private file name of the signing authority.
Will create a self-signed certificate if left void.
Auth:

Enter Issuer identifier text.
Will be truncated to 15-20 ascii-7 chars.
Issuer [arbou] :

Enter the YYYY-MM-DD start date of its validity.
0 will create a never-expiring certificate
Start [2016-09-23] :

Enter the number of days of its validity.
Days [365] :

Enter a private PassPhrase for the new key (at least 8 chars long).
Save this in a safe place: if you forget it, the key will be useless!
NewPass [#weLHn5E.Qfe] :

Enter the PassPhrase iteration round for the new key (at least 1000).
The higher, the safer, but will demand more computation time.
NewRounds [60000] :
```

```
Corresponding TSynPersistentWithPassword.ComputePassword:
  encryption ErHdwro/8jFsCZC
  authMutual 5qMgx6Miv+O71+VYL95zk6U2wP791KL3s1BFnd+a
  authServer 5qMhx6Miv+O71+VYL95zk6U2wP791KL3s1BFnd+a
  authClient 5qMix6Miv+O71+VYL95zk6U2wP791KL3s1BFnd+a
```

```
8BC90201EF55EE34F62DBA8FE8CF14DC.public/.private file created.
```

Here we keep the default values, including the safe generated password (`#weLHn5E.Qfe`). You should write down this password in a safe place, because it will be required for any use of the private key, e.g. when signing or decrypting a message. If you forget about this password, there will be no way of accessing this private key any more - you have been warned!

We will see below (page 588) how enabling the ECC cheat mode may help storing the generated `.private` key passwords in a `.cheat` encrypted local file using a `cheat.public` key, to safely recover a password, from a master `cheat.private` key and its associated password.

The last line contains the *identifier* (or serial) of the generated key. This hexadecimal value (`8BC90201EF55EE34F62DBA8FE8CF14DC`) will be used externally to identify the key, and internally (within other certificates) to map this particular key. Note that you do not need to type all the characters of the serial in the ECC tool: only the first characters are enough (e.g. `8BC9`), as soon as they identify one unique file in the current folder.

You can check the generated files in the current folder:

```
>dir *.p*
23/09/2016 13:46          2 320 8BC90201EF55EE34F62DBA8FE8CF14DC.private
```

23/09/2016 13:46 544 8BC90201EF55EE34F62DBA8FE8CF14DC.public

The .private is some raw binary content, encrypted using the #weLHn5E.Qfe password.
The .public file, on the contrary, is stored as a plain JSON object:

```
{
  "Version": 1,
  "Serial": "8BC90201EF55EE34F62DBA8FE8CF14DC",
  "Issuer": "arbou",
  "IssueDate": "2016-09-23",
  "ValidityStart": "2016-09-23",
  "ValidityEnd": "2017-09-23",
  "AuthoritySerial": "8BC90201EF55EE34F62DBA8FE8CF14DC",
  "AuthorityIssuer": "arbou",
  "IsSelfSigned": true,
  "Base64": "AQA1ADUAogGLyQIB71XuNPYtuo/ozxTcGrOdGAAAAAAAAAAAAAAAAAAIvJAgHvVe409i26j+jPFNwas40AAA
AAAAAAAAAAAAAAAAAqjxQhWz5NjFLoWBSqvWyywne8ncNVSi/MmnVg+IZ4WknxoNvAia6oBBhC/tpo3zTjUQDssB8AId+/QR
SF15RccuOy/j/ebeqX6qxANtZEZ03dT/sWBUjQy/CYIVQe5TSDZy5pQAAAAA"
}
```

You can see all information stored in a TECCCertificate instance. The "Base64" field is in fact a raw serialization of the whole content, so its string value contains all information of a public certificate, e.g. in application settings.

We did not specify any authority at the first Auth: prompt. As a result, this key pair will be a *self-signed* certificate - see the "IsSelfSigned": true field in the above JSON, and that "Serial" and "AuthoritySerial" identifiers do match. We will use it as *root certificate* to create a certificate chain.

All further certificates will eventually be signed by this root authority.
For instance:

```
>ecc new
Enter the first chars of the .private file name of the signing authority.
Will create a self-signed certificate if left void.
Auth: 8

Will use: 8BC90201EF55EE34F62DBA8FE8CF14DC.private

Enter the PassPhrase of this .private file.
AuthPass: #weLHn5E.Qfe

Enter the PassPhrase iteration rounds of this .private file.
AuthRounds [60000] :

Enter Issuer identifier text.
Will be truncated to 15-20 ascii-7 chars.
Issuer [arbou] : toto

Enter the YYYY-MM-DD start date of its validity.
0 will create a never-expiring certificate.
Start [2016-09-23] : 0

Enter a private PassPhrase for the new key (at least 8 chars long).
Save this in a safe place: if you forget it, the key will be useless!
NewPass [b3dEB+DW8BJd] :

Corresponding TSynPersistentWithPassword.ComputePassword:
cIK5hkjDu5/98mwm

Enter the PassPhrase iteration round for the new key (at least 1000).
The higher, the safer, but will demand more computation time.
NewRounds [60000] :
```

```
03B8865C6B982A39E9EFB1DC1A95D227.public/.private file created.
```

As you can see, we entered just 8 for the first Auth: prompt, and the tool identified the single 8*.private file in the current folder. Then we entered its associated #weLHn5E.Qfe password - any wrong password would have broken the generation. This authority will never expire by itself (we entered 0 as Start: prompt) - but since its root certificate has an expiration date, it will expire when the root expires.

Now we can see the two sets of keys:

```
>dir *.p*
23/09/2016  14:27          2 320 03B8865C6B982A39E9EFB1DC1A95D227.private
23/09/2016  14:27          524 03B8865C6B982A39E9EFB1DC1A95D227.public
23/09/2016  13:46          2 320 8BC90201EF55EE34F62DBA8FE8CF14DC.private
23/09/2016  13:46          544 8BC90201EF55EE34F62DBA8FE8CF14DC.public
```

The newly created .public file contains:

```
{
  "Version": 1,
  "Serial": "03B8865C6B982A39E9EFB1DC1A95D227",
  "Issuer": "toto",
  "IssueDate": "2016-09-23",
  "ValidityStart": "",
  "ValidityEnd": "",
  "AuthoritySerial": "8BC90201EF55EE34F62DBA8FE8CF14DC",
  "AuthorityIssuer": "arbou",
  "IsSelfSigned": false,
  "Base64": "AQA1AAAAAADuIZca5gqQenvsdwaldInhiGAAAAAAAAAAAAAAAAAAIvJAgHvVe409i26j+jPFNwas40AAAA
AAAAAAAAAAAAAAAA2rPT7XPmCH6xIt3+710FFYVAPBPWhcsR6uwYoynrdqNI7557iYC7qLrFKPg6EmEENX4Vw0tEexu309SJ
OAG/EHau0BtwoqZBNhJEiUyGqKa0ioMwasbKtjJBNMfX7EMIsnxn4AAAAA"
}
```

You can recognize the expected values of "Serial", "AuthoritySerial" and "IsSelfSigned" fields.

We could create a *certificates chain* of all available keys in the current folder, by running:

```
>ecc chainall
chain.ca file created.
```

The chain.ca file is a JSON object, containing all public information of the whole certificates chain, with the "PublicBase64" JSON array ready to be copied and pasted in your applications settings or source, then used via the TECCCertificateChain class:

```
{
  "PublicBase64":
  [
    "AQA1AAAAAA...",
    "AQA1ADUAog..."
  ],
  "Items":
  [
    {
      "Version": 1,
      "Serial": "03B8865C6B982A39E9EFB1DC1A95D227",
      "Issuer": "toto",
      "IssueDate": "2016-09-23",
      "ValidityStart": "",
      "ValidityEnd": "",
      "AuthoritySerial": "8BC90201EF55EE34F62DBA8FE8CF14DC",
      "AuthorityIssuer": "arbou",
      "IsSelfSigned": false
    },
    {
      "Version": 1,
      "Serial": "8BC90201EF55EE34F62DBA8FE8CF14DC",

```

```
"Issuer": "arbou",
"IssueDate": "2016-09-23",
"ValidityStart": "2016-09-23",
"ValidityEnd": "2017-09-23",
"AuthoritySerial": "8BC90201EF55EE34F62DBA8FE8CF14DC",
"AuthorityIssuer": "arbou",
"IsSelfSigned": true
}
],
"Count": 2,
}
```

In the above sample, we cut down the "PublicBase64" values, to save some paper and trees. They map the content already shown in the .public JSON files. In fact, the same information is stored two times: once in "PublicBase64", and another time in each individual properties ("Version", "Serial", "Issuer"...) of the "Items" items.

An easy way of keys management is to keep a safe mean of storage (e.g. a pair of USB pen-drives, with at least one kept in a physical vault), then put all your certificate chains in dedicated folders. All public keys - i.e. *.public and chain.ca files - are meant to be public, so could be spread away everywhere. Just keep an eye on your .private files, and their associated passwords. A hardware-secured drive may be an overkill, since the .private files are already encrypted and password-protected with state-of-the-art software protection, i.e. AFSplit anti-forensic diffusion and AES256-CFB encryption on a PBKDF2_HMAC_SHA256 derived password, with a huge number of rounds (60000).

Remember that often, the weakest link of the security chain is between the chair and the keyboard, not within the computer. Do not reuse passwords between keys, and remember you have a "rekey" command available on the ECC tool, so that you can change a private key password, without changing its content, nor re-publish its associated .public key:

```
>ecc rekey
Enter the first chars of the .private certificate file name.
Auth: 8

Will use: 8BC90201EF55EE34F62DBA8FE8CF14DC.private

Enter the PassPhrase of this .private file.
AuthPass: #weLHn5E.Qfe

Enter the PassPhrase iteration rounds of this .private file.
AuthRounds [60000] :

Enter a NEW private PassPhrase for the key (at least 8 chars long).
Save this in a safe place: if you forget it, the key will be useless!
NewPass [mPy3kjWHE@LK] :

Corresponding TSynPersistentWithPassword.ComputePassword:
f+Gk8GGCqICA8GoJ

Enter the NEW PassPhrase iteration round for the key (at least 1000).
The higher, the safer, but will demand more computation time.
NewRounds [60000] :

8BC90201EF55EE34F62DBA8FE8CF14DC.private file created.
```

From now on, the root certificate will expect mPy3kjWHE@LK as keyphrase, for accessing its .private content. For instance (using only command line switches including the -noprompt option), you can now write:

```
>ecc infopriv -auth 8B -pass mPy3kjWHE@LK -noprompt
{
```

```
"Version": 1,  
"Serial": "8BC90201EF55EE34F62DBA8FE8CF14DC",  
"Issuer": "arbou",  
"IssueDate": "2016-09-23",  
"ValidityStart": "2016-09-23",  
"ValidityEnd": "2017-09-23",  
"AuthoritySerial": "8BC90201EF55EE34F62DBA8FE8CF14DC",  
"AuthorityIssuer": "arbou",  
"IsSelfSigned": true,  
"Base64": "AQA1ADUAogG..."  
}
```

Here, the "Base64": field only contains the public key information, not the private key content, which is kept secret and never serialized as JSON.

23.2.4. TECCCertificate and TECCCertificateSecret

As reference, here is how creating a new certificate is implemented in the ECC tool, and its .private/.public files generated, using TECCCertificateSecret class:

```
function ECCCommandNew(const AuthPrivKey: TFileName;  
  const AuthPassword: RawUTF8; AuthPasswordRounds: integer;  
  const Issuer: RawUTF8; StartDate: TDateTime; ExpirationDays: integer;  
  const SavePassword: RawUTF8; SavePassordRounds, SplitFiles: integer): TFileName;  
var auth,new: TECCCertificateSecret;  
begin  
  if AuthPrivKey='' then  
    auth := nil else  
    auth :=  
TECCCertificateSecret.CreateFromSecureFile(AuthPrivKey,AuthPassword,AuthPasswordRounds);  
  try  
    // generate pair  
    new := TECCCertificateSecret.CreateNew(auth,Issuer,ExpirationDays,StartDate);  
    try  
      // save private key as .private password-protected binary file  
      new.SaveToSecureFiles(SavePassword, '.',SplitFiles,64,SavePassordRounds);  
      // save public key as .public JSON file  
      result := ChangeFileExt(new.SaveToSecureFileName,ECCCERTIFICATEPUBLIC_FILEEXT);  
      ObjectToJSONFile(new,result);  
    finally  
      new.Free;  
    end;  
  finally  
    auth.Free;  
  end;  
end;
```

See the SynEcc.pas unit API reference, especially the TECCCertificateChain and TECCCertificateChainFile classes, which allow to store a certificate chain as JSON files or as a JSON array of base-64 encoded strings in your settings, using these constructors:

```
constructor CreateFromJson(const json: RawUTF8);  
constructor CreateFromArray(const values: TRawUTF8DynArray);
```

You can use the "source" command of the ECC tool to generate some pascal constant source code, containing an encrypted private key, ready to be embedded to your executable. For instance:

```
>ecc source -auth 8 -pass mPy3kjWHE@LK -const MY_PRIV -noprompt  
Will use: 8BC90201EF55EE34F62DBA8FE8CF14DC.private  
  
8BC90201EF55EE34F62DBA8FE8CF14DC.private.inc file created.
```

When you look at the .private.inc generated file, you can directly use it in your source code, via copy and paste:

```
const
```

```
MY_PRIV: array[0..255] of byte = (
  $C3,$31,$17,$48,$35,$B6,$30,$AA,$87,$ED,$AE,$DF,$84,$29,$AA,$85,
  $8D,$BF,$A0,$05,$92,$7F,$6C,$47,$66,$D7,$23,$B3,$5B,$4C,$42,$97,
  $5B,$07,$73,$3B,$FE,$FA,$BE,$A7,$96,$9B,$F9,$1D,$84,$CC,$6E,$F0,
  $C9,$A1,$A7,$2A,$24,$8D,$4A,$B3,$F3,$B3,$89,$52,$70,$46,$83,$84,
  $5D,$FD,$E7,$E9,$C3,$D9,$DC,$07,$C1,$FF,$82,$F8,$78,$45,$BF,$18,
  $CA,$F7,$EE,$8E,$A3,$42,$0D,$0B,$35,$2F,$20,$4A,$65,$82,$4A,$78,
  $C4,$41,$19,$0E,$98,$77,$7D,$81,$58,$DB,$04,$C9,$52,$2E,$5F,$07,
  $CF,$44,$34,$93,$1B,$FD,$00,$38,$E0,$E7,$DC,$3A,$AC,$CB,$14,$73,
  $B2,$E0,$13,$BE,$84,$79,$F7,$55,$8A,$12,$4F,$9A,$09,$97,$CC,$9B,
  $8E,$7C,$04,$92,$93,$24,$73,$50,$41,$B3,$92,$54,$D7,$66,$05,$4A,
  $3E,$4F,$D4,$1B,$94,$71,$AA,$04,$29,$42,$B3,$57,$B0,$F3,$24,$74,
  $19,$8E,$BA,$52,$FA,$D6,$56,$99,$7B,$73,$1B,$D0,$8B,$3A,$95,$AB,
  $94,$63,$C2,$C0,$78,$05,$9C,$8B,$85,$B7,$A1,$E3,$ED,$93,$27,$18,
  $F6,$DD,$87,$D7,$E9,$35,$74,$01,$2E,$35,$DF,$1A,$6E,$FA,$4A,$3F,
  $E3,$70,$19,$A3,$D7,$E3,$39,$37,$59,$15,$43,$B2,$F4,$36,$B5,$64,
  $D6,$BF,$75,$12,$6B,$C5,$89,$95,$2D,$E5,$70,$64,$EB,$70,$98,$9D);
MY_PRIV_LEN = SizeOf(MY_PRIV);
MY_PRIV_ROUNDS = 100;
MY_PRIV_SERIAL = '8BC90201EF55EE34F62DBA8FE8CF14DC';
MY_PRIV_PASS = 'Oute?/I#JSxL0VcLeR/HY(yr';
MY_PRIV_CYPH = '2R3VSFXfikiNaKTM3MqbTlw+PiMBwshk';
```

With these classes, you have everything needed to implement your own private and secure PKI logic in your client/server applications.

23.2.5. File Signature

Starting from those two text files:

```
>dir test*.*
19/09/2016 21:46          94 161 test1.txt
05/09/2016 10:37          72 209 test2.txt
```

In order to sign test1.txt, as proposed in *Asymmetric Digital Signature* (page 574), we will run the following command:

```
>ecc sign -file test1.txt
Enter the first chars of the .private file name of the signing authority.
Auth: 8B

Will use: 8BC90201EF55EE34F62DBA8FE8CF14DC.private

Enter the PassPhrase of this .private file.
Pass: mPy3kjWHE@LK

Enter the PassPhrase iteration rounds of this .private file.
Rounds [60000] :

test1.txt.sign file created.
```

As you can see, a new .sign file appeared:

```
>dir test*.*
19/09/2016 21:46          94 161 test1.txt
24/09/2016 16:24          369 test1.txt.sign
05/09/2016 10:37          72 209 test2.txt
```

It is a simple JSON object, with some information about the associated test1.txt file:

```
{
  "meta": {
    "name": "test1.txt",
    "date": "2016-09-19T21:46:24"
  },
  "size": 94161,
```

```
}
  "md5": "e80f2bf959c943e240f2c1f5efcf1e89",
  "sha256": "6bc2d25e9cc93201914e7c6588624696778de80c6f63a590262ccf610310ea0e",
  "sign": "AQA2AIvJAghVVe409i26j+jPFNwas40AAAAAAAAAAAA..."
}
```

In addition to some general information (name, date, size), you have unsigned hashes ("md5" and "sha256"), and an ECC digital signature, stored as a base-64 encoded string in the "sign": field. This signature has been computed using the 8BC90201EF55EE34F62DBA8FE8CF14DC.private key, and the SHA256 hash of the test1.txt file content. Note that you can add whatever JSON field you need to any .sign file, especially in the "meta": nested object, as soon as you don't modify the size/md5/sha256/sign values.

To verify the file, ensure that both test1.txt and test1.txt.sign files are in the current directory, then run:

```
>ecc verify -file test1.txt
test1.txt file verified as valid self signed.
```

Since the 8BC90201EF55EE34F62DBA8FE8CF14DC.private key has been signed using itself as authority, it is reported as "valid self signed". A signature verified against a certificate itself issued from another authority would have returned "valid signed".

Now if you modify test1.txt, e.g. changing one character, the verification will fail:

```
>ecc verify -file test1.txt
test1.txt file verification failure: invalid signature (9).
```

Don't forget to fix the test1.txt content back, since we will use it now as encryption source.

To check that you reverted to the original file content, run:

```
>ecc verify -file test1.txt
test1.txt file verified as valid self signed.
```

23.2.6. Signing in Code

From the source code point of view, you can easily add asymmetric digital signatures in your project using the TECCCertificateSecret.SignFile method, or working with memory buffer instead of files thanks to TECCCertificateSecret.SignToBase64 overloaded methods.

As reference, here is how the signing is implemented in the ECC tool:

```
function ECCCommandSignFile(const FileToSign, AuthPrivKey: TFileName;
  const AuthPassword: RawUTF8; AuthPasswordRounds: integer): TFileName;
var auth: TECCCertificateSecret;
begin
  auth := TECCCertificateSecret.CreateFromSecureFile(AuthPrivKey, AuthPassword, AuthPasswordRounds);
  try
    result := auth.SignFile(FileToSign, []);
  finally
    auth.Free;
  end;
end;
```

Verification can be done via the dedicated TECCSignatureCertified class:

```
function ECCCommandVerifyFile(const FileToVerify, AuthPubKey: TFileName;
  const AuthBase64: RawUTF8): TECCValidity;
var content: RawByteString;
  auth: TECCCertificate;
  cert: TECCSignatureCertified;
begin
  content := StringFromFile(FileToVerify);
  if content='' then
    raise ECCCException.CreateUTF8('File not found: %',[FileToVerify]);
```

```
cert := TECCSignatureCertified.CreateFromFile(FileToVerify);
try
  if not cert.Check then begin
    result := ecvInvalidSignature;
    exit;
  end;
  auth := TECCCertificate.Create;
  try
    if auth.FromAuth(AuthPubKey,AuthBase64,cert.AuthoritySerial) then
      result := cert.Verify(auth,pointer(content),length(content)) else
      result := ecvUnknownAuthority;
    finally
      auth.Free;
    end;
  finally
    cert.Free;
  end;
end;
```

Here, the signing authority is supplied as a single .public local file, loaded in a TECCCertificate instance, but your projects may use TECCCertificateChain for a full PKI authority chain.

23.2.7. File Encryption

In order to encrypt out both test files, as proposed in *Asymmetric Encryption Scheme* (page 575), we will run the following commands:

```
>ecc crypt -file test1.txt -auth 03 -saltpass monsecret -noprompt
Will use: 03B8865C6B982A39E9EFB1DC1A95D227.public

test1.txt.synecc file created.

>ecc crypt -file test2.txt -auth 03 -saltpass monsecret2 -noprompt
Will use: 03B8865C6B982A39E9EFB1DC1A95D227.public

test2.txt.synecc file created.
```

As we can see, two new .synecc encrypted files have been computed:

```
>dir test*
24/09/2016 16:36          94 161 test1.txt
24/09/2016 16:24          369 test1.txt.sign
24/09/2016 17:13         22 436 test1.txt.synecc
05/09/2016 10:37          72 209 test2.txt
24/09/2016 17:13         15 220 test2.txt.synecc
```

You may notice that the .synecc files are smaller than the original .txt files... in fact, SynEcc did recognize that the plain content was easily compressible, then applied SynLZ compression on it, before the encryption step.

If we ask for information about the test1.txt.synecc file:

```
>ecc infocrypt -file test1.txt.synecc
{
  "Date": "2016-09-24",
  "Size": 94161,
  "Recipient": "toto",
  "RecipientSerial": "03B8865C6B982A39E9EFB1DC1A95D227",
  "FileTime": "2016-09-24T16:36:59",
  "Algorithm": "ecaPBKDF2_HMAC_SHA256_AES256_CFB_SYNLZ",
  "RandomPublicKey": "038C73D421D9A7F2F7FC0F3EF62C79897D13064EF2D6FAA0DB0F246CD9B173B90",
  "HMAC": "c6bf56792e58c68c45ebdff1fbd6a3b2e4d3e95e522f41eba2ecab41fd53183b",
  "Signature": {
    "Version": 1,
    "Date": "2016-09-24",
```

```

    "AuthoritySerial": "8BC90201EF55EE34F62DBA8FE8CF14DC",
    "AuthorityIssuer": "arbou",
    "ECDA": "2AwyyNYAcfSyJW+5BzvksbSdXc0UbYNqm...."
  }
}

```

We can see the information stored in the file header, including the recipient name and .publickey identifier, and also the "PBKDF2_HMAC_SHA256_AES256_CFB_SYNLZ" algorithm, which indeed includes _SYNLZ compression. Other algorithms are available (with diverse AES chaining modes), and some new methods may be added in the future.

The ecc crypt command did also include the digital signature available in the test1.txt.sign file in the current folder - so was in fact following *Asymmetric Sign-Then-Encrypt Scheme* (page 576) - whereas test2.txt.synecc does not have any embedded signature, since there was no test2.txt.sign file available at encryption time:

```

>ecc infocrypt -file test2.txt.synecc
{
  "Date": "2016-09-24",
  "Size": 72209,
  "Recipient": "toto",
  "RecipientSerial": "03B8865C6B982A39E9EFB1DC1A95D227",
  "FileTime": "2016-09-05T10:37:50",
  "Algorithm": "ecaPBKDF2_HMAC_SHA256_AES256_CFB_SYNLZ",
  "RandomPublicKey": "03914AA67BCC92F78A9D670B2209587E3C97A3E08FD39A38B459558511F88F7651",
  "HMAC": "07ddc90f7695fff8ca0683be98f7b1043e13a7bceb79f0d6a929069c5d9767d1",
  "Signature": null
}

```

As you can see, encryption is defined by its "Algorithm": field, and uses two additional properties:

- "RandomPublicKey" which contains a genuine key generated by ecc crypt, allowing *perfect forward secrecy*, meaning that a shared secret key is computed for every encryption: if someone achieves to break the AES256-CFB secret key used to encrypt a particular .synecc file (e.g. spending lots of money in brute force search), this secret key won't be reusable for any other file: each "RandomPublicKey" value above is indeed unique for each .synecc file;
- "HMAC": which uses a safe way of message authentication - known as *keyed-hash message authentication code* (HMAC) - stronger than the hashing algorithm it is based on, i.e. SHA256 in our case.

In practice, SynEcc implements state-of-the-art *Elliptic Curve Integrated Encryption Scheme* (ECIES) using PBKDF2_HMAC_SHA256 as key derivation function, AES256-CFB as symmetric encryption scheme, and HMAC-SHA256 algorithm for message authentication.

See https://en.wikipedia.org/wiki/Integrated_Encryption_Scheme..

ECIES provides semantic security against an adversary who is allowed to use chosen-plaintext and chosen-ciphertext attacks. In addition to the expected genuine secret and message authentication in "RandomPublicKey" and "HMAC" properties, SynEcc implementation allows to customize the default "salt" value, to add a password protection for each .synecc encrypted file.

Decryption is pretty straightforward:

```

>ecc decrypt -file test1.txt.synecc
Enter the name of the decrypted file
Out [test1.txt.2] :

Enter the PassPhrase of the associated .private file.
AuthPass: b3dEB+DW8BJd

Enter the PassPhrase iteration rounds of this .private file.
AuthRounds [60000] :

```

```
Enter the optional PassPhrase to be used for decryption.  
SaltPass [salt] : monsecret
```

```
Enter the PassPhrase iteration rounds.  
SaltRounds [60000] :
```

```
test1.txt.2 file verified as valid self signed.  
test1.txt.synecc file decrypted with signature.  
test1.txt.2 file created.
```

To decrypt the second file in a single step, and no console interaction:

```
>ecc decrypt -file test2.txt.synecc -authpass b3dEB+DW8BJd -saltpass monsecret2 -noprompt  
test2.txt.synecc file decrypted.  
test2.txt.2 file created.
```

As expected, the second file didn't contain any digital signature, so there is no "test2.txt.2 file verified as valid self signed." message.

The decrypted files are available in the current folder:

```
> dir test*  
24/09/2016 16:36          94 161 test1.txt  
24/09/2016 16:36          94 161 test1.txt.2  
24/09/2016 16:24          369 test1.txt.sign  
24/09/2016 17:13          22 436 test1.txt.synecc  
05/09/2016 10:37          72 209 test2.txt  
05/09/2016 10:37          72 209 test2.txt.2  
24/09/2016 17:13          15 220 test2.txt.synecc
```

The *.2 decrypted files have the expect size (and content), after decompression. Even the file timestamp has been set to match the original.

23.2.8. Private Keys Passwords Cheat Mode

In order to follow best practice, our .private key files are always protected by a password. A random value with enough length and entropy is always proposed by the ECC tool when a key pair is generated, and could be used directly. It is always preferred to trust a computer to create true randomness (and SynCrypto.pas's secure TAESPRNG was designed to be the best possible seed, using hardware entropy if available), than using our human brain, which could be defeated by dictionary-based password attacks. Brute force cracking would be almost impossible, since PBKDF2_HMAC_SHA256 Password-Based Key Derivation Function with 60,000 rounds is used, so rainbow tables (i.e. pre-computed passwords list) will be inoperative, and each password trial would take more time than with a regular Key Derivation Function.

The issue with strong passwords is that they are difficult to remember. If you use not pure random passwords, but some easier to remember values with good entropy, you may try some tools like <https://xkpasswd.net/s..> which returns values like \$\$19*wrong*DRIVE*read*61\$\$\$. But even then, you will be able to remember only a dozen of such passwords. In a typical public key infrastructure, you may create hundredths of keys, so remembering all passwords is no option for an average human being as you and me.

At the end, you end up with using a tool to store all your passwords (last trend is to use an online service with browser integration), or - admit it - store them in an Excel document protected by a password. Most IT people - and even security specialists - end with using such a mean of storage, just because they need it.

The weaknesses of such solutions can be listed:

- How could we trust closed source software and third-party online services?

- Even open source like <http://keepass.info/help/base/security.html> may appear weak (no PBKDF, no AFSplit, managed C#, SHA as PRNG);
- The storage is as safe as the "master password" is safe;
- If the "master password" is compromised, all your passwords are published;
- You need to know the master password to add a new item to the store.

The ECC tool is able to work in "cheat mode", storing all .private key files generated passwords in an associated .cheat local file, encrypted using a cheat.public key.

As a result:

- Each key pair will have its own associated .cheat file, so you only unleash one key at a time;
- The .cheat file content is meaningless without the cheat.private key and its master password, so you can manage and store them together with your .private files;
- Only the cheat.public key is needed when creating a key pair, so you won't leak your master password, and even could generate keys in an automated way, on a distant server;
- The cheat.private key will be safely stored in a separated place, only needed when you need to recover a password;
- It uses strong *File Encryption* (page 586), with proven PBKDF, AFSplit, AES-PRNG, and ECDH/ECIES algorithms.

By default, no .cheat files are created. You need to explicitly initialize the "cheat mode", by creating master cheat.public and cheat.private key files:

```
>ecc cheatinit
Enter Issuer identifier text of the master cheat keys.
Will be truncated to 15-20 ascii-7 chars.
Issuer [arbou] :

Enter a private PassPhrase for the master cheat.private key (at least 8 chars).
Save this in a safe place: if you forget it, the key will be useless!
NewPass [uQHH*am39LLj] : verysafelongpassword

Enter iteration rounds for the mastercheat.private key (at least 100000).
NewRounds [100000] :

cheat.public/.private file created.
```

As you can see, the default number of PBKDF rounds is high (100000), and local files have been created:

```
>dir cheat.*

18/10/2016  11:12                4 368 cheat.private
18/10/2016  11:12               568 cheat.public
```

Now we will create a new key pair (in a single command line, with no console interaction):

```
>ecc new -newpass NewKeyP@ssw0rd -noprompt

Corresponding TSynPersistentWithPassword.ComputePassword:
encryption HeOyjDUAsOhvLZkMA0Y=
authMutual 100mv+8VpoFrrFfbFfiNppn1WumaIL+AN3JXEUUpCY=
authServer 100nv+8VpoFrrFfbFfiNppn1WumaIL+AN3JXEUUpCY=
authClient 100kv+8VpoFrrFfbFfiNppn1WumaIL+AN3JXEUUpCY=

D1045FCBAA1382EE44ED2C212596E9E1.public/.private file created.
```

An associated .cheat file has been created:

```
>dir D10*  
  
18/10/2016  11:15                1 668 D1045FCBAA1382EE44ED2C212596E9E1.cheat  
18/10/2016  11:15                2 320 D1045FCBAA1382EE44ED2C212596E9E1.private  
18/10/2016  11:15                588 D1045FCBAA1382EE44ED2C212596E9E1.public
```

Imagine you forgot about the NewKeyP@ssw0rd value. You could use the following command to retrieve it:

```
>ecc cheat  
  
Enter the first chars of the .private certificate file name.  
Auth: D10  
  
Will use: D1045FCBAA1382EE44ED2C212596E9E1.private  
  
Enter the PassPhrase of the master cheat.private file.  
AuthPass: verysafelongpassword  
  
Enter the PassPhrase iteration rounds of the cheat.private file.  
AuthRounds [100000] :  
  
{  
    "pass": "NewKeyP@ssw0rd",  
    "rounds": 60000  
}  
Corresponding TSynPersistentWithPassword.ComputePassword:  
encryption He0yjDUAsOhvLZkMA0Y=  
authMutual 100mv+8VpoFrrFfbBFilNppn1WumaIL+AN3JXEUUpCY=  
authServer 100nv+8VpoFrrFfbBFilNppn1WumaIL+AN3JXEUUpCY=  
authClient 100kv+8VpoFrrFfbBFilNppn1WumaIL+AN3JXEUUpCY=
```

If your .private key does not have its associated .cheat file, you won't be able to recover your password:

```
>ecc cheat  
  
Enter the first chars of the .private certificate file name.  
Auth: 8BC9  
  
Will use: 8BC90201EF55EE34F62DBA8FE8CF14DC.private  
  
Enter the PassPhrase of the master cheat.private file.  
AuthPass: verysafelongpassword  
  
Enter the PassPhrase iteration rounds of the cheat.private file.  
AuthRounds [100000] :  
  
Fatal exception EECCEException raised with message:  
Unknown file 8BC90201EF55EE34F62DBA8FE8CF14DC.cheat
```

In practice, this "cheat mode" will help you implement a safe public key infrastructure of any size. It will be as secure as the main cheat.private key file and its associated password remain hidden and only wisely spread, of course. Don't forget to use the ecc rekey command on a regular basis, so that you change the master password of cheat.private. The main benefit of this implementation is that for all key generation process, only the cheat.public key file is needed.

23.2.9. Encryption in Code

From the source code point of view, you can easily add asymmetric encryption in your project using `TECCCertificate.EncryptFile` and `TECCCertificateSecret.DecryptFile` methods, even working with memory buffers, thanks to `TECCCertificate.Encrypt` and `TECCCertificateSecret.Decrypt` methods.

As reference, here is how the encryption is implemented in the ECC tool:

```
procedure ECCCommandCryptFile(const FileToCrypt, DestFile, AuthPubKey: TFileName;  
  const AuthBase64, AuthSerial, Password: RawUTF8; PasswordRounds: integer; Algo: TECIESAlgo);  
var content: RawByteString;  
  auth: TECCCertificate;  
begin  
  content := StringFromFile(FileToCrypt);  
  if content='' then  
    raise EECCEXception.CreateUTF8('File not found: %',[FileToCrypt]);  
  auth := TECCCertificate.Create;  
  try  
    if auth.FromAuth(AuthPubKey,AuthBase64,AuthSerial) then begin  
      auth.EncryptFile(FileToCrypt,DestFile>Password,PasswordRounds,Algo,true);  
    end;  
  finally  
    auth.Free;  
    FillZero(content);  
  end;  
end;
```

You may note here the use of `FillZero()` in the finally block of the function, which is a common - and strongly encouraged - way of protecting your sensitive data from remaining in RAM, after use. Both `SynCrypto.pas` and `SynEcc.pas` code has been checked to follow similar safety patterns, and not leave any sensitive information in the program stack or heap.

23.3. Application Locking

A common feature request for professional software is to prevent abuse of published applications. For licensing or security reasons, you may be requested to "lock" the execution of programs, maybe tools or services.

mORMot can use Asymmetric Cryptography to ensure that only allowed users could run some executables, optionally with dedicated settings, on a given computer. The framework offers the first brick, on which you should build upon your dedicated system.

The `dddInfraApps.pas` unit publishes the following `ECCAuthorize` function and type:

```
type  
  TECCAuthorize = (eaSuccess, eaInvalidSecret, eaMissingUnlockFile,  
    eaInvalidUnlockFile, eaInvalidJson);  
  
function ECCAuthorize(aContent: TObject; aSecretDays: integer; const aSecretPass,  
  aDPAPI, aDecryptSalt, aAppLockPublic64: RawUTF8; const aSearchFolder: TFileName = '');  
  aSecretInfo: PECCCertificateSigned = nil; aLocalFile: PFileName = nil): TECCAuthorize;
```

This function will use several asymmetric key sets:

- A *main key set*, named e.g. `applock.public` and `applock.private`, shared for all users of the system;
- Several *user-specific key sets*, named e.g. `user@host.public` and `user@host.secret`, one for each user and associated computer host name.

When the `ECCAuthorize` function is executed, it will search for a local `user@host.unlock` file, named

after the current logged user and the computer host name. Of course, the first time the application is launched for this user, there will be no such file. It will create two local `user@host.public` and `user@host.secret` files and return `eaMissingUnlockFile`.

The *main key set* will be used to digitally *sign* the unlock file:

- `applock.public` will be supplied as plain base64-encoded `aAppLockPublic64` text parameter in the executables - for safety, you should ensure its value is not replaced by a forged one by an attacker: the executable should be signed, or at least the constant value should be checked with a CRC for its content during the program execution;
- On the contrary, `applock.private` will be kept secret - with its associated secret password.

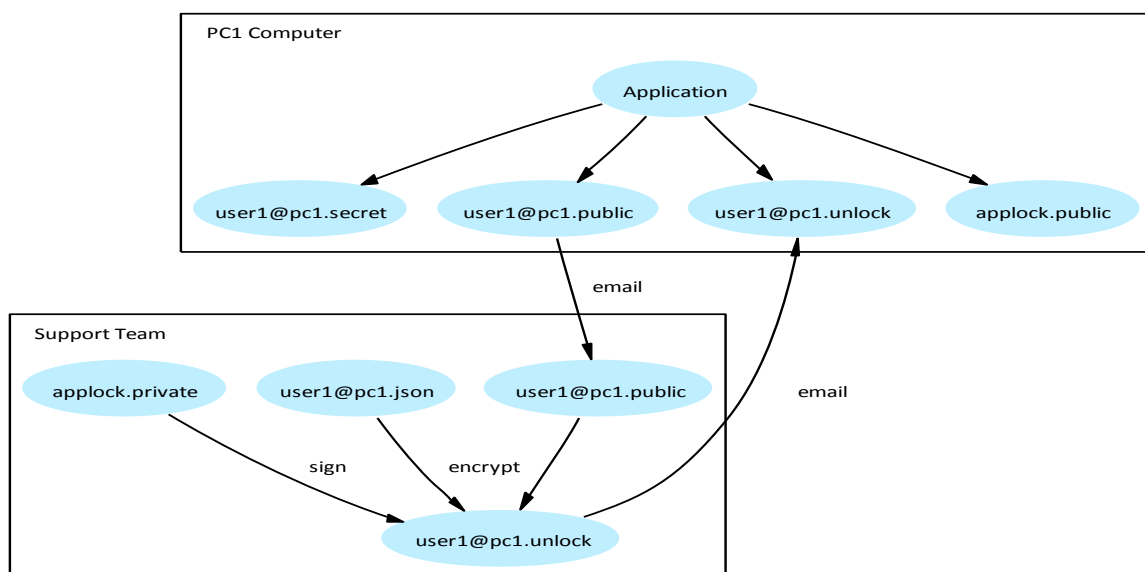

User-specific key sets will be used to *encrypt* the unlock file:

- The `user@host.secret` file contains in fact a genuine private key, encrypted using `CryptDataForCurrentUser` (i.e. DPAPI under *Windows*) for the specific computer and user: this will avoid `user@host.unlock` reuse on another computer, even if the user and host names are identical, and the `user@host.secret` file is copied. This file should remain local, and doesn't need to be transmitted.
- The `user@host.public` file will be sent to the product support team, e.g. by email - but you may setup an automated server, if needed. The support team will create a `user@host.unlock` matching this `user@host.public` key, which will unlock the application for the given user.

On the support team side, a `user@host.json` file is created for the given user, and will contain the JSON serialization of the `aContent: TObject` parameter of the `ECCAuthorize` function. This object may contain any published properties, matching the security expectations for this user, e.g. the available features or resource access.

23.3.1. From the User perspective

The resulting process is therefore the following:

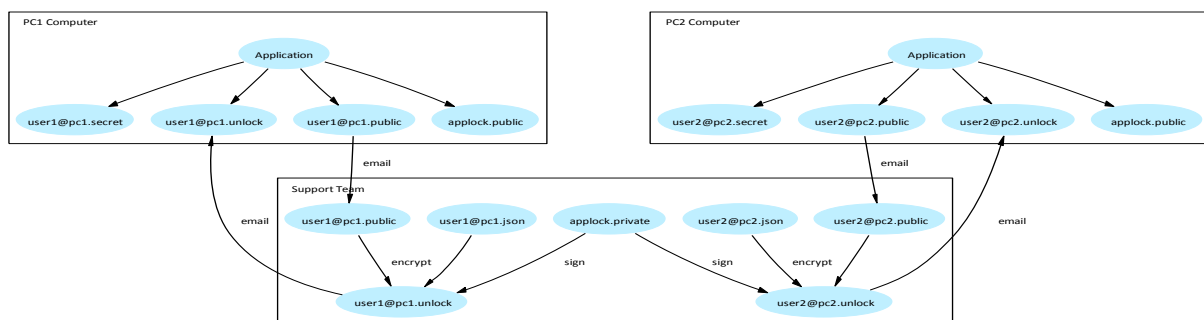

Application Unlocking via Asymmetric Cryptography

In short, every user/computer combination will have its own set of public/secret/unlock files.

- In practice, `applock.public` could be hardcoded as plain base64-encoded `aAppLockPublic64`

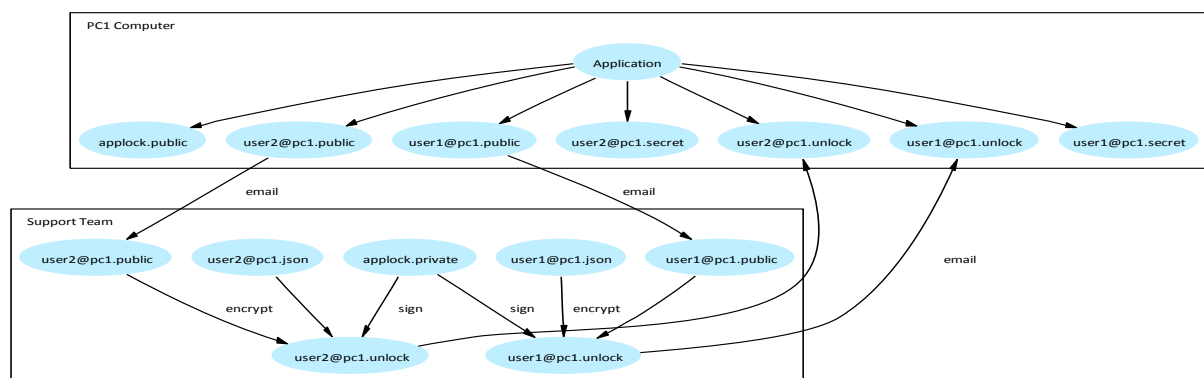

- constant string in the Application code - of course, the executable should be signed with a proper authority, to ensure this constant is not replaced by a fake value;
- The location of those local `user@host.*` files is by default the executable folder, but may be specified via the `aSearchFolder` parameter - especially if this folder is read-only (e.g. due to Windows UAC), or if you use some custom GUI for the user interactivity;
- The `user@host.json` will be signed using `applock.private` secret key, to testify that the resulting `user@host.unlock` file was indeed provided by the Support Team;
- The `user@host.json` will be encrypted using the `user@host.public` key received by email, so will be specific to a single user/computer combination.

If two users share the application on the very same computer, another set of files will appear:

Application Unlocking on Two Computers

Several users on the same computer will be handled as such:

Application Unlocking for Two Users

From the User point of view, he/she will transmit its `user@host.public` file, then receives a corresponding `user@host.unlock` file, which will unlock the application. Pretty easy to understand - even if some complex asymmetric encryption is involved behind the scene.

23.3.2. From the Support Team perspective

The Support Team will maintain a list of `user@host.public` and `user@host.json` files, one per user/computer. Both files have small JSON content, so may be stored in a dedicated folder of the project source code repository - or in a dedicated repository. The use of a source code repository allows to track user management information between several support people, including history and audit trail of this sensitive information. For safety, the `applock.private` file may not be archived in the source code repository, but copied on purpose on each support people's (or developer's) computer. A separated, and dedicated computer, may be used, for additional safety.

In fact, even developers may define their own set of `.unlock` files. For local test builds, they may use their own `applock.public` and `applock.private` key pairs, diverse from the main content.

The content of each `user@host.json` may be easily derivated from a set of reference `.json` files, acting like templates of group of users. Or an existing file may be used as source for a new user. The ability to use JSON and a text editor, with customizable object and arrays fields, allows any needed kind of licensing or security scope, depending on the application.

Since the `user@host.json` is a serialized `aContent: TObject`, you can define enumerates properties, or even schema-less structures as `TDocVariant` - see *TDocVariant custom variant type* (page 112) - to refine the authorization scope.

The `user@host.json` file is encrypted using the genuine `user@host.public` key, and its associated `user@host.secret` is strongly encrypted for the given PC and logged user: therefore, only the application is able to decipher the `user@host.unlock` content. You can let those files be transmitted via an unsafe mean of transport, e.g. plain email, with no compromising risk. Last but not least, passwords or IP addresses can be safely stored in its content, as part of the security policy of your project.

In practice, the team may use a `unlock.bat` file running the ECC tool over secret `applock.private` keys, containing the secret:

```
@echo off
echo Usage:  unlock user@host
echo.
ecc sign -file %1.json -auth applock -pass applockprivatepassword -rounds 60000
ecc crypt -file %1.json -out %1.unlock -auth %1 -saltpass decryptsalt -saltrounds 10000
del %1.json.sign
```

For safety, you may not include the `-pass applockprivatepassword` value in this `unlock.bat` file. Removing this `-pass` command-line switch will let the ecc tool prompt for the password secret key on the console:

```
ecc sign -file %1.json -auth applock -rounds 60000
```

Also note that you can use the `ecc rekey` command to customize the password of a given `applock.private` file: each support team member may have his/her custom password to run the *sign-then-encrypt* process.

Of course, if you need to create a lot of `.unlock` files, you may want to automate this process, e.g. in a server or a GUI tool, using `SynEcc.pas` classes.

23.3.3. Benefits of Asymmetric Encryption for License management

In most licensing systems, the weak point is the transmission of the licensing file. Thanks to Asymmetric Encryption, both `user@host.public` and `user@host.unlock` files can be transmitted as plain emails, without any possibility of compromising.

The `applock.private` secret key and its associated password are used to digitally sign (using ECDSA) the plain content of the `user@host.unlock` file. This *sign-then-encrypt* pattern will ensure that only your support team will be able to generate the proper `.unlock` files for a given application. The `applock.private/public` keys could have their own deprecation date.

As we have seen, the `user@host.unlock` file is encrypted, so you can use it to transmit sensitive information. Its associated `user@host.secret` key has been generated locally with an expiration date - see the `aSecretDays` parameter of the `ECCAuthorize` function. It will ensure that the registering process should be performed regularly, if the licensing or security policy expect it.

Of course, any such system is as weak as its weakest point. In particular, under Windows the executable should be digitally signed (as any professional software). You could also ensure that the `aAppLockPublic64` public key has not been replaced by a fake value forged by an attacker - e.g. by checking its value by computing its CRC in several places of your application:

```
if crc32($1239438,pointer(AppLock64),length(AppLock64))<>$ae293c10 then Close;
```

The security of this system does not rely on code obfuscation, but on proven safety of asymmetric encryption. Even if the executable is modified in-place to by-pass the license check, the fact that the application expects some additional information to be provided within the `user@host.unlock` file will make it much more difficult to hack.

As always with Open Source, any feedback is welcome, in order to enhance the safety of this system. The fact that the code is available - so that the algorithms could be proven - make it safer than any proprietary solution developed in-door.

24. Domain-Driven-Design

Adopt a mORMot

We have now discovered how *mORMot* offers you some technical bricks to play with, but it is up to you to build the house (castle?), according to your customer needs.

This is where *Domain-Driven Design* (page 99) - abbreviated DDD - patterns are worth looking at.

24.1. Domain

What do we call *Domain* here?

The domain represents a sphere of knowledge, influence or activity.

As we already stated above, the domain has to be clearly identified, and your software is expected to solve a set of problems related to this domain.

DDD is some special case of *Model-Driven Design*. Its purpose is to create a *model* of a given domain. The code itself will express the model: as a consequence, any code refactoring means changing the model, and vice-versa.

24.2. Modeling

Even the brightest programmer will never be able to convert a real-life domain into its software code. What we can do is to create an *abstraction* system that describes selected aspects of a domain.

Modeling is about *filtering* the reality, for a given use context: "All models are wrong, some are useful"
G. Box, statistician.

24.2.1. Several Models to rule them all

As first consequence, *several models may coexist* for a given reality, depending of the knowledge level involved - what we call a *Bounded Context*. Don't be afraid if the same reality is defined several times in your domain code: you should use only one class in a given context, but you may have another class defined in another context, with diverse attributes or methods.

Just open *Google maps* for instance, and think how the same reality may be modeled depending on the zoom level, or you current view options. See also the M1, M2, M3 models as defined in *Meta-Object Facility*. When you define several models, you just need to clearly state the current model you are using.

Even models could be abstracted. This is what DDD does: the code itself is some kind of *meta-model*, conforming a given conceptual model to the grammar of a given programming language.

24.2.2. The state of the model

Most models express the reality in two dimensions:

- *Static*: to abstract a given *state* of the reality;
- *Dynamic*: to abstract how reality *evolves* (i.e. its behavior).

In both dimensions, we can clearly understand the purpose of *abstraction*.

Since it is impossible to model all the details of reality (e.g. describe a physical reality down to atomic / sub-atomic level), the static modeling will *forget* the non significant details, and focus on the essentials, for a given *knowledge level*, which is specific to a given context.

Similarly, most changes are continuous in the world, but dynamic modeling will create static snapshots of the reality (called *state transitions*), to embrace the deterministic nature of computers.

State always brings complexity to the model. As a consequence, our code should be as stateless as possible.

Therefore:

- Try to always separate value and time in state;
- Reduce statefulness to the only necessary;
- Implement your logic as state machines instead of blocking code or sessions;
- Persistence should handle one-way transactions.

In DDD, *Value Objects* and *Entity Objects* are the mean to express a given system state. Immutable *Value Objects* define a static value. *Entity* refers to a given state of given identity (or reality).

For instance, the same identity (named "John Doe") may be, at a given state, single and minor, then, at another state, married and adult. The model will help to express the given states, and the state transitions between them (e.g. John's marriage).

In DDD, the *Factory / Repository / Unit Of Work* patterns will introduce transactional support in a stateless approach.

And in situations where a reality does change its state very often, with complex impacts on other components, DDD will model these state changes as *Events*. It could lead into introducing some Event-Driven Design even or Event Sourcing within the global model.

24.2.3. Composition

In order to refine your model, you have two main tools at hand to express the model modularity:

- *Partitioning*: the more your elements have a *separated concern*, the better;
- *Grouping*: to express *constraints*, elements may be grouped - but usually, you should not put more than 6 or 8 elements in the same diagram, or your model may need to be refined.

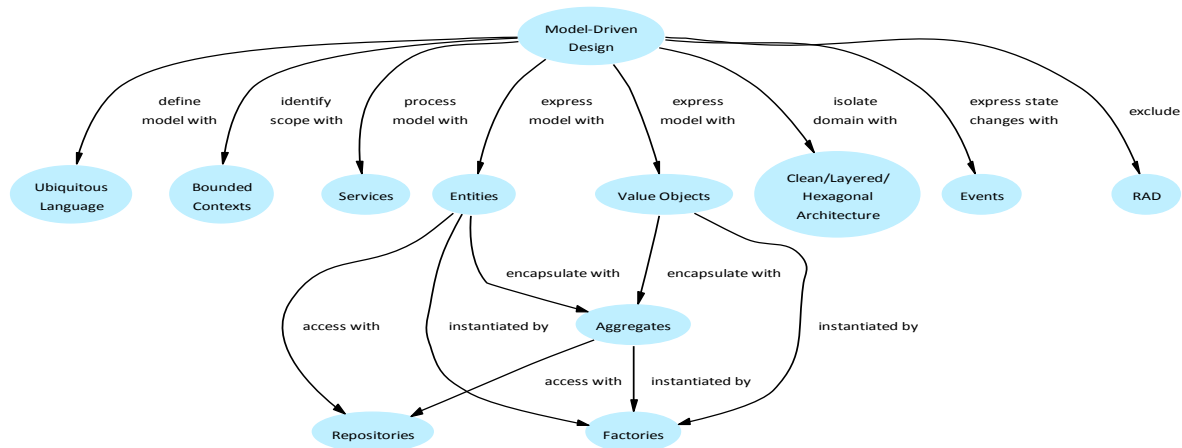

In DDD, a lot of small objects have to be defined, in order to properly *partition* the logic. When we start with Object Oriented Programming, we are tempted to create huge classes with a lot of methods and parameters. This is a symptom of a weak model. We should always favor composition of small simple objects, just like the *Unix* tools philosophy or the *Single Responsibility Principle* - see *SOLID design principles* (page 390).

Some DDD experts also do not favor inheritance. In fact, inheriting may be also a symptom of some coupled context. Having two diverse realities sharing properties may be a bad design smell: if two or more classes inherit from one parent class, the state and behavior of the parent class may limit any future evolution of any of its children. In practice, trying to follow the *Open/Closed principle* - see *Open/Closed Principle* (page 394) - at class level may induce unexpected complexity, therefore reducing code maintainability.

In DDD, the *Aggregate Root* is how you *group* your objects, in order to let constraints (e.g. business rules) to be modeled. *Aggregates* are the main entry point to the domain, since they should contain, by design, the whole execution context of a given process. Their extent may vary during development, e.g. when a business rule evolves - remember that the same reality can appear several times in the same domain, but once per Bounded Context. In other words, *Aggregates* could be seen as the smallest and biggest extent needed to express a given model context.

24.3. DDD model

It is now time to define which kind of *Model-Driven Design* is DDD:

Domain-Driven Design - Building Blocks

24.3.1. Ubiquitous Language

Ubiquitous Language is where DDD begins.

DDD expects the domain model to be expressed via a shared language, and used by all team members to connect their activities with the software. Those terms should be used in speech, writing, and any presentation or diagram.

In the real outside world, i.e. for the other 10th kind of people how do not know about binary, domain experts use company- or industry-standard terminology.

As developers, we have to understand this vocabulary and not only use it when speaking with domain experts but also see the same terminology reflected in our code. If the terms "class code" or "rate sets" or "exposure" are frequently used in conversation, we shall find corresponding class names in the code. In DDD, it is critical that developers use the business language in code consciously and as a disciplined rule. As a consequence, browsing the code should lead into a clear comprehension of the business model.

Domain experts will be the guard keepers of the consistency of this language, and its proper definition. Even if the terms are expected to be consistent, they are not to be written in stone, especially during the initial phase of software development. As soon as one domain activity cannot be expressed using the existing set of concepts, the model needs to be extended. Removing ambiguities and inconsistencies is a need, and will, very often, resolve several not-yet-identified software issues.

24.3.2. Value Objects and Entities

For the definition of your objects or internal data structures (what good programmers care about), you are encouraged to make a difference between several kind of objects. Following DDD, model-level representation are, generally speaking, rich on behavior, therefore also of several families/species of objects.

Let us list the most high-level definitions of objects involved to define our DDD model:

- *Value Objects* contain attributes (value, size) but no conceptual identity - e.g. money bills, or seats in a Rock concert, as they are interchangeable;
- *Entity objects* are not defined by their attributes (values), but by their *thread of continuity*, signified by an identity - e.g. persons, or seats in most planes, as each one is unique and identified.

The main difference between *Value Objects* and *Entities* is that instances of the second type are tied to one reality, which evolves in the time, therefore creating a thread of continuity.

Value objects are *immutable* by definition, so should be handled as read-only. In other words, they are incapable of change once they are created.

Why is it important that they be immutable? With *Value objects*, you're seeking side-effect-free functions, yet another concept borrowed by DDD to functional languages (and not available in most OOP languages, until latest concurrent object definition like in *Rust* or *Immutable Collections* introduced in C#/.NET 4.5). When you add \$10 to \$20, are you changing \$20? No, you are creating a new money descriptor of \$30. A similar behavior should be visible at code level.

Entities will very likely have an ID field, able to identify a given reality, and model the so-called *thread of continuity* of this identity. But this ID is an implementation detail, only used at *Persistence Layer* level: at the *Domain Layer* level, you should not access *Entities* individually, but via a special *Entity* bounded to a specific context, called *Aggregate Root* (see next paragraph).

When we define some objects, we should focus on making the implicit become *explicit*. For instance, if we have to store a phone number, we won't use a plain string type for it, but we will create a dedicated *Value object* type, making explicit all the behavior of its associated reality. Then we will be free to combine all types into explicit grouped types, on need.

24.3.3. Aggregates

Aggregates are a particular case of *Entities*, defined as collection of objects (nested *Values* and/or *Entities*) that are grouped together by a *root Entity*, otherwise known as an *Aggregate Root*, which scope has been defined by a given execution context - see "*Composition*" above.

Typically, *Aggregates* are persisted in a database, and guarantee the consistency of changes by isolating its members from external objects (i.e. you can link to an aggregate via its ID, but you can not directly access to its internal objects). See *Shared nothing architecture (or sharding)* (page 155) which sounds like <http://martinfowler.com/bliki/AggregateOrientedDatabase.html>.

In practice, *Aggregates* may be the only kind of objects which will be persisted at the *Application layer*, before calling the domain methods: even if each nested *Entity* may have its own persistence method (e.g. one RDBMS table per Entity), *Aggregates* may be the unique access point to retrieve or update a given state. It will ensure so-called *Persistence Ignorance*, meaning that domain should remain uncoupled to any low-level storage implementation detail.

DDD services may just permit remote access to *Aggregates* methods, where the domain logic will be defined and isolated.

24.3.4. Factory and Repository patterns

DDD then favors some patterns to use those objects efficiently.

The *Factory pattern* is used to create object instances. In strongly-typed OOP (like in *Delphi*, Java or C#), this pattern is in fact its *constructor* method and associated class type definition, which will define a fixed set of properties and methods at compilation time (this is not the case e.g. in JavaScript or weak-typed script languages, in which you can add methods and properties at runtime).

In fact, Delphi is ahead of Java or C#, since it allows virtual constructors to be defined. Those virtual constructors are in fact a clean and efficient way of implementing a *Factory*, and also fulfill SOLID principles, especially the *Liskov Substitution Principle* (page 396): the parent class define an *abstract* constructor on which you rely, but the implementation will take place in the *overridden* constructor.

The *Factory pattern* can also be used to create interface instances - see *Interfaces* (page 386). Main benefit is that alternative implementations may be easily interchanged. Such abstraction helps testing - see *Interfaces in practice: dependency injection, stubs and mocks* (page 407) - but also introduces interface-based services - see *Client-Server services via interfaces* (page 420).

Repository pattern is used to save and dispense each *Aggregate Root*.

It matches the "Layer Supertype" pattern (see above), e.g. via our *mORMot* *TSQLRecord* and *TSQLRest* classes and their Client-Server ORM features, or via dedicated repository classes - saving data is indeed a concern orthogonal to the model itself. DDD architects claim that persistence is infrastructure, not domain. You may benefit in defining your own repository interface, if the standard ORM / CRUD operations are not enough.

24.3.5. DTO and Events to avoid domain leaking

The main DDD architecture principle - and benefit - is to isolate the domain code. As will be defined by the *Hexagonal architecture* - see below (page 603), everything is made to ensure that the domain won't "leak" outside its core. The domain objects and services are the most precious part of any DDD project, especially in the long term, so proper isolation and uncoupling sound mandatory.

The *Aggregates* should always be isolated and stay at the *Application layer*, given access to its methods and nested objects via proper high-level remote *Services* - see below (page 602) - which should not be published directly to the outer world either.

In practice, if your domain is properly defined, most of your *Value Objects* may be sent to the outer world, without explicit translation. Even *Entities* may be transmitted directly, since their methods should not refer to nothing but their internal properties, so may be of some usefulness outside the domain itself.

But the real world may be rough and cruel, and optimism will better be replaced by some kind of pragmatism, and a pinch of cynicism. DDD experience told its pioneers (sometimes in a painful manner), that *Adapters* types should better be defined, especially at *Application layer* and *Presentation layer* levels.

As a result, a new family of objects will secure any DDD implementation:

- *Data Transfer Objects* (DTO) are transmission objects, which purpose is to not send your domain across the wire (i.e. separate your layers, following the *Anti-Corruption Layer* pattern). It encourages you to create gatekeepers (e.g. in the Application layer) that work to prevent non-domain concepts from leaking into your model.
- *Commands* and *Events* are some kind of DTO, since they communicate data about an event and they themselves encapsulate no behavior.

Using such dedicated types will eventually help *uncoupling* the domain, for several reasons:

- You can refactor your domain, without the need to modify the published interfaces, but just the tiny *Anti-Corruption layer*: no need for your customers to spend money upgrading their client applications, just because your domain changed; no fear to refine your precious domain code, in which you put all your money and expectations, just because it may be unpleasant to your customers.

- End-user application expectations won't pollute your domain. For instance, you will better define a per-customer set of public APIs, rather than exposing your domain services. In practice, a "one to rule them all" public API may sound like a good idea at first, but it will eventually end up as a monstrous, flat, unreadable and anemic interface, far away from *SOLID design principles* (page 390).
- Since the domain tends to be as generic as possible, its objects may sometimes be overkill to the end user applications: if some properties will never be used, or will always be void, why will you pollute your end user code, and waste bandwidth or resources? Just stick to what is needed.
- Dedicated types will help focusing on the needed use cases, so will ease documentation, maintainability, testing and integration with client applications: even translating your *Ubiquitous language* objects into more common or expected terms in the presentation layer will be beneficial.
- Consider that in your company, the *Domain* and *Infrastructure* layers may be maintained by your most valuable teams, whereas some less skilled developers (or even *offshore* teams) may be involved on *Application* and *Presentation* layers. Writing *adapter/translator* classes is not difficult, and will help your company focus and invest on where long term ROI is more likely to appear. Some access restrictions may therefore appear at source code level: it may be safe that only the wiser programmers will be allowed to modify the domain code, and even hide the domain implementation by publishing only its interfaces, protecting your most valuable intellectual property from being copied and stolen.

In *mORMot*, we try to let the framework do all the plumbing, letting those types be implemented via interfaces over simple dedicated types like records or *dynamic arrays* - see *Service Methods Parameters* (page 424) and *Asynchronous callbacks* (page 445). So defining DTOs, *Commands* and *Events* in dedicated *Anti-Corruption layers* will be pretty much quick, easy and safe.

24.3.6. Services

Aggregate roots (and sometimes *Entities*), with all their methods, often end up as *state machines*, and the behavior matches accordingly.

In the domain, since *Aggregate roots* are the only kind of entities to which your software may hold a reference, they tend to be the main access point of any process. It could be handy to publish their methods as stateless *Services*, isolated at *Application layer* level.

Domain services pattern is used to model primary operations.

Domain *Services* give you a tool for modeling processes that do not have an identity or life-cycle in your domain, that is, that are not linked to one aggregate root, perhaps none, or several. In this terminology, services are not tied to a particular person, place, or thing in my application, but tend to embody processes. They tend to be named after verbs or business activities that domain experts introduce into the so-called *Ubiquitous Language*. If you follow the interface segregation principle - see *Interface Segregation Principle* (page 401), your domain services should be exposed as dedicated client-oriented methods. Do not leak your domain! In DDD, you develop your *Application layer* services directly from the needs of your client applications, letting the *Domain layer* focus on the business logic.

Unit Of Work can be used to maintain a list of objects affected by a business transaction and coordinates the writing out of changes and the resolution of concurrency problems.

In short, it implements transactional process at Domain level, and may be implemented either at service or ORM level. It features so-called *Persistence Ignorance*, meaning that your domain code may not be tied to a particular persistence implementation, but "hydrate" *Aggregate roots* class instances as abstractly as possible.

A *dual-phase commit* approach - with some methods preparing and validation the data, then applying it by a dedicated *Commit* command in a second step - may be defined. In this pattern, the repository is

just some simple storage, and data consistency will take place at domain level: for instance, you will not define any SQL constraints, but validate your data *before* storing the information. Your business rules should be written in high level domain code, and you may forget about the FOREIGN KEY, or CHECK SQL syntax flavors. As a result, you may safely change from a SQL database to a NoSQL engine, or even a TObjectList. You will be able to define and maintain any complex business rules, using the *Ubiquitous Language* of your domain. And a change of business logic will not impact the database metadata, which may be painful to modify.

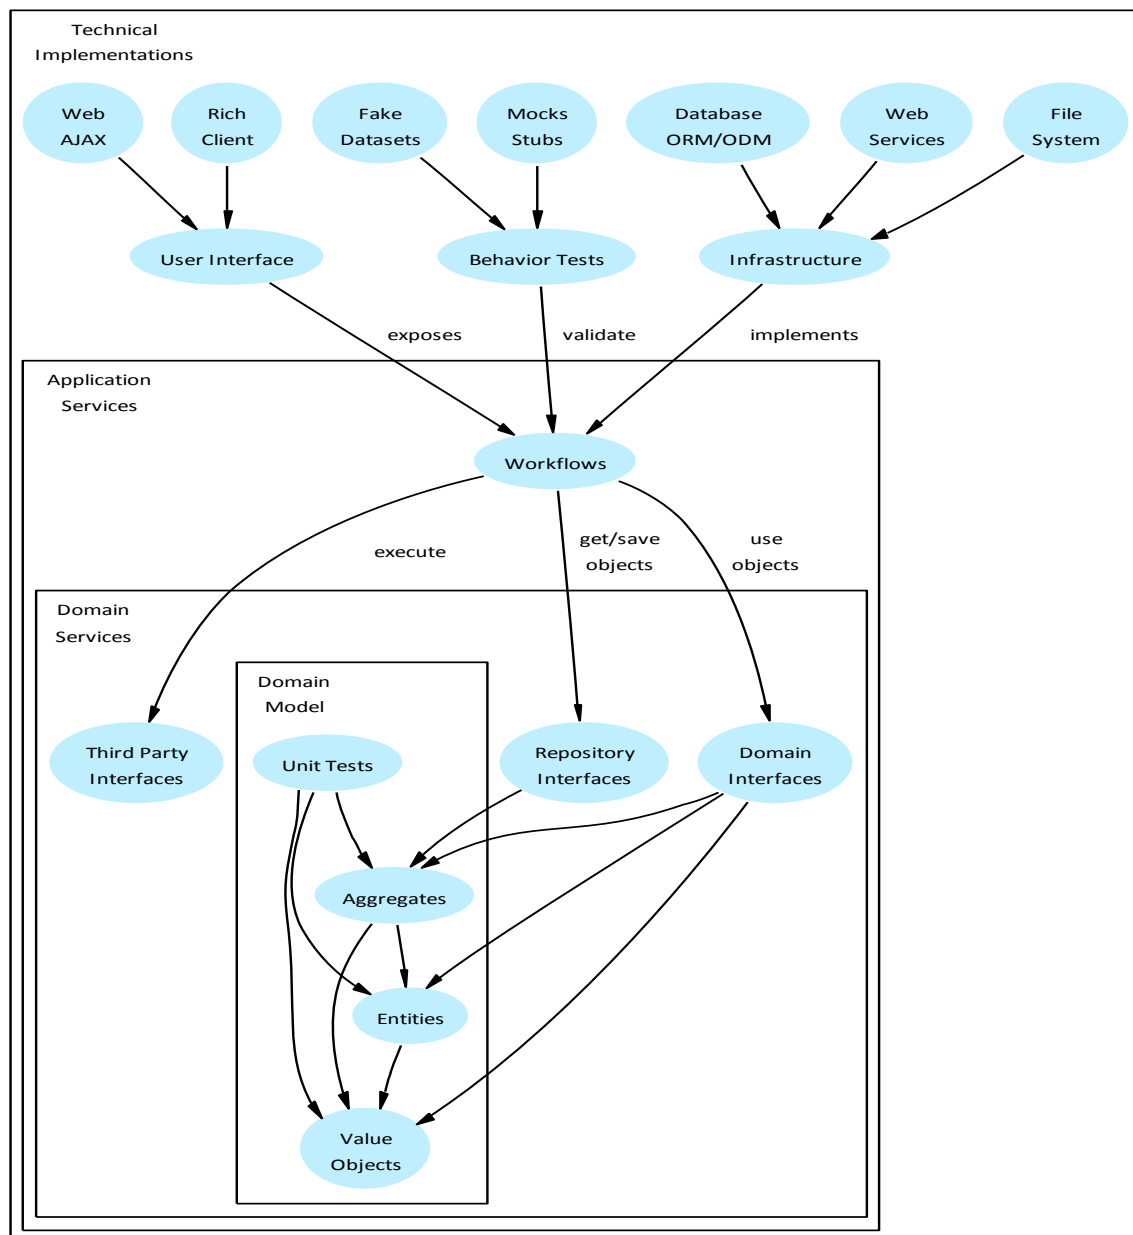

The DDD Services may therefore be stateless for most of the time, but allowing some flavor of transactional process, when needed. The uppermost/peripheral architecture layers - i.e. *Application* or *Presentation Layers* - will ensure that those services will be properly orchestrated. The application *workflows* will not be defined in the domain core itself, but in those outer layers, resulting in a cleaner, uncoupled architecture.

24.3.7. Clean Uncoupled Architecture

If you follow properly the DDD patterns, your classic *Multi-tier architecture* (page 88) architecture will evolve into a so-called *Clean Architecture* or *Hexagonal architecture*.

Even if *physically*, this kind of architecture may still look like a classic *layered* design (with presentation on the top, business logic in the middle and a database at the bottom - and in this case we speak of *N-Layered Domain-Oriented Architecture*), DDD tries to isolate the *Domain Model* from any dependency, including technical details.

As a consequence, the *logical* architecture of any DDD solution should appear as such:

Clean Uncoupled Domain-Oriented Architecture

That kind of architecture is not designed in layers any more, but more like an Onion.

At the core of the bulb - sorry, of the system, you have the *Domain Model*.

It implements all *Value Objects* and *Entity Objects*, including their state and behavior, and associated unit tests.

Around this core, you find *Domain Services* which add some more behavior to the inner model. Typically, you will find here abstract interfaces that provides persistence (*Aggregates* saving and retrieving via the *Repository* pattern), let Domain objects properties and methods be defined (via the *Factory* pattern), or access to third-party services (for service composition in a SOA world, or e.g. to send a notification email).

Then *Application Services* will define the *workflows* of all end-user applications.

Even if the core Domain is to be as stable as possible, this outer layer is what will change more often,

depending on the applications consuming the *Domain Services*. Typically, workflows will consist in deshydrating some *Aggregates* via the *Repository* interface, then call the *Domain* logic (via its objects methods, or for primary operations with wider Domain services), call any external service, and validate ("commit", following Unit-Of-Work or transactional terms) objects modifications. Some non data-centric process will also benefit from a *dual-phase commit* pattern, to allow safe orchestration of uncoupled domain and third party services.

Out on the edges you see User Interface, Infrastructure (including e.g. database persistence), and Tests. This outer layer is separated from the other three internal layers, which are sometimes called *Application Core*.

This is where all technical particularities will be concentrated, e.g. where RDBMS / SQL / ORM mapping will be defined, or platform-specific code will reside. This is the right level to test your end-user workflows, e.g. using Behavior-Driven Development (abbreviated BDD), with the help of your Domain experts.

The premise of this Architecture is that *it controls coupling*. The main rule is that all coupling is toward the center: all code can depend on layers more central, but code cannot depend on layers further out from the core. This is clearly stated in the *Clean Uncoupled Domain-Oriented Architecture* (page 604) diagram: just follow the arrows, and you will find out the coupling order. This architecture is unashamedly biased toward object-oriented programming, and it puts objects before all others.

This *Clean Architecture* relies heavily on the *Dependency Inversion* principle - see *SOLID design principles* (page 390). It emphasizes the use of interfaces for behavior contracts, and it forces the externalization of infrastructure to dedicated implementation classes. The *Application Core* needs implementation of core interfaces, and if those implementing classes reside at the edges of the application, we need some mechanism for injecting that code at runtime so the application can do something useful. *mORMot's Client-Server services via interfaces* (page 420) provide all needed process to access, even remotely, e.g. to persistence or any third party services, in an abstract way.

With *Clean Architecture*, the database is not the center of your logic, nor the bottom of your physical design - it is *external*. Externalizing the database can be quite a challenge for some people used to thinking about applications as "database applications", especially for *Delphi* programmers with a RAD / TDataSet background. With Clean Architecture, there are no database applications. There are applications that might use a database as a storage service but only through some external infrastructure code that implements an interface which makes sense to the application core. The domain could be even decoupled from any ORM pattern, if needed. Decoupling the application from the database, file system, third party services and all technical details lowers the cost of maintenance for the life of the application, and allows proper testing of the code, since all Domain interface types could be mocked on purpose - see *Stubs and mocks* (page 408).

24.4. mORMot's DDD

24.4.1. Designer's commitments

Before going a bit deeper into the low-level stuff, here are some key sentences we should better often refer to:

- I shall collaborate with *domain experts*;
- I shall focus on the *ubiquitous language*;
- I shall not care about technical stuff or framework, but about modeling the *Domain*;
- I shall make the implicit *explicit*;
- I shall use end-user *scenarios* to get real and concrete;
- I shall not be afraid of defining *one model per context*;
- I shall focus on my *Core Domain*;
- I shall *let my Domain code uncoupled* to any external influence;
- I shall *separate values and time* in state;
- I shall *reduce statefulness* to the only necessary;
- I shall always *adapt my model* as soon as possible, once it appears inadequate.

As a consequence, you will find in *mORMot* no magic powder to build your DDD, but all the tools you need to focus on your business, without losing time in re-inventing the wheel, or fixing technical details.

24.4.2. Defining objects in Delphi

How to implement all those DDD concepts in an object-oriented language like *Delphi*? Let's go back to the basics. Objects are defined by a *state*, a *behavior* and an *identity*. A *factory* helps creating objects with the same state and behavior.

In *Delphi* and most Object-Oriented (OOP) languages - including C# or Java, each `class` instance has the following behavior:

- *State* is defined by all its property / member values;
- *Behavior* are defined by all its methods;
- *Identity* is defined *by reference*, i.e. `a=b` is true only if `a` and `b` refers to the same object;
- *Factory* is in fact the `class` type definition itself, which will force each instance to have the same members and methods.

In *Delphi*, the record type (and deprecated object type for older versions of the compiler) has an alternative behavior:

- *State* is also defined by all its property / member values;
- *Behavior* are also defined by all its methods;
- But *identity* is defined *by content*, i.e. `RecordEquals(a,b)` is true only if `a` and `b` have the same exact property values;
- *Factory* is in fact the record / object type definition itself, which will force each instance to have the same members and methods.

In practice, you may use either one of the two kinds of object types (i.e. either `class` or `record`), depending on the behavior expected by DDD patterns:

- DDD's *DTO* may be defined as record, and directly serialized as JSON via text-based *Record serialization* (page 298) - as an alternative, you may consider using *TDocVariant custom variant type* (page 112);

- But other kinds of DDD objects, i.e. *Value Objects*, *Entity Objects* and *Aggregates*, should better be defined as dedicated class, since class type definition offers more possibility than plain record structures. The framework defines some parent classes (e.e. `TSynPersistent` and `TSynAutoCreateFields`) which makes working with class instances almost as easy than stack-allocated record values.

24.4.3. Defining DDD objects in mORMot

When defining domain objects, we should always make the implicit *explicit*, i.e. writing one class type per reality in the model, in every *bounded context*. Thanks to *Delphi's* strong typing, you will ensure that the Domain *Ubiquitous language* will appear in the code, and that your model will be expressed in a clean, uncoupled way.

If those class types are defined as plain PODO, even your domain experts - which may not know anything about writing code - may be part of the class definition: we usually write the domain objects and services with the domain experts, writing the code in real time during a meeting. The domain is therefore expressed as plain code, and experts are able to validate the workflows and properties of the model as soon as possible. Such coding sessions truly benefit of being a cooperative team work, not only coders'.

Once the domain model is stabilized, we may start implementing the interfaces using this common work as contract. In this implementation process, the *mORMot* framework offers a lot of tools to make it happen in a quick and efficient manner.

There are in fact two ways of implementing DDD objects as class types, in *mORMot*:

- Directly using the framework types, e.g. `TSQLRecord` specialized class for *Entities* or *Aggregates*;
- Or relying on no framework structure, but clean PODOs (*Plain Old Delphi Object* - see so-called POJO or POCO for Java or C#) class types, then use the `mORMotDDD.pas` unit for automatic marshalling.

Of course, the second option may be preferred, since it sounds like a better implementation path, uncoupled from the framework itself. Remember that DDD is mainly about *uncoupling* the Domain code from any external dependency, even from *mORMot* itself. You should better not be forced to use the framework ORM, if you have some existing legacy SQL statements, for instance.

24.4.3.1. Use framework types for DDD objects

If you want to directly use framework structure, DDD's *Value Objects* are probably meant to be defined as record, with methods (i.e. in this case as object for older versions of *Delphi*). You may also use `TComponent` or `TSQLRecord` classes, ensuring the published properties do not have setters but just read `FO...definition`, to make them read-only, and, at the same time, directly serializable.

If you use record / object types, you may need to customize the JSON serialization - see *Record serialization* (page 298) - when targeting AJAX clients, especially for any version prior to *Delphi* 2010 (by default, records are serialized as binary + Base64 encoding due to the lack of enhanced RTTI, but you can define easily the record serialization e.g. from text). Note that since record / object defines in *Delphi by-value* types (whereas class defines *by-reference* types - see previous paragraph), they are probably the cleanest way of defining *Value Objects*.

In this context, DDD's *Entity objects* could inherit from `TSQLRecord`. It will give access to a whole set of methods supplied by *mORMot*, implementing some kind of "Layer Supertype", as explained by Martin Fowler.

Finally, DDD's *Aggregates* will benefit of using *mORMot's Object-Relational Mapping* (page 130). *Entities* will be stored as regular `TSQLRecord`, e.g. using "*One to one*" or "*One to many*" (page 151)

cardinality, as available from the framework.

For most simple cases, this solution may be just good enough. But it may have the drawback of coupling your *Domain logic* with *mORMot* internals. Your Domain will eventually be polluted by the framework implementation details, which should better be avoided.

24.4.3.2. Define uncoupled DDD objects

In order to uncouple our *Domain* code from its persistence layer, *mORMot* offers some dedicated types and units to use PODO class definitions within your DDD core.

You may use regular *TPersistent* as parent class, but you may consider using *TSynPersistent* and *TSynAutoCreateFields* fields instead - we will see soon their benefit.

Let's start from existing code, available in the `SQLite3\DDD\dom` sub-folder of the framework source code repository, in the `dddDomUserTypes.pas` unit. This unit defined some reusable class types, able to store user information, in a clean DDD way.

24.4.3.3. Specialize your simple types

Each reality in this unit will have its own type definition, using the extended pascal syntax, even for simple types like string or integer:

```
type
  TSpecifiedType = type TParentType;
```

You may not be familiar with this syntax. But it is a pretty powerful mean of defining your DDD model with a plain pascal syntax. Here *TSpecifiedType* is defined as a specific type, which will behave like *TParentType*, but *strong-typing* will apply in your code, so that the compiler will complain if you pass e.g. a *TParentType* instead of a *TSpecifiedType* as a var parameter. It will help to resolve some ambiguities when transmitting information.

For instance, in the `dddDomUserTypes.pas` unit, you may see:

```
type
  TLastName = type RawUTF8;
  TFirstName = type RawUTF8;
  TMiddleName = type RawUTF8;
```

Thanks to those type definitions, you will be able to make a difference between a last name, a first name and a middle name. We used *RawUTF8* as parent type, but we may have used *string*. Since we wanted our code to work seamlessly with all versions of Delphi and FPC, we rather rely on *RawUTF8* - see *Unicode and UTF-8* (page 105).

Once compiled, there won't be any difference between the three types, which will behave like a *RawUTF8*. But at compile time, and in your Domain source code, you will be able to know exactly which reality is stored in a given variable.

So instead of this method definition:

```
function UserExists(const aUserName: RawUTF8): boolean;
```

You will rather write:

```
function UserExists(const aUserName: TLastName): boolean;
```

With such a method signature, we will ensure that we won't supply a *TFirstName* or a *TPetName* by mistake.

It may sound like a small enhancement, but be sure that it will increase your code safety, and

expressiveness. One of the biggest failure in NASA history was *Mars Climate Orbiter*. A variable type error burn up a \$327.6 million project in minutes, when one engineering group working on the thrusters measured in English units of pounds-force seconds, whereas the others used metric Newton-seconds. The result of that inattention is now lost in space, possibly in pieces.

Remember when our physic teachers leaped all over answers that consisted of a number. If the answer was 2.5, they will take their red pens and write "2.5 what? Weeks? Puppies? Demerits?" And proceed to mark the answer wrong. In our DDD code, we should rather follow this rule, and try to make the implicit *explicit*.

24.4.3.4. Define your PODO classes

Main point is first to define your DDD Objects as plain Delphi class types - the famous PODOs, following the *Ubiquitous Language*. We will in fact define *Value Objects* class types, which may be grouped and nested to become *Entity Objects* or *Aggregates*.

To define a TPerson object, able to modelize a person identity, we may write the following classes:

```
type
  /// Person full name
  TPersonFullName = class(TSynPersistent)
  protected
    fFirst: TFirstName;
    fMiddle: TMiddleName;
    fLast: TLastName;
  public
    function Equals(another: TPersonFullName): boolean; reintroduce;
    function FullName(country: TCountryIdentifier=ccUndefined): TFullName; virtual;
  published
    property First: TFirstName read fFirst write fFirst;
    property Middle: TMiddleName read fMiddle write fMiddle;
    property Last: TLastName read fLast write fLast;
  end;

  /// Person birth date
  TPersonBirthDate = class(TSynPersistent)
  protected
    fDate: TDateTime;
  public
    function Equals(another: TPersonBirthDate): boolean; reintroduce;
    function Age: integer; overload;
    function Age(FromDate: TDateTime): integer; overload;
  published
    property Date: TDateTime read fDate write fDate;
  end;

  /// Person object
  TPerson = class(TSynAutoCreateFields)
  protected
    fBirthDate: TPersonBirthDate;
    fName: TPersonFullName;
  public
    function Equals(another: TPerson): boolean; reintroduce;
  published
    property Name: TPersonFullName read fName;
    property Birth: TPersonBirthDate read fBirthDate;
  end;
```

First of all, you will see that we inherit from TSynPersistent and TSynAutoCreateFields. The benefit of those classes are the following:

- TSynPersistent has a virtual constructor, and a little less overhead than TPersistent, so may be preferred, especially when we will use *Dependency Injection and Interface Resolution* (page 418);

- TSynAutoCreateFields inherits from TSynPersistent, and its overridden Create will allocate all published class properties auto-magically - whereas its overridden Destroy will release those instances for you. As such, inheriting from TSynAutoCreateFields makes it a perfect fit for a *Value Object*, nesting sub objects as properties;
- Both have the RTTI enabled, so all published properties will be easily serialized as JSON (when used as DTO), or persisted later on on a database, when joined as *Aggregate Roots*.

In the above code, we defined TPerson.Name as a TPersonFullName class. So that we may use aPerson.Name.First or aPerson.Name.Last or even the runtime-computed aPerson.Name.FullName method which is able to display the full name, depending on per-country culture. We also reintroduced the Equals() method, which will allow to compare the objects per value, and not per reference.

Even if the birth date is just a date, we introduced a dedicated TPersonBirthDate class. The benefit is to have the overloaded Age() methods, which are pretty convenient in practice.

Once serialized as JSON, a TPerson content may be:

```
{
  "Name": {
    "First": "John",
    "Middle": "",
    "Last": "Smith"
  },
  "Birth": {
    "Date": "1972-10-29"
  }
}
```

During the modelization phase, you will just define such class types, trying to reflect DDD's *Ubiquitous Language* into regular Delphi classes.

Take a look at the dddDomUserTypes.pas unit, to identify such patterns, and how we may be able to define an application user, gathering our TPerson class with a TAddress, in which a TCountry class will be used to store the corresponding country:

```
/// a Person object, with some contact information
// - an User is a person, in the context of an application
TPersonContactable = class(TPerson)
protected
  fAddress: TAddress;
  fPhone1: TPhoneNumber;
  fPhone2: TPhoneNumber;
  fEmail: TEmailAddress;
public
  function Equals(another: TPersonContactable): boolean; reintroduce;
published
  property Address: TAddress read fAddress;
  property Phone1: TPhoneNumber read fPhone1 write fPhone1;
  property Phone2: TPhoneNumber read fPhone2 write fPhone2;
  property Email: TEmailAddress read fEmail write fEmail;
end;
```

You can see that we did not pollute the class definition with any detail about persistence. What we did by now was to define a plain *Value Object*. We did not even specify that this class may be any *Entity*, nor introduce a primary key to identify it from a single access point. We found this way much cleaner than the approach of most other Java or C# DDD frameworks, which usually require to inherit from a parent Entity class, or use *attributes* to define the persistence expectations (like the primary key). We think that the domain types should not be polluted with those implementation details, and focus on expressing the model.

We will finally define a *TUser Entity* (or *Aggregate Root*), inheriting from *TPersonContactable*, i.e. modeling any application user account with all its personal information, with a flag to testify that its email was validated:

```
TUser = class(TPersonContactable)
private
  fLogonName: TLogonName;
  fEmailValidated: TDomUserEmailValidation;
published
  property LogonName: TLogonName read fLogonName write fLogonName;
  property EmailValidated: TDomUserEmailValidation read fEmailValidated write fEmailValidated;
end;
```

Such a *TPersistent*-inheriting class could be used as a *Value Object* (or even a *DTO*), but become an *Entity* or *Aggregate* in the bounded context of the user account personal information. In order to store this data, we will now define an interface, implementing a *Persistence Service*.

24.4.3.5. Store your Entities in CQRS Repositories

When persisting our precious DDD Objects, the framework tries to follow some DDD patterns:

- Define *Aggregate Root* (or *Entities*) from *Value Objects*, as practical data context for storing the information;
- Use a *Repository* service to store those *Aggregates* instances;
- Follow *CQRS* (*Command Query Responsibility Segregation*) via a dedicated dual interface, splitting reads (*Queries*) and writes (*Commands*) in the *Repository* contract;
- Use *Factory* to instantiate *CQRS Repository* contracts on need.

In practice, we will use a *Factory* to create *Repository* class instances implementing the *CQRS* service methods, defined as a hierarchy of interface types, for a given *Aggregate Root*.

Let's start from an example, i.e. implement *CQRS Repository* services for our *TUser* class.

24.4.3.5.1. CQRS Interfaces

The *mORMotDDD.pas* unit defines the following interface, which will benefit of being the root interface of all *Repository* services:

```
type
  ICQRSservice = interface(IInvokable)
    ['{923614C8-A639-45AD-A3A3-4548337923C9}']
    function GetLastError: TCQRSResult;
    function GetLastErrorInfo: variant;
  end;
```

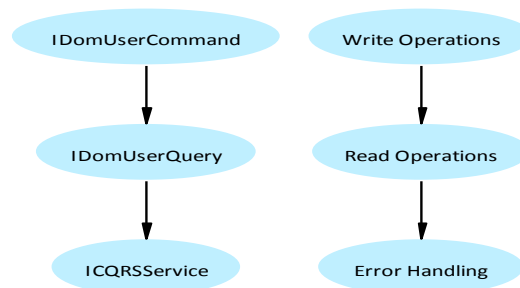

This interface does nothing but allowing a generic access to the last error which occurred. This will be used instead of *Exception*, via the *TCQRSResult* enumeration, as a safe way of handling errors in a remote *Service*.

Exceptions are very convenient when running code in a process, but are difficult to handle over a remote connection, since the execution context is spread on both client and server sides. It is very difficult to propagate an exception raised on the server side to the client side, without leaking the server implementation. For instance, the SOAP standard provides a way of transmitting execution errors as dedicated XML messages - but it turns out to be a very verbose and complex path.

In *mORMot*, we defined a generic way of sending errors to the client side, for *CQRS Services*. By convention, any method will be defined as a function, returning its execution state as a *TCQRSResult* enumeration. If *cqrsSuccess* is returned, no error did happen on the server side, and execution may continue on the client side. Otherwise, an error "kind" is specified in the *TCQRSResult* transmitted value, and additional information is available as string or a *TDocVariant custom variant type* (page

112) in the `ICQRSService.GetLastErrorInfo` method. This allows to safely handle any kind of execution error on the client side, without the need to define dedicated exceptions. As we already stated about *Error handling* (page 459), exception should be *exceptional* - please refer to this paragraph for more details, including the benefit of that any stubbed or mocked interface will return `cqrsSuccess` (i.e. 0) by default, so let the test pass.

For our `TUser CQRS Repository` service, we will therefore define two interface types, one inheriting from `ICQRSService` for the *Queries* methods, and another one inheriting from this later interface to define the *Commands* methods:

CQRS Repository Service Interface for TUser

In `dddDomUserCQRS.pas`, we therefore defined two interface types, one `IDomUserQuery` for the read operations (i.e. *Queries*) of `TUser` aggregates, and an inherited `IDomUserCommand` for the write operations (i.e. *Commands*) of `TUser` aggregates.

We may argue that `IDomUserCommand` inheriting from `IDomUserQuery` is actually a violation of the *Command Query Responsibility Segregation* principle. Here, *Commands* are tied to *Queries*. Of course, we may have defined two diverse interfaces, both inheriting from `ICQRSService` as parent:

CQRS Dogmatic Repository Service Interface for TUser

Nothing prevent you from doing this. But in our case, especially with the *mORMot* underlying ORM, or a RDBMS database, the benefit is not obvious - sounds more like a dogmatic approach. To *update* a resource, you will need two interfaces: one `IDomUserQuery` instance to retrieve the existing value object, then one `IDomUserCommand` to modify it. From our pragmatic point of view, it is not mandatory. Also note that interface inheritance may differ from actual implementation class inheritance. `IDomUserCommand` may inherit from `IDomUserQuery`, but, e.g. if performance matters, you may still be able to implement a plain `IDomUserQuery` service with a dedicated class, on a separated database. In our case, interface inheritance is a common way of increasing code reuse. So if you want to be dogmatic about CQRS, you could - but only if it is worth the effort.

24.4.3.5.2. Queries Interface

Since we will separate queries and commands, we will first define the interface for actually reading `TUser` information:

```
type
IDomUserQuery = interface(ICQRSservice)
  ['{198C01D6-5189-4B74-AAF4-C322237D7D53}']
  function SelectByLogonName(const aLogonName: RawUTF8): TCQRSResult;
  function SelectByEmailValidation(aValidationState: TDomUserEmailValidation): TCQRSResult;
  function SelectByLastName(const aName: TLastName; aStartWith: boolean): TCQRSResult;
  function Get(out aAggregate: TUser): TCQRSResult;
  function GetAll(out aAggregates: TUserObjArray): TCQRSResult;
  function GetNext(out aAggregate: TUser): TCQRSResult;
  function GetCount: integer;
  function HowManyValidatedEmail: integer;
end;
```

As we stated previously, all those methods do return a `TCQRSResult` enumeration, which will be used on the service consumer side to notify on any execution error.

Instances of those interface will in fact have a limited life-time. To access the `TUser` persistence layer, a `CQRS` interface will be injected - via *Dependency Injection and Interface Resolution* (page 418), then allow to handle one or several `TUser` instances.

For queries, you could use `IDomUserQuery.SelectByLogonName`, `IDomUserQuery.SelectByLastName` or `IDomUserQuery.SelectByEmailValidation` methods to initialize a request. As you can see, there is no mention of primary key or ID in this interface definition. Even if under the hood, the implementation *may* use our ORM, and a `TSQLRecord` with its `TSQLRecord.ID: TID` property, the `CQRS` interface themselves make not those implementation details appear - unless it will be necessary. In our use case of an application targeting a single user, it is enough to be able to retrieve a user by its logon name, or by its last name.

If the `Select*` method executed without error (i.e. returned `cqrsSuccess`), we can later on retrieve the content by calling:

- `IDomUserQuery.Get` for filling the properties of a single already existing `TUser` object);
- `IDomUserQuery.GetAll` to return a list of `TUser` instances - for storage, we will use a `TUserObjArray` dynamic array, which should be released by the caller using `ObjArrayClear()` on the result variable;
- `IDomUserQuery.GetNext` to retrieve the actual matching `TUser`, one by one, following the principle of a database *cursor*;
- `IDomUserQuery.GetCount` will return the number of items matching the `Select*`.

Since the `IDomUserQuery` interface has a lifetime, you could call `IDomUserQuery.Get` or `IDomUserQuery.GetAll` several times after a single `Select*`. Note that in the common ORM-based implementation we will define below, the `TUser` information is actually *retrieved* and stored in memory by the `Select*` method.

Note that in the `IDomUserQuery` contract, the `IDomUserQuery.HowManyValidatedEmail` method, on the other hand, is stateless, and could be used without any prior `Select*`. Such methods may appear, depending on the Domain expectations.

The main point here is that, when defining your `CQRS` interface, you should focus on *which* data you need to access, in the most convenient way for you, and forget about the real persistence implementation - i.e. *how* data is stored. This is called, in DDD methods, as *Persistence Ignorance*, and is a very convenient way of uncoupling your business logic from actual technical details. If you was never asked by your commercials to support a new database engine, or even be able to switch from a SQL to a NoSQL storage, or an existing legacy proprietary obscure database used by a given customer... you are a lucky programmer, but - you know - it happens in real life!

Another advantage of starting from what you need in your domain, by using interface types as

contracts, is that you will probably focus on the domain, and may avoid the risk of an *anemic domain model* symptom, which appears when your persistence service is just a CRUD operation in disguise. If we need only CRUD operations, an ORM, or even plain SQL is enough. But if we want to have our domain code follow the ubiquitous language, and stick to the use cases of our business model, we should better design the persistence this way.

Last but not least, you will be able to *mock* or *stub* the persistence service - see *Stubs and mocks* (page 408), so ease unit test of your *Domain* code, without any dependency to any actual database layer. Following *Test Driven Design*, you will even be able to write the Domain core tests first, validate all your interfaces, even write the *Application layer* and test it with the current mock-up of the end-user application, and eventually finalize and tune the SQL or NoSQL storage at the final step, when the whole workflow is stabilized. It will help testing sooner, therefore fix sooner, and... hopefully release sooner.

24.4.3.5.3. Commands Interface

Following the CQRS (*Command Query Responsibility Segregation*) principle, we defined the write operations (i.e. *Commands*) in a separate interface. This type will inherit from `IDomUserQuery`, since it may be convenient to be able to first *read* the `TUser`, for instance before applying a modification to the stored information, like updating existing data, or adding some a missing entry.

```
type
  IDomUserCommand = interface(IDomUserQuery)
    ['{D345854F-7337-4006-B324-5D635FBED312}']
    function Add(const aAggregate: TUser): TCQRSResult;
    function Update(const aUpdatedAggregate: TUser): TCQRSResult;
    function Delete: TCQRSResult;
    function DeleteAll: TCQRSResult;
    function Commit: TCQRSResult;
    function Rollback: TCQRSResult;
  end;
```

The main method of this *Command* interface is `Commit`. Following the *dual-phase commit* pattern, nothing will be written to the actual persistence storage unless this `IDomUserCommand.Commit` method is actually called.

In short, you query then update your data using the other `Add/Update/Delete/...` methods, then you run `Commit`.

For instance, to modification an existing record, you will call:

- `IDomUserQuery.SelectByLogonName`;
- `IDomUserCommand.Update`;
- `IDomUserCommand.Commit`.

If the logon name is unknown, an error will raise at the first step. If the updated modification transmitted at the second step is invalid (i.e. you forgot to fill a mandatory field, or a value which should be unique, like a serial number, appear to exist already), then another error will be reported. But even after a successful `Update`, nothing will be stored in the database. Why? Because in most use cases, you will probably need to synchronize several operations: for instance, you may have to send an email, or call a third-party service, and write the new data only if everything was right. As such, you will need a two-phase write operation: first, you prepare and validate your data on each involved service, then, once everyone did give its green light, you eventually launch the process, which is, in the case of a persistence layer, calling `Commit`. In a real application, an unexpected low-level error may happen during the *Commit* phase - e.g. a network failure, a concurrency issue, or a problem between a chair and a keyboard - but it will not be likely to happen often. The *dual-phase* commit will ensure that

most errors will be identified during the first phase, using our ORM's *Filtering and Validating* (page 172) abilities.

Of course, if you want to run the `IDomUserCommand.Add` method, no prior `IDomUserQuery.Select*` call is mandatory. But for `Update` and `Delete` or `DeleteAll` commands, you will need first to define the data extend you will work on, by a previous call to `Select*`.

To use those CQRS interfaces, you could use IoC as usual:

```
var cmd: IDomUserCommand;  
    user: TUser;  
    itext: RawUTF8;  
...  
aServer.Services.Resolve(IDomUserCommand,cmd);  
user := TUser.Create;  
try  
    for i := 1 to MAX do begin  
        UInt32ToUtf8(i,itext);  
        user.LogonName := ' '+itext;  
        user.EmailValidated := evValidated;  
        user.Name.Last := 'Last'+itext;  
        user.Name.First := 'First'+itext;  
        user.Address.Street1 := 'Street '+itext;  
        user.Address.Country.Alpha2 := 'fr';  
        user.Phone1 := itext;  
        if cmd.Add(user)<>cqrsSuccess then  
            raise EMyApplicationException.CreateFmt('Invalid data: %s',[cmd.GetLastErrorInfo]);  
    end;  
    // here nothing is actually written to the database  
    if cmd.Commit<>cqrsSuccess then  
        raise EMyApplicationException.CreateFmt('Commit error: %s',[cmd.GetLastErrorInfo]);  
    // here everything has been written to the database  
finally  
    user.Free;  
end;
```

This *dual-phase* commit appears to be a clean way of implement the *Unit Of Work pattern* (page 354). Under the hood, when used with our ORM - as we will now explain - *Unit Of Work* will be expressed as a `I*Command` service, uncoupled from the persistence layer it runs on.

24.4.3.5.4. Automated Repository using the ORM

As you may have noticed, we did just defined the interface types we needed. That is, we have the *contract* of our persistence services, but no actual implementation of it. As such, those interface definitions are useless. Luckily for us, the `mORMotDDD.pas` unit offers an easy way to implement those using *Object-Relational Mapping* (page 130), with minimal coding.

24.4.3.5.4.1. DDD / ORM mapping

First we will need to map our domain object (i.e. our `TUser` instance and its properties) into a `TSQLRecord`. We may do it by hand, but you may find an handy way. Just run the following in the context of your application:

```
TDDDRepositoryRestFactory.ComputeSQLRecord(TUser);
```

This class procedure will create a `ddsqlrecord.inc` file in the executable folder, containing the needed field definition, with one `TSQLRecord` type corresponding to each hierarchy level of the original `TPersistent` definition. Nested fields will be defined as a single column in the `TSQLRecord`, e.g. `Address.Country.Iso` will be flattened as a `Address_Country` property.

So if we follow the class hierarchy, we will have:

CQRS Class Hierarchy Mapping for ORM and DDD Entities

Which will be defined as such in the `ddsqlrecord.inc` generated content:

```

type
  TSQLRecordPerson = class(TSQLRecord)
  ...
  published
    property Name_First: RawUTF8 read fFirst write fFirst;
    property Name_Middle: RawUTF8 read fMiddle write fMiddle;
    property Name_Last: RawUTF8 read fLast write fLast;
    property Birth: TDateTime read fBirthDate;
  end;

  TSQLRecordPersonContactable = class(TSQLRecordPerson)
  ...
  published
    property Address_Street1: RawUTF8 read fStreet1 write fStreet1;
    property Address_Street2: RawUTF8 read fStreet2 write fStreet2;
    property Address_CityArea: RawUTF8 read fCityArea write fCityArea;
    property Address_City: RawUTF8 read fCity write fCity;
    property Address_Region: RawUTF8 read fRegion write fRegion;
    property Address_Code: RawUTF8 read fCode write fCode;
    property Address_Country: integer read fCountry;
    property Phone1: RawUTF8 read fPhone1 write fPhone1;
    property Phone2: RawUTF8 read fPhone2 write fPhone2;
    property Email: RawUTF8 read fEmail write fEmail;
  end;

  TSQLRecordUser = class(TSQLRecordPersonContactable)
  ...
  published
    property LogonName: RawUTF8 read fLogonName write fLogonName;
    property EmailValidated: TDomUserEmailValidation read fEmailValidated write fEmailValidated;
  end;

```

In practice, the following property will need to be tuned as such:

```

property LogonName: RawUTF8 read fLogonName write fLogonName
  stored AS_UNIQUE;

```

Take a look at the `dddInfraRepoUser.pas` and `dddDomUserTypes.pas` units to make a comparison between the DDD objects and their corresponding `TSQLRecord*` types.

You may wonder why we will introduce a separate level of classes, between the DDD Aggregates and the database engine. Why not directly persist the Domain objects (as most DDD implementations do)?

In fact, our approach has several benefits:

- Most of the time, simple mapping will be done automatically: once you called `TDDRRepositoryRestFactory.ComputeSQLRecord`, there is a very little additional coding to be done;
- But you still have access to the full mapping process, not using attributes (which may sound

- convenient, but are *polluting* the DDD classes definition), but at *Persistence Service* method level;
- You could persist the same DDD classes as *Value Objects*, *Entities* or *Aggregates*, depending on the use context, by a custom mapping over a dedicated *Persistence Service* - your domain objects are uncoupled from their use context - remember that the same Value Object may become an Aggregate, or an Entity, depending on the context: why define again and again the same classes? just reuse the same tuned types via *Composition* (page 598);
- No need to inherit your DDD classes from a parent *Entity* class, or pollute it with an ID field (as most DDD implementations do);
- TSQLRecord allows to be truly persistent agnostic: you may do the storage on a regular RDBMS engine, on a NoSQL database, or in memory, at runtime, without touching your DDD objects;
- Practice did show that introducing ORM concepts at DDD classes level: just think about how the ID field may break your modelization, since the same object may be a *Value Object* in a context (so without any ID), but an *Entity* or an *Aggregate* in another context (so an ID is probably needed there) - it does indeed break the *Persistence Ignorance* pattern, and tend to produce an *anemic domain model*, i.e. CRUD operations in disguise;
- TSQLRecord classes give you direct access to how your data will be actually stored: most ORMs, when dealing with complex classes (like our Domain objects), tend to hide the mapping complexity, and therefore make it difficult to debug and tune the storage itself: which object field is mapped to which column? which tables are involved and joined for the queries? - whereas TSQLRecord make it clear how data will actually been stored: you may consider the TSQLRecord properties as a map of the SQL storage columns, or as the document stored in a NoSQL engine - database reuse and tuning will definitively be easier, when the TSQLRecord type definition shows you e.g. where the indexes should be created;
- You are not tied to use TSQLRecord: you can easily define a mORMotDDD.pas CQRS repository service fully abstracted from mORMot's ORM, e.g. using existing tuned SQL statements, or any other mean of storage;
- Also consider that you are able to easily *Stubs and mocks* (page 408) the CQRS persistence service, whereas a direct ORM-oriented implementation will force you to create fake databases.

If you worry about performance of adding such a layer, you may be confident it won't be a bottleneck: the CQRS mapping shares the same code than the framework ORM for RTTI and marshalling. Mapping process is just a fast loop over the properties, using cached RTTI, and assigning all content by reference, avoiding most memory allocations or content transformation.

24.4.3.5.4.2. Define the Factory

Since the generated TSQLRecordUser type follows known conventions, the mORMotDDD.pas unit is able to do almost all the persistence work in an automated way, by inheriting of two classes:

- Defining a *Repository Factory* (i.e. a class able to generate IDomUserQuery or IDomUserCommand instances on requests) by inheriting from TDDDRepositoryRestFactory
- Defining the actual IDomUserCommand methods by inheriting from TDDDRepositoryRestCommand, and using high level protected methods to access the TUser from internal TSQLRecordUser ORM values.

First of all, we define the Factory:

```
type
  TInfraRepoUserFactory = class(TDDDRepositoryRestFactory)
  public
    constructor Create(aRest: TSQLRest; aOwner: TDDDRepositoryRestManager=nil); reintroduce;
  end;

constructor TInfraRepoUserFactory.Create(aRest: TSQLRest;
```

```
    aOwner: TDDDRepositoryRestManager);  
begin  
  inherited Create(IDomUserCommand, TInfraRepoUser, TUser, aRest, TSQLRecordUser, aOwner);  
  AddFilterOrValidate(['*'], TSynFilterTrim.Create);  
  AddFilterOrValidate(['LogonName'], TSynValidateNonVoidText.Create);  
end;
```

As you can see, the main point of this constructor is to supply the right parameters to the inherited `TDDDRepositoryRestFactory.Create`:

- We would like to implement a `IDomUserCommand` contract - and, by the way, implement also its parent `IDomUserQuery` interface;
- The actual implementation class will be `TInfraRepoUser` - which will be defined just after;
- The *Aggregate/Entity* class is a `TUser` kind of object;
- The associated `TSQLRest` server will be the one supplied to this class;
- The ORM class, defining the actual SQL table or NoSQL collection which will store the data, is `TSQLRecordUser`;
- An optional `TDDDRepositoryRestManager` instance may be supplied as owner of this factory - but it is not used in most cases.

The `AddFilterOrValidate()` method allows to set some *Filtering and Validating* (page 172) expectations at DDD level. Those rules will be applied before `Commit` will take place, without any use of the ORM rules. In the above code, `TSynFilterTrim` will remove any space from all text fields of the `TUser` instance, and `TSynValidateNonVoidText` will ensure that the `TUser.LogonName` field will not be ' ' - after space trimming. You may consider those rules as the SQL constraints you may be used to. But since they will be defined at DDD level, they will apply on any database back-end, even if it does not support any constraint - e.g. if it is a NoSQL engine, or a third-party persistence service you do not have the hand on.

You will probably want to use those CQRS interfaces, via usual IoC, at `TSQLRest` level, just like any *Client-Server services via interfaces* (page 420):

```
var cmd: IDomUserCommand;  
...  
aServer.Services.Resolve(IDomUserCommand, cmd);
```

or, for a *Query*:

```
var qry: IDomUserQuery;  
...  
aServer.Services.Resolve(IDomUserQuery, qry);
```

In order to be able to get a `IDomUserCommand` or `IDomUserQuery` instance from `aServer.Services.Resolve()`, you will need to register the `TInfraRepoUserFactory` first:

```
aServer.ServiceContainer.InjectResolver([TInfraRepoUserFactory.Create(aServer)], true);
```

or if you want to maintain the factory instance life-time (e.g. to share it with other interface resolvers):

```
var factory: TInfraRepoUserFactory;  
...  
factory := TInfraRepoUserFactory.Create(aServer);  
try  
  aServer.ServiceContainer.InjectResolver([factory]);  
...  
finally  
  factory.Free;  
end;
```

This single `TInfraRepoUserFactory` will allow to implement both `IDomUserCommand` and `IDomUserQuery` contracts.

Of course, having the ability to let `aServer` own the factory, via the `InjectResolver([...], true)`

parameter, sounds easier to work with.

In practice, for a Client/Server environment, you may write:

```
// Server side
RestServer := TSQLRestServerFullMemory.CreateWithOwnModel([TSQLRecordUser]);
...
RestServer.ServiceContainer.InjectResolver([TInfraRepoUserFactory.Create(RestServer)],true);
RestServer.ServiceDefine(TInfraRepoUser,[IDomUserCommand,IDomUserQuery],sicClientDriven);
// now you can use the services on the Server side
if RestServer.Services.Resolve(IDomUserCommand,cmd) then
  ... use cmd
if RestServer.Services.Resolve(IDomUserQuery,qry) then
  ... use qry
...
// Client side
RestClient := TSQLRestClientURIDll.Create(TSQLModel.Create(...),@URIRequest);
...
RestClient.ServiceDefine([IDomUserCommand],sicClientDriven);
// now you can use the services on the Client side
if RestServer.Services.Resolve(IDomUserCommand,cmd) then
  ... use cmd
if RestServer.Services.Resolve(IDomUserQuery,qry) then
  ... use qry
```

Note that `InjectResolver()` should be called *before* `ServiceDefine()`, otherwise the IoC won't take place as expected, and the `TInfraRepoUserFactory` class will be nil.

The CQRS services should be defined as `sicClientDriven` - and not as `sicSingle` or `sicShared`, since their lifetime is expected to be synchronized by the consumer side, i.e. the interface variable use on the client side.

On the client side, defining `IDomUserCommand` is enough to be able to use both `IDomUserCommand` and `IDomUserQuery` services, but on the server side you will have to explicitly define both interfaces, otherwise the Client/Server contracts won't match and you will not be able to use `IDomUserQuery` from the client side.

You could check the `TInfraRepoUserFactory.ReggressionTests` method, as defined in `dddInfraRepoUser.pas`, to find out how such services may be defined and consumed.

24.4.3.5.4.3. Implement the CQRS methods

We have defined the factory, and registered the services.

Now we define the needed methods of `IDomUserCommand` and `IDomUserQuery` in our custom class:

```
type
  TInfraRepoUser = class(TDDDRepositoryRestCommand,IDomUserCommand,IDomUserQuery)
  public
    function SelectByLogonName(const aLogonName: RawUTF8): TCQRSResult;
    function SelectByEmailValidation(aValidationState: TDomUserEmailValidation): TCQRSResult;
    function SelectByLastName(const aName: TLastName; aStartWith: boolean): TCQRSResult;
    function Get(out aAggregate: TUser): TCQRSResult;
    function GetAll(out aAggregates: TUserObjArray): TCQRSResult;
    function GetNext(out aAggregate: TUser): TCQRSResult;
    function Add(const aAggregate: TUser): TCQRSResult;
    function Update(const aUpdatedAggregate: TUser): TCQRSResult;
    function HowManyValidatedEmail: integer;
  end;
```

Note that we defined the `TInfraRepoUser` class as implementing both interface we need, via `= class(...,IDomUserCommand,IDomUserQuery)`. We need both types to be explicit in the class type definition, otherwise, IoC - i.e. `aServer.Services.Resolve()` calls - won't work for both.

As you can see, some methods appear to me missing. There is no Commit, nor Delete - which are required by IDomUserCommand. But in fact, those commands are so generic that they are already implemented for you in TDDRepositoryRestCommand!

What we need know is to implement those methods, using the internal protected ORM*() methods inherited by this parent class:

```
function TInfraRepoUser.SelectByLogonName(const aLogonName: RawUTF8): TCQRSResult;
begin
  result := ORMSelectOne('LogonName=?',[aLogonName],[aLogonName='']);
end;

function TInfraRepoUser.SelectByEmailValidation(aValidationState: TDomUserEmailValidation):
TCQRSResult;
begin
  result := ORMSelectAll('EmailValidated=?',[ord(aValidationState)]);
end;

function TInfraRepoUser.SelectByLastName(const aName: TLastName; aStartWith: boolean): TCQRSResult;
begin
  if aStartWith then
    result := ORMSelectAll('Name_Last LIKE ?',[aName+'%'],(aName='')) else
    result := ORMSelectAll('Name_Last=?',[aName],[aName='']);
end;

function TInfraRepoUser.Get(out aAggregate: TUser): TCQRSResult;
begin
  result := ORMGetAggregate(aAggregate);
end;

function TInfraRepoUser.GetAll(out aAggregates: TUserObjArray): TCQRSResult;
begin
  result := ORMGetAllAggregates(aAggregates);
end;

function TInfraRepoUser.GetNext(out aAggregate: TUser): TCQRSResult;
begin
  result := ORMGetNextAggregate(aAggregate);
end;

function TInfraRepoUser.Add(const aAggregate: TUser): TCQRSResult;
begin
  result := ORMAdd(aAggregate);
end;

function TInfraRepoUser.Update(const aUpdatedAggregate: TUser): TCQRSResult;
begin
  result := ORMUpdate(aUpdatedAggregate);
end;

function TInfraRepoUser.HowManyValidatedEmail: integer;
begin
  if ORMSelectCount('EmailValidated=?',[ord(evValidated)],[],result)<>cqrsSuccess then
    result := 0;
end;
```

Almost everything is already defined at TDDRepositoryRestCommand level. Our TInfraRepoUser class, implementing a full CQRS service, fully abstracted from the ORM, is implemented by a few internal ORM*() method calls.

All the error handling, including server-side exception catching, and conversion into TCQRSResult / ICQRSService.GetLastErrorInfo content, is already implemented in

TDDDRepositoryRestCommand.

All the data access via the TSQLRecordUser REST persistence layer, with any *Filtering and Validating* (page 172) defined rule, is also incorporated in TDDDRepositoryRestCommand. The conversion to/from TUser properties has been optimized, so that fields will be moved *by reference*, with no memory allocation nor content modification, for best performance and data safety. The type mapping specified by TInfraRepoUserFactory.Create is enough to make the whole process as automated as possible.

In fact, our TInfraRepoUser class is just a thin wrapper forcing use of strong typing in its methods parameters (i.e. using TUser/TUserObjArray whereas the ORM*() methods are more relaxed about actual typing), and ensuring that the ORM specificities are followed as expected, e.g. a search against the TUser.Name.Last DDD field will use the TSQLRecordUser.Name_Last ORM column, with the proper LIKE operator.

Internally, TDDDRepositoryRestCommand.ORMPrepareForCommit will call all DDD and ORM TSynFilter and TSynValidate rules, as previously defined. It sounds indeed like a real advantage not to wait until the database layer is reached, to have those constraints verified. The sooner an error is notified, the better - especially in a complex SOA system.

Under the hood, TDDDRepositoryRestCommand will define a TSqlRestBatch - see *BATCH sequences for adding/updating/deleting records* (page 351) - for storing all write commands in memory (as JSON) - e.g. cmd.Add - and will send them to the database engine, with optimized SQL or NoSQL statements, only when cmd.Commit will be executed.

24.4.3.6. Isolate your Domain using DTOs

DDD's *DTO* may also be defined as record, and directly serialized as JSON via text-based serialization. Don't be afraid of writing some translation layers between TSQLRecord and DTO records or, more generally, between your *Application layer* and your *Presentation layer*. It will be very fast, on the server side. If your service interfaces are cleaner, do not hesitate.

But defining *DTO* types, just for uncoupling, may become time consuming. If you start writing a lot of wrapping code, forget about it, and expose your Domain *Value Objects* or even your *Entities*, as stated above. Or automate the wrapper coding, using RTTI and code generators. You have to weight the PROs and the CONs, like always... And never forget to write proper unit testing of this marshalling code, since it may induce some unexpected issues.

If you expect your DDD's objects to be *schema-less* or with an evolving structure (e.g. for *DTO*), depending on each context, you may benefit of not using a fixed type like class or record, but use *TDocVariant custom variant type* (page 112). This kind of variant will be serialized as JSON, and allow late-binding access to its properties (for *object* documents) or items (for *array* documents). In the context of interface-based services, using *per-reference* option at creation (i.e. _ObjFast() _ArrFast() _JsonFast() _JsonFmtFast() functions) does make sense, in order to spare the server resources.

24.4.4. Defining services

In practice, mORMot's Client-Server architecture may be used as such:

- *Services via methods* - see *Client-Server services via methods* (page 374) - can be used to publish methods corresponding to your aggregate roots defined as TSQLRecord. This will make it pretty RESTful compatible.
- *Services via interfaces* - see *Client-Server services via interfaces* (page 420) - can be used to publish

all your processes.

Dedicated factories can be used on both Client and Server side, to define your repositories and/or domain operations.

Client-Server services via methods (page 374) may be preferred if you expect your service to be consumed in a truly RESTful way. But since in DDD you should better protect your *Domain* via a dedicated Adapter layer, such compatibility should be an implementation smell. In practice, *Client-Server services via interfaces* (page 420) will offer better integration and automation of its process, e.g. parameter type validation (with JSON marshalling), session handling, interface-level multi-threading and security abilities, logging, ability to be emulated via *Stubs and mocks* (page 408), and - last but not least - *Publish-subscribe for events* (page 449).

24.4.5. Event-Driven Design

Event-Driven could be implemented in *mORMot* by at least two ways:

- Using interface callbacks of the framework *Client-Server services via interfaces* (page 420);
- Storing the system *states* in a table, and let *Real-time synchronization* (page 183) generate the events.

Both ways have their own benefits and drawbacks, and you may pick up the one which match your particular use case. The first may be more easy to implement and versatile to use, but the second will work with *off-line* periods, and

24.4.5.1. Events as Callbacks

DDD's *Events* could easily be implemented as *Asynchronous callbacks* (page 445), when an interface callback is defined as *Service Methods Parameters* (page 424). In this case, the interface type will define the various DDD events, ready to be notified and propagated in real-time across the whole system.

An application layer may provide a specific callback to the domain, which will push the notification as a regular Delphi call, but in fact transmitted via *WebSockets* from the corresponding Domain Service to the right application layer. The current implementation relies on *WebSockets* for remote access, but other protocols may be available in the future, since interface parameters callbacks may be implemented by any actual transmission class.

No need to encapsulate your events within a dedicated message class (as most Event-Driven implementations require), or pollute your *Domain* code to follow a fixed protocol expectations: just run a notification method corresponding to the event, and you are done - all subscribers will be notified.

No need to put in production a Message bus, or a centralized system. Using callbacks, you will your outer layers (e.g. *Application* or *Presentation* layers) be cleanly notified by the Domain Services, without any waste of resource, and without potential bottleneck. Each node of your system will communicate directly with its subscriber, from a pure interface method call, as if it was a local process. See *Publish-subscribe for events* (page 449) for implementation details.

In practice, the callbacks may be propagated from the *Domain* layer to the *Application* or *Presentation* layers, which may also have their own callbacks definitions, using not *Domain* objects, but their own DTOs. Marshalling an event will be as easy as writing a class implementing an *I*Callback* interface as defined in the *Domain*, translating its parameters into the DTO types are defined for the outer *Application* or *Presentation* services.

On the server side, you may even define the callbacks in the very same process, without the *WebSockets* overhead, but calling directly the *Domain* services, whose interface type will be defined at *Domain* level, but the class type implemented at *Infrastructure* level:

- The application layer may be able to run directly the *Domain* code in its own service/daemon, calling the actual implementation at *Infrastructure* level, with a single straight *WebSockets* transmission - the DDD's *Adapters* types being pure Delphi classes, running in process, with no overhead.
- Or, you may gather *Domain* Services in some specific stand-alone daemons, which may be able to cache the events, and/or centralize some process - as a benefit, it may help those services be truly *stateless*, so the *Application* Layer may become redundant for better scaling.

Using interface values and call their methods is a natural way of writing callbacks in *Delphi* code, very close to the VCL/RAD Events you may be used to, but with the benefit of the abstraction of *Interfaces* (page 386), especially *SOLID design principles* (page 390). If your need is to react in real time to some change of the system, they are probably the preferred way.

24.4.5.2. Event Sourcing via Event Oriented Databases

Another new, and popular DDD's *Events* implementation pattern is to define some kind of event persistence, which will be used as *Event Sourcing*. Here, we won't rely on explicit messages to transmit the events (as we just proposed via asynchronous interface callbacks), but we will use some *state* storage in an *Event Oriented Persistence*, then let subscribers be notified for each state change.

In this pattern, there are not directly any kind of *Event* defined. The state of the *Domain* is stored somewhere, then any change of state should be notified to whom has interest for it. Obviously, one potential easy implementation may be via *Real-time synchronization* (page 183), as proposed by the framework.

The *Domain* services - see e.g. *Services* (page 602) or if you *Store your Entities in CQRS Repositories* (page 611) - may modify a dedicated *TSQLRecord* table, which will contain only a small part of the state of the model. For instance, its *TSQLRecord fields definition* (page 131) may store only a few evolving values, like the latest order placed, or the price of an item, or the connection state of a peripheral. The main point is to restrict the data stored to its minimum, e.g. this evolving value and the name (or ID) of the object.

Thanks to the framework *Real-time synchronization* (page 183), any client process or service, via its own *Slave* copy of this *TSQLRecord State* storage, will be notified asynchronously. This notification will reflect each change of state, and will let the consumer react as expected. One *OnNotify* event is available, to track each individual change of state, as specified as parameter to *TSQLRestServer.RecordVersionSynchronizeSlaveStart*.

When using *Events as Callbacks* (page 622), you may miss some events: if the consumer service is off-line, there won't be any event notified. It may be as expected, but may be a huge issue in some cases. On the other hand, the *Event Oriented Persistence* model will allow the consumers to be safely off-line at some time. Each ORM *Slave* will have its own copy of the data, then will be able to retrieve all the missed changes of state, when it goes on-line.

This implementation pattern is in fact the base of any true *Event Sourcing* process. Following this DDD pattern, each node of the system should *store* the data it needs. The system nodes won't ask for a given information (e.g. "What is the current temperature?"), but will be notified of each temperature change, then store the value, and being able to propagate any incoming events with almost no dependency. The main benefit is that you could add some node to the system, without any prior knowledge of what is already there. Such *Events-driven Architecture* (EDA) or *Domain Event Driven*

Service Oriented Architecture (D-EDA) may be complex to maintain and debug, once they reach a given size. For instance, some unexpected *Event Cascade* may happen, when you get a sequence of events triggering other events: you may induce an infinite rebound in the whole system. As a consequence, a "pure Event Driven" system will probably be a wrong idea. *Event Sourcing* may be introduced for some part of your *Domain*, where it does make better sense. See <http://martinfowler.com/eaDev/EventCollaboration.html> for more material.

As a side benefit, scaling of the whole system may be increased by this pattern. Each *Event State* storage may be seen as a safe cache of the system state, in the bounded context of a given set of values. When your business logic wonder about this particular state, it may ask this dedicated service, leveraging the main database. You may even consider storing the whole state history in a dedicated *Audit Trail for change tracking* (page 178) storage, without impacting the whole system.

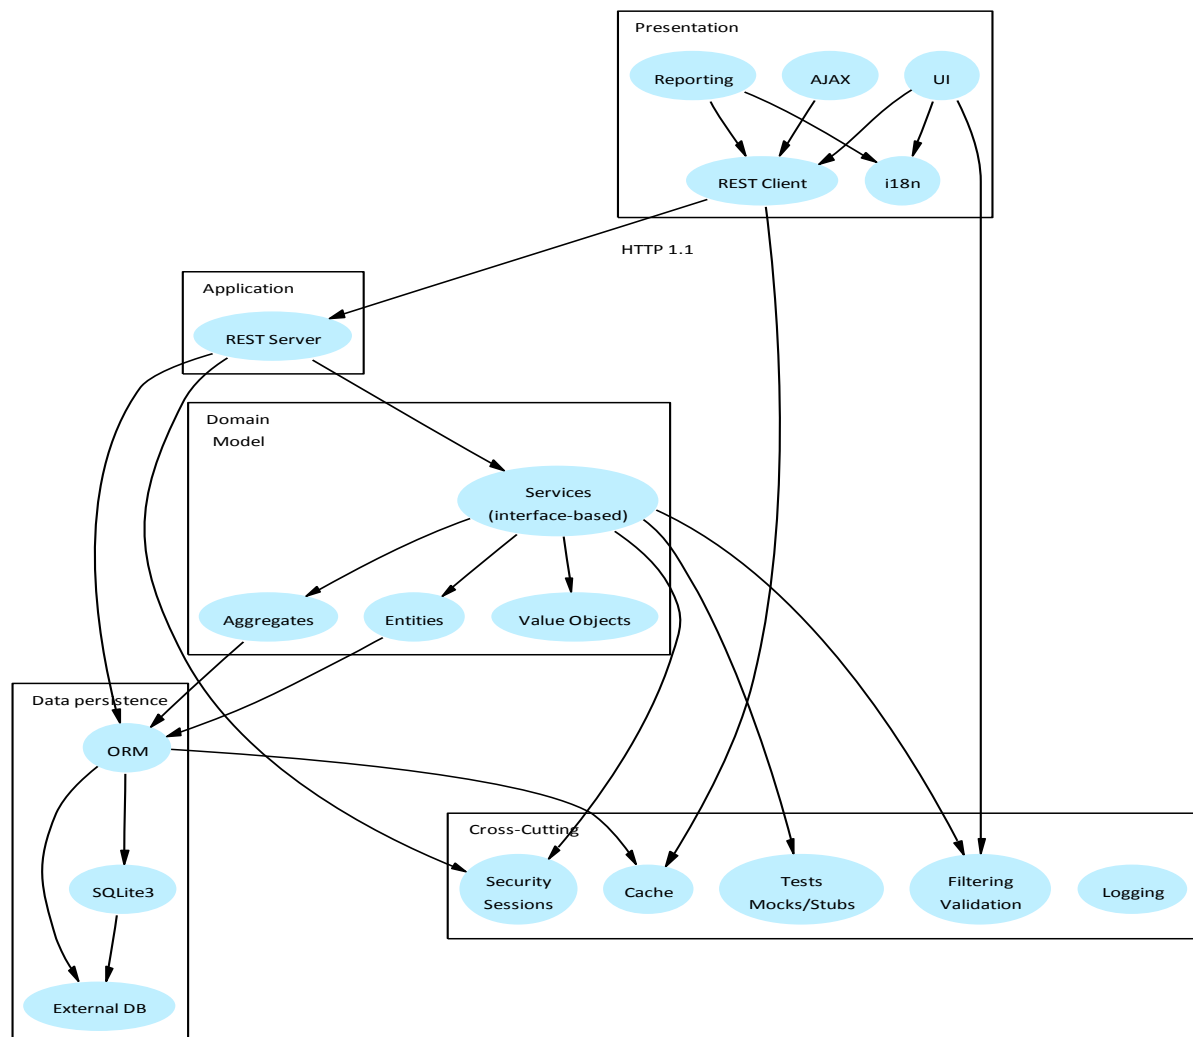

24.4.6. Building a Clean architecture

A common DDD architecture is expressed as in the following model, which may look like a regular *Multi-tier architecture* (page 88) design at first, but should be implemented as a *Clean Uncoupled Domain-Oriented Architecture* (page 604):

Layer	Description
Presentation	MVC UI generation and reporting
Application	Services and high-level adapters
Domain Model	Where business logic remains
Data persistence	ORM and external services
Cross-Cutting	Horizontal aspects shared by other layers

Physically, it involves a common *n-Tier* representation splitting the classical *Logic Tier* into two layers, i.e. *Application layer* and *Domain Model layer*. At *logical* level, DDD will try to uncouple the *Domain Model layer* from other layers, so the code itself will rely on interfaces and *dependency injection* to let the core *Domain* focus on the business logic, not on implementation details (e.g. persistence or communication).

The RESTful SOA components of our *Synopse mORMot framework* can therefore define such an Architecture:

Clean Domain-Oriented Architecture of mORMot

As we already stated, the main point of this *Clean Architecture* is to control coupling, and isolate the *Domain* core from the outer layers. In *Delphi*, unit dependencies (as displayed e.g. by our *SynProject* tool) will be a good testimony of proper objects uncoupling: in the units defining your domain, you may split it between *Domain Model* and *Domain Services* (the 2nd using the first, and not vice-versa), and you should *never* have any dependency to a particular DB unit, just to the framework's core units, i.e. *SynCommons.pas* and *mORMot.pas*. *Interfaces in practice: dependency injection, stubs and mocks* (page 407) - via *Client-Server services via interfaces* (page 420) or at ORM initialization level - will ensure that your code is uncoupled from any low-level technical dependency. It will also allow proper testing of your application workflows, e.g. stubbing the database if necessary.

In fact, since a *Service-Oriented Architecture (SOA)* (page 90) tends to ensure that services comprise unassociated, loosely coupled units of functionality that have no calls to each other embedded in them, we may define two levels of services, implemented by two interface factories, using their own hosting and communication:

- One set of services at *Application layer*, to define the uncoupled contracts available from Client applications;
- One set of services at *Domain Model layer*, which will allow all involved domains to communicate with each other, without exposing it to the remote clients.

Therefore, those layers could be also implemented as such:

Alternate Domain-Oriented Architecture of mORMot

In order to provide the better scaling of the server side, cache can be easily implemented at every level, and hosting can be tuned in order to provide the best response time possible: one central server, several dedicated servers for application, domain and persistence layers...

Due to the SOLID design of *mORMot* - see *SOLID design principles* (page 390) - you can use as many Client-Server services layers as needed in the same architecture (i.e. a Server can be a Client of other processes), in order to fit your project needs, and let it evolve from the simplest architecture to a full scalable *Domain-Driven* design.

25. Testing and logging

Adopt a mORMot

Since we covered most architectural and technical aspects of the framework, it is time to put the last missing bricks to the building, meaning testing and logging.

25.1. Automated testing

You know that testing is (almost) everything if you want to avoid regression problems in your application.

How can you be confident that any change made to your software code won't create any error in other part of the software?

Automated unit testing is a good candidate for avoiding any serious regression.

And even better, testing-driven coding can be encouraged:

- Write a void implementation of a feature, that is code the interface with no implementation;
- Write a test code;
- Launch the test - it must fail;
- Implement the feature;
- Launch the test - it must pass;
- Add some features, and repeat all previous tests every time you add a new feature.

It could sounds like a waste of time, but such coding improve your code quality a lot, and, at least, it help you write and optimize every implementation feature.

The framework has been implemented using this approach, and provide all the tools to write tests. In addition to what other *Delphi* frameworks offer (e.g. *DUnit* / *DUnitX*), the `SynTests.pas` unit is very much integrated with other elements of the framework (like logging), is cross-platform and cross-compiler, and provides a complete *stubbing* / *mocking* mechanism to cover *Interfaces in practice: dependency injection, stubs and mocks* (page 407).

25.1.1. Involved classes in Unitary testing

The `SynTests.pas` unit defines two classes (both inheriting from `TSynTest`), implementing a complete Unitary testing mechanism similar to *DUnit*, with less code overhead, and direct interface with the framework units and requirements (UTF-8 ready, code compilation from *Delphi* 6 up to the latest available *Delphi* version and FPC, no external dependency).

The following diagram defines this class hierarchy:

TSynTest classes hierarchy

The main usable class types are:

- `TSynTestCase`, which is a class implementing a test case: individual tests are written in the published methods of this class;
- `TSynTests`, which is used to run a suit of test cases, as defined with the previous class.

In order to define tests, some `TSynTestCase` children must be defined, and will be launched by a `TSynTests` instance to perform all the tests. A text report is created on the current console, providing statistics and Pass/Fail.

25.1.2. First steps in testing

Here are the functions we want to test:

```
function Add(A,B: double): Double; overload;
begin
  result := A+B;
end;

function Add(A,B: integer): integer; overload;
begin
  result := A+B;
end;

function Multiply(A,B: double): Double; overload;
begin
  result := A*B;
end;

function Multiply(A,B: integer): integer; overload;
begin
  result := A*B;
end;
```

So we create three classes one for the whole test suit, one for testing addition, one for testing multiplication:

```
type
  TTestNumbersAdding = class(TSynTestCase)
  published
    procedure TestIntegerAdd;
    procedure TestDoubleAdd;
  end;

  TTestNumbersMultiplying = class(TSynTestCase)
  published
    procedure TestIntegerMultiply;
    procedure TestDoubleMultiply;
  end;

  TTestSuit = class(TSynTests)
  published
    procedure MyTestSuit;
  end;
```

The trick is to create published methods, each containing some tests to process.

Here is how one of these test methods are implemented (I let you guess the others):

```
procedure TTestNumbersAdding.TestDoubleAdd;
var A,B: double;
    i: integer;
begin
  for i := 1 to 1000 do
  begin
    A := Random;
    B := Random;
    CheckSame(A+B,Adding(A,B));
  end;
end;
```

The CheckSame() is necessary because of floating-point precision problem, we can't trust plain = operator (i.e. Check(A+B=Adding(A,B)) will fail because of rounding problems).

And here is the test case implementation:

```
procedure TTestSuit.MyTestSuit;  
begin  
  AddCase([TTestNumbersAdding,TTestNumbersMultiplying]);  
end;
```

And the main program (this .dpr is expected to be available as a console program):

```
with TTestSuit.Create do  
try  
  ToConsole := @Output; // so we will see something on screen  
  Run;  
  readln;  
finally  
  Free;  
end;
```

Just run this program, and you'll get:

```
Suit  
-----  
  
1. My test suit  
  
1.1. Numbers adding:  
- Test integer add: 1,000 assertions passed 92us  
- Test double add: 1,000 assertions passed 125us  
Total failed: 0 / 2,000 - Numbers adding PASSED 360us  
  
1.2. Numbers multiplying:  
- Test integer multiply: 1,000 assertions passed 73us  
- Test double multiply: 1,000 assertions passed 117us  
Total failed: 0 / 2,000 - Numbers multiplying PASSED 324us  
  
Generated with: Delphi 7 compiler  
  
Time elapsed for all tests: 1.51ms  
Tests performed at 25/03/2014 10:59:33  
  
Total assertions failed for all test suits: 0 / 4,000  
All tests passed successfully.
```

You can see that all text on screen was created by "UnCamelCasing" the method names (thanks to our good old Camel), and that the test suit just follows the order defined when registering the classes. Each method has its own timing, which is pretty convenient to track performance regressions.

This test program has been uploaded in the SQLite3\Sample\07 - SynTest folder of the Source Code Repository.

25.1.3. Framework test coverage

The SAD # DI-2.2.2 (page 2559) defines all classes released with the framework source code, which covers all core aspects of the framework. Global testing coverage is good, excellent for core components (more than 25,000,000 individual checks are performed for revision 1.18), but there is still some User-Interface related tests to be written.

Before any release all unitary regression tests are performed with the following compilers:

- Delphi 5 (for a limited scope, including SynCommons.pas, SynLog.pas, SynTests.pas, SynCrypto.pas, SynEcc.pas, SynPdf.pas and SynDB.pas);

- *Delphi 6*;
- *Delphi 7*, with and without our Enhanced Run Time Library;
- *Delphi 2007*;
- *Delphi 2010* (we assume that if it works with *Delphi 2010*, it will work with *Delphi 2009*, with the exception of generic compilation);
- *Delphi XE4*;
- *Delphi XE7*;
- *Delphi XE8*;
- *Delphi 10.3 Rio*;
- *Delphi 10.4 Sydney*;
- *CrossKylix 3.0*;
- *FPC 3.x* - preferred is *3.2 fixes*.

Target platforms are *Win32* and *Win64* for *Delphi* and *FPC*, plus *Linux 32/64* for *FPC* and *CrossKylix*.

Then all sample source code (including the *Main Demo* and *SynDBExplorer* sophisticated tools) are compiled, and user-level testing is performed against those applications.

You can find in the `compil.bat` and `compilpil.bat` files of our source code repository how incremental builds and tests are performed.

25.2. Enhanced logging

A logging mechanism is integrated with cross-cutting features of the framework. It includes stack trace exception and such, just like *MadExcept*, using *.map* file content to retrieve debugging information from the source code.

Here are some of its features:

- Logging with a *set* of levels, not only a level scale;
- Fast, low execution overhead;
- Can load *.map* file symbols to be displayed in logging (i.e. source code file name and line numbers are logged instead of a hexadecimal value);
- Compression of *.map* into binary *.mab* (900 KB -> 70 KB);
- Inclusion of the *.map*/*.mab* into the *.exe*, with very slow size increase;
- Exception logging (*Delphi* or low-level exceptions) with unit names and line numbers;
- Optional stack trace with units and line numbers;
- Methods or procedure recursive tracing, with *Enter* and *auto-Leave* (using a fake interface instance);
- High resolution time stamps, for customer-side profiling of the application execution;
- Set / enumerates / TList / TPersistent / TObjectList / dynamic array JSON serialization;
- Per-thread or global logging;
- Optional multiple log files on the same process;
- Optional rotation when main log reaches a specified size, with compression of the rotated logs;
- Integrated log archival (in *.zip* or any other format, including our *.synlz*);
- Optional colored echo to a console window, for interactive debugging;
- Fast log viewer tool available, including thread filtering and customer-side execution profiling;
- Optional remote logging via HTTP - the log viewer can be used as server;
- Optional events transmission to a UDP syslog server.

25.2.1. Setup logging

Logging is defined mainly by a per-class approach. You usually define your logging expectations by using a *TSynLog* class, and setting its *Family* property. Note that it is perfectly feasible to use you own *TSynLog* class instance, with its own *TSynLog* family settings, injected at the constructor level; but in *mORMot*, we usually use the per-class approach, via *TSynLog*, *TSQLLog*, *SynDBLog* and *SQLite3Log* - see below (page 642).

For sample code (and the associated log viewer tool), see "*11 - Exception logging*" folder in "*Sqlite3\Samples*".

In short, you can add logging to your program, just by using the *TSynLog* class, as such:

```
TSynLog.Add.Log(sllInfo,Stats.DebugMessage);
```

This line will log the *Stats.DebugMessage* text, with a *sllInfo* notification level. See the description of all *Log()* overloaded methods of the *ISynLog* interface, to find out how your project can easily log events.

First of all, you need to define your logging setup via code:

```
with TSynLog.Family do begin
  Level := LOG_VERBOSE;
  //Level := [sllException,sllExceptionOS];
  //HighResolutionTimestamp := true;
  //AutoFlushTimeOut := 5;
```

```
OnArchive := EventArchiveSynLZ;  
//OnArchive := EventArchiveZip;  
ArchiveAfterDays := 1; // archive after one day  
end;
```

The main setting here is `TSynLog.Family.Level := ...` which defines which levels are to be logged. That is, if `sllInfo` is part of `TSynLog.Family.Level`, any `TSynLog.Add.Log(sllInfo,...)` command will log the corresponding content - otherwise, it will be a no-operation. `LOG_VERBOSE` is a constant setting all levels at once.

You have several debugging levels available, and even 4 custom types:

```
TSynLogInfo = (  
  sllNone, sllInfo, sllDebug, sllTrace, sllWarning, sllError,  
  sllEnter, sllLeave,  
  sllLastError, sllException, sllExceptionOS, sllMemory, sllStackTrace,  
  sllFail, sllSQL, sllCache, sllResult, sllDB, sllHTTP, sllClient, sllServer,  
  sllServiceCall, sllServiceReturn, sllUserAuth,  
  sllCustom1, sllCustom2, sllCustom3, sllCustom4, sllNewRun);
```

Here are the purpose of each logging level:

- `sllInfo` will log general information events;
- `sllDebug` will log detailed debugging information;
- `sllTrace` will log low-level step by step debugging information;
- `sllWarning` will log unexpected values (not an error);
- `sllError` will log errors;
- `sllEnter` will log every method start;
- `sllLeave` will log every method quit;
- `sllLastError` will log the `GetLastError` OS message;
- `sllException` will log all exception raised - available since Windows XP;
- `sllExceptionOS` will log all OS low-level exceptions (`EDivByZero`, `ERangeError`, `EAccessViolation...`);
- `sllMemory` will log memory statistics;
- `sllStackTrace` will log caller's stack trace (it is by default part of `TSynLogFamily.LevelStackTrace` like `sllError`, `sllException`, `sllExceptionOS`, `sllLastError` and `sllFail`);
- `sllFail` was defined for `TSynTestsLogged`. Failed method, and can be used to log some customer-side assertions (may be notifications, not errors);
- `sllSQL` is dedicated to trace the SQL statements;
- `sllCache` should be used to trace any internal caching mechanism (it is used for instance by our SQL statement caching);
- `sllResult` could trace the SQL results, JSON encoded;
- `sllDB` is dedicated to trace low-level database engine features;
- `sllHTTP` could be used to trace HTTP process;
- `sllClient/sllServer` could be used to trace some Client or Server process;
- `sllServiceCall/sllServiceReturn` to trace some remote service or library;
- `sllUserAuth` to trace user authentication (e.g. for individual requests);
- `sllCustom1..sllCustom4` items can be used for any purpose by your programs;
- `sllNewRun` will be written when a process re-opens a rotated log.

Logging is not using directly a `TSynLogInfo` level, but the following set:

```
/// used to define a Logging Level  
// - i.e. a combination of none or several Logging event  
// - e.g. use LOG_VERBOSE constant to Log all events  
TSynLogInfos = set of TSynLogInfo;
```

Most logging tools in the wild use a level scale, i.e. with a hierarchy, excluding the lower levels when

one is selected.

Our logging classes use a *set*, and not directly a particular level, so you are able to select which exact events are worth recording. In practice, we found this pattern to make a lot of sense and to be much more efficient for support.

25.2.2. Call trace

The logging mechanism can be used to trace recursive calls. It can use an interface-based mechanism to log when you enter and leave any method:

```
procedure TMyDB.SQLExecute(const SQL: RawUTF8);
var ILog: ISynLog;
begin
  ILog := TSynLogDB.Enter(self, 'SQLExecute');
  // do some stuff
  ILog.Log(sllInfo, 'SQL=%', [SQL]);
end; // when you leave the method, it will write the corresponding event to the log
```

It will be logged as such:

```
20110325 19325801 + MyDBUnit.TMyDB(004E11F4).SQLExecute
20110325 19325801 info SQL=SELECT * FROM Table;
20110325 19325801 -
```

Note that by default you have human-readable *time and date* written to the log, but it is also possible to replace this timing with *high-resolution timestamps*. With this, you'll be able to profile your application with data coming from the customer side, on its real computer. Via the Enter method (and its *auto-Leave* feature), you have all information needed for this.

25.2.3. Including symbol definitions

In the above logging content, the method name is set in the code (as 'SQLExecute'). But if the logger class is able to find a .map file associated to the .exe, the logging mechanism is able to read this symbol information, and write the exact line number of the event.

By default, the .map file information is not generated by the compiler. To force its creation, you must ensure the {\$D+} compiler directive is set in every unit (which is the case by default, unless you set {\$D-} in the source), and the "Detailed Map File" option selected in the *Project > Options > Linker* page of the *Delphi IDE*.

In the following log entries, you'll see both high-resolution time stamp, and the entering and leaving of a TTestCompression.TestLog method traced with no additional code (with accurate line numbers, extracted from the .map content):

```
000000000000B56 + TTestCompression(00AB3570).000E6C79 SynSelfTests.TTestCompression.TestLog
(376)
0000000000001785 -
```

There is already a dedicated TSynLogFile class able to read the .log file, and recognize its content.

The first time the .map file is read, a .mab file is created, and will contain all symbol information needed. You can send the .mab file with the .exe to your client, or even embed its content to the .exe (see the Map2Mab.dpr sample file located in the Samples\11 - Exception logging\ folder).

This .mab file is very optimized: for instance, a .map of 927,984 bytes compresses into a 71,943 .mab file.

25.2.4. Exception handling

Of course, this logging mechanism is able to intercept the raise of exceptions, including the worse (e.g. `EAccessViolation`), to be logged automatically in the log file, as such:

```
00000000000090B EXCOS EAccessViolation (C0000005) at 000E9C7A SynSelfTests.Proc1 (785) stack trace
000E9D51 SynSelfTests.Proc2 (801) 000E9CC1 SynSelfTests.Proc1 (790) 000E9D51 SynSelfTests.Proc2 (801)
000E9CC1 SynSelfTests.Proc1 (790) 000E9D51 SynSelfTests.Proc2 (801) 000E9CC1 SynSelfTests.Proc1 (790)
000E9D51 SynSelfTests.Proc2 (801) 000E9CC1 SynSelfTests.Proc1 (790) 000E9D51 SynSelfTests.Proc2 (801)
000E9CC1 SynSelfTests.Proc1 (790) 000E9E2E SynSelfTests.TestsLog (818) 000EA0FB SynSelfTests (853)
00003BF4 System.InitUnits 00003C5B System.@StartExe 000064AB SysInit.@InitExe 000EA3EC TestSQL3 (153)
```

The `TSynLogInfo` logging level makes a difference between high-level *Delphi* exceptions (`sllException`) and lowest-level OS exceptions (`sllExceptionOS`) like `EAccessViolation`.

For instance, if you add to your program:

```
uses
  SynLog;
(...)
TSynLog.Family.Level := [sllExceptionOS];
```

all OS exceptions (excluding pure *Delphi* exception like `EConvertError` and such) will be logged to a separated log file.

```
TSynLog.Family.Level := [sllException, sllExceptionOS];
```

will trace also *Delphi* exceptions, for instance.

You can specify some Exception class to be ignored, by adding them to `Family.ExceptionIgnore` internal list. It could make sense to add this setting, if your code often triggers some non-breaking exceptions, e.g. with `StrToInt()`:

```
TSynLog.Family.ExceptionIgnore.Add(EConvertError);
```

If your *Delphi* code executes some *.Net* managed code (e.g. exposed via some COM wrapper components), the unit is able to recognize most un-handled *.Net* exceptions, and log them with their original C# class name (for instance, `EoleSysError 80004003` will be recorded as a much more user-friendly "[.NET/CLR unhandled ArgumentNullException]" message.

You can set the following global variable to assign a customized callback, and be able to customize the logging content associated to any exception:

```
type
  /// global hook callback to customize exceptions logged by TSynLog
  /// - should return FALSE if Context.EAddr and Stack trace is to be appended
  TSynLogExceptionToStr = function(WR: TTextWriter; const Context: TSynLogExceptionContext): boolean;

var
  /// allow to customize the Exception logging message
  TSynLogExceptionToStrCustom: TSynLogExceptionToStr = nil;
```

The `Context: TSynLogExceptionContext` content is to be used to append some text to the specified `TTextWriter` instance.

An easier possibility is to inherit your custom exception class from `ESynException`, and override its unique virtual method:

```
/// generic parent class of all custom Exception types of this unit
ESynException = class(Exception)
public
  /// can be used to customize how the exception is logged
  /// - this default implementation will call the DefaultSynLogExceptionToStr()
  /// callback or TSynLogExceptionToStrCustom, if defined
  /// - override this method to provide a custom logging content
  /// - should return TRUE if Context.EAddr and Stack trace is not to be
  /// written (i.e. as for any TSynLogExceptionToStr callback)
```

```
function CustomLog(WR: TTextWriter; const Context: TSynLogExceptionContext): boolean; virtual;
end;
```

See `TSynLogExceptionContext` to check the execution context, and the implementation of the function `DefaultSynLogExceptionToStr()` function.

25.2.5. Serialization

dynamic arrays can also be serialized as JSON in the log on request, via the default `TSynLog` class, as defined in `SynLog.pas` unit - see *TDynArray dynamic array wrapper* (page 107).

The `TSQLLog` class (using the enhanced RTTI methods defined in `mORMot.pas` unit) is even able to serialize `TSQLRecord`, `TPersistent`, `TList` and `TCollection` instances as JSON, or any other class instance, after call to `TJSONSerializer.RegisterCustomSerializer`.

For instance, the following code:

```
procedure TestPeopleProc;
var People: TSQLRecordPeople;
    Log: ISynLog;
begin
  Log := TSQLLog.Enter;
  People := TSQLRecordPeople.Create;
  try
    People.ID := 16;
    People.FirstName := 'Louis';
    People.LastName := 'Croivébaton';
    People.YearOfBirth := 1754;
    People.YearOfDeath := 1793;
    Log.Log(sllInfo, People);
  finally
    People.Free;
  end;
end;
```

will result in the following log content:

```
0000000000001172 + 000E9F67 SynSelfTests.TestPeopleProc (784)
000000000000171B info
{"TSQLRecordPeople(00AB92E0)":{"ID":16,"FirstName":"Louis","LastName":"Croivébaton","Data":"","YearOfBirth":1754,"YearOfDeath":1793}}
0000000000001731 -
```

25.2.6. Multi-threaded applications

You can define several log files per process, and even a per-thread log file, if needed (it could be sometimes handy, for instance on a server running the same logic in parallel in several threads).

The logging settings are made at the logging class level. Each logging class (inheriting from `TSynLog`) has its own `TSynLogFamily` instance, which is to be used to customize the logging class level. Then you can have several instances of the individual `TSynLog` classes, each class sharing the settings of the `TSynLogFamily`.

You can therefore initialize the "family" settings before using logging, like in this code which will force to log all levels (`LOG_VERBOSE`), and create a per-thread log file, and write the `.log` content not in the `.exe` folder, but in a custom directory:

```
with TSynLogDB.Family do
begin
  Level := LOG_VERBOSE;
  PerThreadLog := ptOneFilePerThread;
  DestinationPath := 'C:\Logs';
end;
```

If you specifies `PerThreadLog := ptIdentifiedInOnFile` for the family, a new column will be added for each log row, with the corresponding `ThreadID` - the supplied `LogView` tool will handle it as expected. This can be very useful for a multi-threaded server process, e.g. as implement with *mORMot's Client-Server classes* *Client-Server process* (page 319).

25.2.7. Log to the console

For debugging purposes, it could be very handy to output the logging content to a console window. It enables interactive debugging of a Client-Server process, for instance: you can interact with the Client, then look in real time at the server console window, and inspect which requests are processed, without the need to open the log file.

The `EchoToConsole` property enable you to select which events are to be echoed on the console (perhaps you expect only errors to appear, for instance).

```
with TSQLLog.Family do begin
  Level := LOG_VERBOSE;
  EchoToConsole := LOG_VERBOSE; // Log all events to the console
end;
```

Depending on the events, colors will be used to write the corresponding information. Errors will be displayed as light red, for instance.

Note that this echoing process slow down the logging process a lot, since it is currently implemented in a blocking mode, and writing to the console under *Windows* is much slower than writing to a file. This feature is therefore disabled by default, and not to be enabled on a production server, but only to make interactive debugging easier.

25.2.8. Remote logging

By default, `TSynLog` writes its activity to a local file, and/or to the console. The log file can be transmitted later on (once compressed) to support, for further review and debugging. But sometimes, it may be handy to see the logging in real-time, on a remote computer.

You can enable such remote monitoring for a given `TSynLog` class, by adding the `mORMotHTTPClient.pas` unit in your use clause, then calling the following constructor:

```
TSQLHttpClient.CreateForRemoteLogging('192.168.1.15',SQLite3Log,'8091','LogService');
```

This command will let any `SQLite3Log` event be sent to a remote server running at `http://192.168.1.15:8091/LogService/RemoteLog` - in fact this should be a *mORMot* server, but may be any REST server, able to answer to a PUT command sent to this URI.

A `TSQLHttpClient` instance will be created, and will be managed by the `SQLite3Log` instance. It will be released when the application will be closed, or when the `SQLite3Log.Family.EchoRemoteStop` method will be called.

In practice, our *Log View* tool - see below (page 640) - is able to run as a compatible remote server. Execute the tool, set the expected *Server Root* name ('LogService' by default), and the expected *Server Port* (8091 by default), then click on the "Server Launch" button.

The *Log View* tool will now display in real time all incoming events, search into their content, and allow to save all received events into a regular `.log` or `.synlz` file, for further archiving and study.

Note that since the *Log View* tool will run a `http.sys` based server - see *High-performance http.sys server* (page 327) - you may have to run once the tool with administrator rights, to register the *Server Root / Server Port* combination for binding.

Implementation of this remote logging has been tuned on both client and server side.

On client side, log events are gathered and sent in a dedicated background thread: if a lot of events are generated, they will be transferred in chunks of several rows, to minimize resource and bandwidth. On server side, incoming events are stored in memory, and indexed on the fly, with a periodic refresh rate of 500 ms: even a very active client logger will just let the *Log View* tool be responsive and efficient.

Thanks to the nature of the `http.sys` based server, several *Server Root* URI can be accessed in parallel with several *Log View* tool instance, on the same HTTP port: it will ease the IT policy of your network, since a single forwarded port will be able to handle several incoming connections.

See the "RemoteLoggingTest.dpr" sample from "11 - Exception logging", in conjunction with the *LogView.dpr* tool available in the same folder, for a running example of remote logging.

Note that our cross-platform clients - see *Cross-Platform clients* (page 482) - are able to log to a remote server, with the same exact format as used by our *TSynLog* class.

25.2.9. Log to third-party libraries

Our *TSynLog* class was designed to write its information to a file, and optionally to the console or a remote log server (as we just saw). In fact, *TSynLog* is extensively used by the *mORMot* framework to provide various levels of details on what happens behind the scene: it is great for debugging purposes.

It may be convenient to let *TSynLog* work with any third party logging applications such as *CodeSite* or *SmartInspect*, or any proprietary solution. As a result, *mORMot* logs can be mixed with existing application logs.

You can define the *TSynLogFamily.EchoCustom* property to specify a simple event to be triggered for each log operation: the application can then decide to log to a third party logger application.

Note that there is also the *TSynLogFamily.NoFile* property, which allows to disable completely the built-in file logging mechanism.

For instance, you may write:

```
procedure TMyClass.Echo(Sender: TTextWriter; Level: TSynLogInfo; const Text: RawUTF8);
begin
  if Level in LOG_STACKTRACE then // filter only errors
    writeln(Text); // could be any third-party logger
end;

...
with TSQLLog.Family do begin
  Level := LOG_VERBOSE;
  // EchoToConsole := LOG_VERBOSE; // Log all events to the console
  EchoCustom := aMyClass.Echo; // register third-party logger
  NoFile := true; // ensure TSynLog won't use the default log file
end;
```

A process similar to *TSynLogFile.ProcessOneLine()* could then parse the incoming *Text* value, if needed.

25.2.10. Automated log archival

Log archives can be created with the following settings:

```
with TSynLogDB.Family do
begin
  (...)
```

```
OnArchive := EventArchiveZip;  
ArchivePath := '\\Remote\WKS2302\Archive\Logs'; // or any path  
end;
```

The ArchivePath property can be set to several functions, taking a timeout delay from the ArchiveAfterDays property value:

- nil is the default value, and won't do anything: the .log will remain on disk until they will be deleted by hand;
- EventArchiveDelete in order to delete deprecated .log files;
- EventArchiveSynLZ to compress the .log file into a proprietary *SynLZ* format: resulting file name will be located in ArchivePath\log\YYYYMM*.log.synlz, and the command-line UnSynLz.exe tool (calling FileUnSynLZ function of SynCommons.pas unit) can be used to uncompress it in to plain .log file;
- SynZip.EventArchiveZip will archive the .log files in ArchivePath\log\YYYYMM.zip files, grouping every .

SynLZ files are less compressed, but created much faster than .zip files. However, .zip files are more standard, and on a regular application, compression speed won't be an issue for the application.

25.2.11. Log files rotation

You can set TSynLogFamily.RotateFileCount and RotateFileSizeKB properties, to enable log file rotation:

- If both values are > 0, the log file will have a fixed name, without any time-stamp within;
- RotateFileSizeKB will define the maximum size of the main uncompressed log file
- RotateFileCount will define how many files are kept on disk - note that rotated files are compressed using *SynLZ*, so compression will be very fast.

Log file rotation is as easy as:

```
with TSQLLog.Family do begin  
  Level := LOG_VERBOSE;  
  RotateFileCount := 5;           // will maintain a set of up to 5 files  
  RotateFileSizeKB := 20*1024; // rotate by 20 MB logs  
end;
```

Such a logging definition will create those files on disk, e.g. for the TestSQL3.dpr regression tests:

- TestSQL3.log which will be the latest (current) log file, uncompressed;
- TestSQL3.1.synlz to TestSQL3.4.synlz will be the 4 latest log files, after compression. Our *Log Viewer* tool - see below (page 640) - is able to uncompress those .synlz files directly.

Note that as soon as you active file rotation, PerThreadLog = ptOneFilePerThread and HighResolutionTimestamp properties will be ignored, since both features expect a single file to exist per TSynLog class.

As an alternative, or in addition to this *by-size* rotation pattern, you could specify a fixed time of the day to perform the rotation.

For instance, the following will perform automatic rotation of the log files, whatever their size, at 23:00 each evening:

```
with TSQLLog.Family do begin  
  Level := LOG_VERBOSE;  
  RotateFileCount := 5;           // will maintain a set of up to 5 files  
  RotateFileDailyAtHour := 23; // rotate at 11:00 PM  
end;
```

If the default behavior - which is to compress all rotated files into .synlz format, and delete the older files - does not fit your needs, you can set a custom event to the TSynLogFamily.OnRotate property,

which will take care of the file rotation process.

25.2.12. Integration within tests

Logging is integrated within the unit testing classes, so that any failure will create an entry in the log with the source line, and stack trace:

```
C:\Dev\lib\SQLite3\exe\TestSQL3.exe 0.0.0.0 (2011-04-13)
Host=Laptop User=MyName CPU=2*0-15-1027 OS=2.3=5.1.2600 Wow64=0 Freq=3579545
TSynLogTest 1.13 2011-04-13 05:40:25

20110413 05402559 fail TTestLowLevelCommon(00B31D70) Low level common: TDynArray "dynamic array
failure" stack trace 0002FE0B SynCommons.TDynArray.Init (15148) 00036736 SynCommons.Test64K (18206)
0003682F SynCommons.TTestLowLevelCommon._TDynArray (18214) 000E9C94 TestSQL3 (163)
```

The difference between a test suit without logging (TSynTests) and a test suit with logging (TSynTestsLogged) is only this overridden method:

```
procedure TSynTestsLogged.Failed(const msg: string; aTest: TSynTestCase);
begin
  inherited;
  with TestCase[fCurrentMethod] do
    fLogFile.Log(sllFail, '%: % "%"',
      [Ident, TestName[fCurrentMethodIndex], msg], aTest);
end;
```

In order to enable tests logging, you have just to enable it, e.g. with:

```
TSynLogTestLog.Family.Level := LOG_VERBOSE;
```

You can optionally redirect the following global variable at program initialization, to share testing events with the main *mORMot* logs:

```
with TSQLLog.Family do begin
  Level := LOG_VERBOSE;
  TSynLogTestLog := TSQLLog; // share the same log file with whole mORMot
end;
```

25.2.13. Log Viewer

Since the log files tend to be huge (for instance, if you set the logging for our unitary tests, the 17,000,000 test cases do create a huge log file of about 550 MB), a log viewer was definitively in need.

The log-viewer application is available as source code in the "*Samples*" folder, in the "*11 - Exception logging*" sub-folder.

25.2.13.1. Open log files

You can run it with a specified log file on the command line, or use the "*Browse*" button to browse for a file. That is, you can associate this tool with your .log files, for instance, and you'll open it just by double-clicking on such files.

Note that if the file is not in our TSynLog format, it will still be opened as plain text. You'll be able to browse its content and search within, but all the nice features of our logging won't be available, of course.

It is worth saying that the viewer was designed to be *fast*.

In fact, it takes no time to open any log file. For instance, a 390 MB log file is opened in less than one second on my laptop. Under Windows Seven, it takes more time to display the "Open file" dialog window than reading and indexing the 390 MB content.

It uses internally memory mapped files and optimized data structures to access to the data as fast as

possible - see TSynLogFile class.

25.2.13.2. Log browser

The screen is divided into three main spaces:

- On the left side, the panel of commands;
- On the right side, the log events list;
- On the middle, an optional list of method calls, and another list of threads (not shown by default).

The command panel allows to *Browse* your disk for a .log file. This button is a toggle of an optional *Drive / Directory / File* panel on the leftmost side of the tool. When a .log / .synlz / .txt file is selected, its content is immediately displayed. You can specify a directory name as a parameter of the tool (e.g. in a .lnk desktop link), which will let the viewer be opened in "Browse" mode, starting with the specified folder.

A button gives access to the global *Stats* about its content (customer-side hardware and software running configuration, general numbers about the log), and even ask for a source code line number and unit name from a hexadecimal address available in the log, by browsing for the corresponding .map file (could be handy if you did not deliver the .map content within your main executable - which you should have to).

Just below the "Browse" button, there is an edit field available, with a ? button. Enter any text within this edit field, and it will be searched within the log events list. Search is case-insensitive, and was designed to be fast. Clicking on the ? button (or pressing the F3 key) allows to repeat the last search.

In the very same left panel, you can see all existing events, with its own color and an associated check-box. Note that only events really encountered in the .log file appear in this list, so its content will change between log files. By selecting / un-selecting a check-box, the corresponding events will be instantaneously displayed / or not on the right side list of events. You can right click on the events check-box list to select a predefined set of events.

The right colored event list follows the events appended to the log, by time order. When you click on an event, its full line content is displayed at the bottom on the screen, in a memo.

Having all SQL / NoSQL and Client-Server events traced in the log is definitively a huge benefit for customer support and bug tracking.

25.2.13.3. Customer-side profiler

One distinctive feature of the TSynLog logging class is that it is able to map methods or functions entering/leaving (using the Enter method), and trace this into the logs. The corresponding timing is also written within the "Leave" event, and allows application profiling from the customer side. Most of the time, profiling an application is done during the testing, with a test environment and database. But this is not, and will never reproduce the exact nature of the customer use: for instance, hardware is not the same (network, memory, CPU), nor the software (Operating System version, [anti-]virus installed)... By enabling customer-side method profiling, the log will contain all relevant information. Those events are named "Enter" / "Leave" in the command panel check-box list, and written as + and - in the right-sided event list.

The "Methods profiler" options allow to display the middle optional method calls list. Several sort order are available: by name (alphabetical sort), by occurrence (in running order, i.e. in the same order than in the event log), by time (the full time corresponding to this method, i.e. the time written within the "Leave" event), and by proper time (i.e. excluding all time spent in the nested methods).

The "*Merge method calls*" check-box allows to regroup all identical method calls, according to their name. In fact, most methods are not called once, but multiple time. And this is the accumulated time spent in the method which is the main argument for code profiling.

I'm quite sure that the first time you'll use this profiling feature on a huge existing application, you'll find out some bottlenecks you will have never thought about before.

25.2.13.4. Per-thread inspection

If the TSynLog family has specified `PerThreadLog := ptIdentifiedInOnFile` property, a new column will be added for each log row, with the corresponding ThreadID of the logged action.

The log-viewer application will identify this column, and show a "*Thread*" group below the left-side commands. It will allow to go to the next thread, or toggle the optional *Thread view* list. By checking / un-checking any thread of this list, you are able to inspect the execution log for a given process, very easily. A right-click on this thread list will display a pop-up menu, allowing to select all threads or no thread in one command.

25.2.13.5. Server for remote logging

As was stated above, *Remote logging* (page 637) can use our *Log View* tool as server and real-time viewer for any remote client, either using TSynLog, or any cross-platform client - see *Cross-Platform clients* (page 482).

Using a remote logging is specially useful from mobile applications (written with *Delphi* / *FireMonkey* or with *Smart Mobile Studio* / *AJAX*). Our viewer tool allows efficient live debugging of such platforms.

25.2.14. Framework log integration

The framework makes an extensive use of the logging features implemented in the `SynLog.pas` unit - see *Enhanced logging* (page 632).

In its current implementation, the framework is able to log on request:

- Any exceptions triggered during process, via `s11Exception` and `s11ExceptionOS` levels;
- Client and server RESTful URL methods via `s11Client` and `s11Server` levels;
- SQL executed statements in the *SQLite3* engine via the `s11SQL` level;
- JSON results when retrieved from the *SQLite3* engine via the `s11Result` level;
- Main errors triggered during process via `s11Error` level;
- Security User authentication and session management via `s11UserAuth`;
- Some additional low-level information via `s11Debug`, `s11Warning` and `s11Info` levels.

Those levels are available via the `TSQLLog` class, inheriting from `TSynLog`, as defined in `mORMot.pas`.

Three main `TSynLogClass` global variables are defined in order to use the same logging family for the whole framework. Since `mORMot` units are decoupled (e.g. Database or ORM/SOA), several variables have been defined, as such:

- `SynDBLog` for all *SynDB** units, i.e. all generic database code;
- `SQLite3Log` for all *mORMot** units, i.e. all ORM related code;
- `SynSQLite3Log` for the `SynSQLite3` unit, which implements the *SQLite3* engine itself.

By default, redirection to the main `TSQLLog` class is done if you use some features within *mORMot*:

- `mORMot.pas` unit will define `SQLite3Log` as its own `TSQLLog` class;
- `mORMotDB.pas` unit initialization will set `SynDBLog := TSQLLog`;

- mORMotSQLite3.pas unit initialization will set SynSQLite3Log := TSQLLog.

You can set your own class type to SynDBLog / SynSQLite3Log if you expect separated logging.

As a result, if you execute the following statement at the beginning of TestSQL3.dpr, regression tests will produce some logging, and resulting into more than 740 MB of log file content, if executed:

```
TSynLogTestLog := TSQLLog; // share the same log file with whole mORMot
with TSQLLog.Family do begin
  Level := LOG_VERBOSE;
  HighResolutionTimestamp := true;
  PerThreadLog := ptIdentifiedInOnFile;
end;
```

Creating so much log content won't increase the processing time much. On a recent laptop, whole regression tests process will spent only 2 seconds to write the additional logging, which is the bottleneck of the hard disk writing.

If logging is turned off, there is no speed penalty noticeable.

Logging could be very handy for interactive debug of a client application. Since our TSynLog / TSQLLog class feature an optional output to a console, you are able to see in real-time the incoming requests - see for instance how 14 - Interface based services\Project14ServerHttp.pas sample is initialized:

```
begin
  // define the log level
  with TSQLLog.Family do begin
    Level := LOG_VERBOSE;
    EchoToConsole := LOG_VERBOSE; // Log all events to the console
  end;
  // create a Data Model
  aModel := TSQLModel.Create([], ROOT_NAME);
  (...)
```

Of course, this interactive console refresh slows down the process a lot. It is therefore to be defined only for debugging purposes, not on production.

26. Source code

Adopt a mORMot

26.1. License

26.1.1. Three Licenses Model

The framework source code is licensed under a disjunctive three-license giving the user the choice of one of the three following sets of free software/open source licensing terms:

- *Mozilla Public License*, version 1.1 or later (MPL);
- *GNU General Public License*, version 2.0 or later (GPL);
- *GNU Lesser General Public License*, version 2.1 or later (LGPL), with *linking exception* of the *FPC modified LGPL*.

FPC modified LGPL is the *Library GNU General Public License* with the following modification:

As a special exception of the LGPL, the copyright holders of this library give you permission to link this library with independent modules to produce an executable, regardless of the license terms of these independent modules, and to copy and distribute the resulting executable under terms of your choice, provided that you also meet, for each linked independent module, the terms and conditions of the license of that module. An independent module is a module which is not derived from or based on this library. If you modify this library, you may extend this exception to your version of the library, but you are not obligated to do so. If you do not wish to do so, delete this exception statement from your version.

This allows the use of the framework code in a wide variety of software projects, while still maintaining intellectual rights on library code.

In short:

- For GPL projects, use the GPL license - see <http://www.gnu.org/licenses/gpl-2.0.html>.
- For LGPL projects, use the LGPL license - see <http://www.gnu.org/licenses/lgpl-2.1.html>.
- For commercial projects, use the MPL License - see <http://www.mozilla.org/MPL/MPL-1.1.html>, - which is the most permissive, or the FPC modified LGPL license, thanks to its linking exception - see http://wiki.freepascal.org/modified_LGPL.

26.1.2. Publish modifications and credit for the library

In all cases, any modification made to this source code **should** be published by any mean (e.g. a download link), even in case of MPL. If you need any additional feature, use the forums and we may introduce a patch to the main framework trunk.

You do not have to pay any fee for using our MPL/GPL/LGPL libraries.

But please do not forget to put somewhere in your credit window or documentation, a link to <https://synopse.info>, if you use any of the units published under this tri-license.

For instance, if you select the MPL license, here are the requirements:

- You accept the license terms with no restriction - see <http://www.mozilla.org/MPL/2.0/FAQ.html> for additional information;
- You have to publish any modified unit (e.g. SynTaskDialog.pas) in a public web site (e.g. <http://SoftwareCompany.com/MPL>), with a description of applied modifications, and no removal of the original license header in source code;
- You make appear some notice available in the program (About box, documentation, online help), stating e.g.

This software uses some third-party code of the Synopse mORMot framework (C) 2022 Arnaud Bouchez - <https://synopse.info> - under Mozilla Public License 1.1; modified source code is available at <http://SoftwareCompany.com/MPL>.

26.1.3. Derivate Open Source works

If you want to include part of the framework source code in your own open-source project, you may publish it with a comment similar to this one (as included in the great *DelphiWebScript* project by Eric Grange - <http://code.google.com/p/dwscrip>):

```
{
  Will serve static content and DWS dynamic content via http.sys
  kernel mode high-performance HTTP server (available since XP SP2).
  See
http://blog.synopse.info/post/2011/03/11/HTTP-server-using-fast-http.sys-kernel-mode-server
  WARNING: you need to first register the server URI and port to the http.sys stack.
  That is, run the application at least once as administrator.

  Sample based on official mORMot's sample
  "SQLite3\Samples\09 - HttpApi web server\HttpApiServer.dpr"

  Synopse mORMot framework. Copyright (C) 2022 Arnaud Bouchez
  Synopse Informatique - https://synopse.info

  Original tri-license: MPL 1.1/GPL 2.0/LGPL 2.1

  You will need at least the following files from mORMot framework
  to be available in your project path:
  - SynCommons.pas
  - Synopse.inc
  - SynLZ.pas
```

```
- SynZip.pas  
- SynCrtSock.pas  
- SynWinSock.pas  
https://synopse.info/fossil/wiki?name=Downloads
```

```
}
```

Note that this documentation is under GPL license only, as stated in this document front page.

26.1.4. Commercial licenses

Even though our libraries are Open Source with permissive licenses, some users want to obtain a license anyway. For instance, you may want to hold a tangible legal document as evidence that you have the legal right to use and distribute your software containing our library code, or, more likely, your legal department tells you that you have to purchase a license.

If you feel like you really have to purchase a license for our libraries, *Synopse*, the company that employs the architect and principal developer of the library, will sell you one. Please contact us directly for a contract proposal.

26.2. Availability

As a true *Open Source* project, all source code of the framework is available, and latest version can be retrieved from our online repository at <https://synopse.info/fossil..>

As an alternative, you can monitor or fork our projects from our GitHub repository, at <http://github.com/synopse/mORMot..>

The source has been commented following the scheme used by our *SynProject* documentation tool. That is all interface definition of the units have special comments, which were extracted then incorporated into this *Software Architecture Design* (SAD) document, in the following pages.

26.2.1. Obtaining the Source Code

Each official release of the framework is available in a dedicated SynopseSQLite3.zip archive from the official <https://synopse.info..> web site, but you may want to use the latest version available.

The easiest is to download a nightly-generated archive of the latest version of the trunk, from <https://synopse.info/files/mORMotNightlyBuild.zip..>

As an alternative, you can manually obtain a .zip archive containing a snapshot of the latest version of the whole source code tree directly from this repository.

Follow these steps:

- Pointer your web browser at <https://synopse.info/fossil..>
- Click on the "Login" menu button.
- Log in as anonymous. The password is shown on screen. Just click on the "Fill out captcha" button then on the "Login" button. The reason for requiring this login is to prevent spiders from walking the entire website, downloading ZIP archives of every historical version, and thereby soaking up all our bandwidth.
- Click on the *Timeline* or *Leaves* link at the top of the page. Preferred way is *Leaves* which will give you the latest available version.
- Select a version of the source code you want to download: a version is identified by an hexadecimal link (e.g. 6b684fb2). Note that you must successfully log in as "anonymous" in steps 1-3 above in order to see the link to the detailed version information.
- Finally, click on the "Zip Archive" link, available at the end of the "Overview" header, right ahead to the "Other Links" title. This link will build a .zip archive of the complete source code and download it to your browser.

26.2.2. Expected compilation platform

The framework source code tree will compile and is tested for the following platforms:

- *Delphi* 6 up to the latest *Delphi* compiler and IDE version, with *FreePascal Compiler* (FPC) 3.x and *Lazarus* support;
- Server side on Windows 32-bit and 64-bit platforms (FPC or *Delphi* XE2 and up expected when targeting *Win64*);
- *Linux* 32-bit and 64-bit platform for servers using the FPC 3.2 fixes branch - now stable and tested in production since years (especially *Debian/Ubuntu* on x86_64);
- VCL client on Win32/Win64 - GUI may be compiled optionally with third-party non Open-Source TMS Components, instead of default VCL components - see <http://www.tmssoftware.com/site/tmspack.asp..>

- *Delphi FMX / FreePascal FCL cross-platform support* (page 484) clients on any supported platforms;
- *Smart Mobile Studio support* (page 487) startup with 2.1, for creating AJAX / JavaScript / HTML5 / Mobile clients.

Some part of the library (e.g. `SynCommons.pas`, `SynTests.pas`, `SynLog.pas`, `SynPDF.pas` or the *External SQL database access* (page 240) units) are also compatible with *Delphi 5*.

If you want to compile *mORMot* unit into packages, to avoid an obfuscated *[DCC Error] E2201 Need imported data reference (\$G) to access 'VarCopyProc'* error at compilation, you should defined the `USEPACKAGES` conditional in your project's options. Open `SynCommons.inc` for a description of this conditional, and all over definitions global to all *mORMot* units - see *SynCommons unit* (page 104). To avoid related *E1025 Unsupported language feature: 'Object'* compilation error, you should probably also set "Generate DCUs only" in project's options "C/C++ output file generator".

The framework source code implementation and design tried to be as cross-platform and cross-compiler as possible, since the beginning. It is a lot of work to maintain compatibility towards so many tools and platforms, but we think it is always worth it - especially if you try not depend on *Delphi* only, which as shown some backward compatibility issues during its lifetime.

For HTML5 and Mobile clients, our main platform is *Smart Mobile Studio*, which is a great combination of ease of use, a powerful *SmartPascal* dialect, small applications (much smaller than FMX), with potential packaging as native iOS or *Android* applications (via *PhoneGap*).

The latest versions of the *FreePascal Compiler* together with its great *Lazarus IDE*, are now very stable and easy to work with. We don't support *CodeTyphon*, since we found some licensing issue with some part of it (e.g. *Orca* GUI library origin is doubtful). So we recommend using *fpcupdeluxe* - see below (page 656) - which is maintained by Alfred, a *mORMot* contributor. This is amazing to build the whole set of compilers and IDE, with a lot of components, for several platforms (this is a cross-platform project), just from the sources. I like *Lazarus* stability and speed much more than *Delphi* (did you ever tried to browse and debug *included \$I ...* files in the *Delphi IDE*? with *Lazarus*, it is painless), even if the compiler is slower than *Delphi's*, and if the debugger is less integrated and even more unstable than *Delphi's* under Windows (yes, it is possible!). At least, it works, and the *Lazarus IDE* is small and efficient. Official *Linux* support is available for *mORMot* servers, with full features in the *FPC 3.2* branch - we use it on production with *Linux* 64-bit since years.

26.2.3. SQLite3 static linking for Delphi and FPC

Preliminary note: if you retrieved the source code from <https://github.com/synopse/mORMot..> you will have all the needed `.obj/.o` static files available in the expected folders. Just ignore this chapter.

In order to maintain our <https://synopse.info/fossil/timeline..> source code repository in a decent size, we excluded the `sqlite3.obj/.o` storage in it, but provide the full source code of the *SQLite3* engine in a custom `sqlite3.c` file, ready to be compiled with all conditional defined as expected by `SynSQLite3Static.pas`. You need to add the official *SQLite3* amalgamation file from <https://www.sqlite.org/download.html..> and put its content into a `SQLite3\amalgamation` sub-folder, for proper compilation. Our custom `sqlite3.c` file will add encryption feature to the engine. Also look into `SynSQLite3Static.pas` comments if there is any manual patch needed for proper compilation of the amalgamation source.

Of course, you are not required to do the compilation: `sqlite3.obj` (for *Delphi Win32*) and `sqlite3.o` files (for *Delphi Win64*) are available for *Delphi*, as a separated download, from <https://synopse.info/files/sqlite3obj.7z..>

For Delphi, please download the latest compiled version of these .obj/.o files from this link. You can also use the supplied c.bat and c64.bat files to compile from the original sqlite3.c file available in the repository, if you have the bcc32/bcc64 C command-line compiler(s) installed.

For Win32, the free version works and was used to create the .obj file, i.e. *C++Builder Compiler (bcc compiler) free download* - as available from *Embarcadero* web site.

For native Windows 64-bit applications (since Delphi XE2), a sqlite3.o static file is also available from the same archive. If you need an external dynamic .dll for Win64, since there is no official SQLite3 download for Win64 yet, you can use the one we supply at <https://synopse.info/files/SQLite3-64.7z..>

For FPC, you need to download static .o files from <https://synopse.info/files/sqlite3fpc.7z..> then uncompress the embedded static folder and its sub-folders at the mORMot root folder (i.e. where Synopse.inc and SynCommons.pas stay). If you retrieved the source code from our GitHub repository at <https://github.com/synopse/mORMot..> you already got the static sub-folder as expected by the framework. Those static files have been patched to support optional encryption of the SQLite3 database file. Then enable the FPCSQLITE3STATIC conditional in your project, or directly modify Synopse.inc to include it, so that those .o files will be statically linked to the executable.

You could also compile the static libraries from the sqlite3.c source, to run with FPC - do not forget to enable the FPCSQLITE3STATIC conditional in this case also.

Under Windows, ensure the MinGW compiler is installed, then execute c-fpcmingw.bat from the SQLite3 folder. It will create the sqlite3.o and sqlite3fts.o files, as expected by FPC.

Under Linux, Use the c-fpcgcclin.sh bash script.

26.2.4. SpiderMonkey library

To enable JavaScript support in mORMot, we rely on our version of the SpiderMonkey library. See *Scripting Engine* (page 562).

You can download the needed files from <https://synopse.info/files/synsm.7z..>

Do not forget to copy both files in the executable folder. For instance, put both mozjs.dll and nspr4.dll files with your JSHttpApiServer.exe.

By now, this library will work only under Win32, with Delphi as compiler - it has not yet been tested nor ported to FPC and other platforms.

26.2.5. Folder layout

As retrieved from our source code repository, you'll find the following folder layout:

mORMot Source Code Folders

In fact, you will get:

Directory	Description
/	Root folder, containing common files
CrossPlatform	Contains code for cross-platform clients
HtmlView/	A fork of the freeware THtmlView component, used as a demo of the SynPdf unit - not finished, and not truly Unicode ready
LVCL/	<i>Light VCL</i> replacement files for standard VCL (for <i>Delphi</i> 6-7 only)
RTL7/	Enhanced RTL .dcu for <i>Delphi</i> 7 (not mandatory at all), and <i>FastMM4</i> memory manager to be used before <i>Delphi</i> 2006
SQLite3/	Contains all ORM / SOA related files of the framework (i.e. <i>mORMot</i> itself) and its documentation
SynDBDataset/	DB .pas-based external database providers
SynProject/	Source code of the <i>SynProject</i> tool, used to edit and generate this documentation

26.2.5.1. Root folder

In the *Root folder*, some common files are defined:

File	Description
CPort.*	A fork of the freeware <i>ComPort</i> Library ver. 2.63
PasZip.pas	ZIP/LZ77 Deflate/Inflate Compression in pure pascal (SynZip.pas is faster)
SynBigTable.pas	class used to store huge amount of data with fast retrieval
SynBz.pas bunzipasm.inc	fast BZ2 compression/decompression
SynBzPas.pas	pascal implementation of BZ2 decompression
SynCommons.pas	common functions used by most Synopse projects
SynCrtSock.pas SynBidirSock.pas	classes implementing HTTP and WebSockets client and server protocol
SynCrypto.pas	fast cryptographic routines (hashing and cypher)
SynDprUses.inc	generic header included in the beginning of the uses clause of a .dpr source code
SynEcc.pas	certificate-based public-key cryptography using ECC-secp256r1
SynGdiPlus.pas	GDI+ library API access with anti-aliasing drawing
SynLog.pas	logging functions used by most Synopse projects

SynLizard.pas	Lizard (LZ5) compression/decompression unit
SynLZ.pas	SynLZ compression/decompression unit - used by SynCommons.pas
SynLZO.pas	LZO compression/decompression unit
SynMemoEx.pas	Synopse extended TMemo visual component (used e.g. in <i>SynProject</i>) - for pre-Unicode <i>Delphi</i> only
SynMongoDB.pas	Direct <i>MongoDB</i> NoSQL database access
SynMustache.pas	<i>Mustache</i> logic-less template engine
SynPdf.pas	PDF file generation unit
SynScaleMM.pas	multi-thread friendly memory manager unit - not finished yet
SynSelfTests.pas	automated tests for <i>mORMot</i> Framework
SynSMAPI.pas	<i>SpiderMonkey</i> JavaScript engine API definition
SynSM.pas	<i>SpiderMonkey</i> JavaScript engine higher level classes
SynSQLite3.pas	<i>SQLite3</i> embedded Database engine
SynSQLite3Static.pas	statically linked <i>SQLite3</i> engine (with associated .obj/.o)
SynSSPIAuth.pas	low level access to Windows Authentication
SynTaskDialog.*	implement TaskDialog window (native on Vista/Seven, emulated on XP)
SynTests.pas	cross-compiler unitary tests functions
SynWinSock.pas	low level access to network Sockets for the Windows platform
SynZip.pas deflate.obj trees.obj	low-level access to ZLib compression, 1.2.5
SynZipFiles.pas	high-level access to .zip archive file compression
Synopse.inc	generic header to be included in all units to set some global conditional definitions
vista.*	A resource file enabling theming under XP
vistaAdm.*	A resource file enabling theming under XP and Administrator rights under Vista

In the same *Root folder*, the external database-agnostic units are located:

File	Description
SynDB.pas	abstract database direct access classes
SynOleDB.pas	fast OleDB direct access classes
SynDBODBC.pas	fast ODBC direct access classes

SynDBOracle.pas	Oracle DB direct access classes (via OCI)
SynDBSQLite3.pas	SQLite3 direct access classes
SynDBDataset.pas	TDataSet / TQuery-like access classes (drivers included in SynDBDataset sub-folder)
SynDBRemote.pas	remote access over HTTP
SynDBVCL.pas	DB VCL read-only dataset using SynDB.pas data access
SynDBZEOS.pas	ZeosLib / ZDBC direct access classes

26.2.5.2. SynDBDataset folder

In a SynDBDataset folder, some external database providers are available, to be used with the SynDBDataset.pas classes:

File	Description
SynDBBDE.pas	BDE access classes
SynDBNexusDB.pas	NexusDB access classes
SynDBFireDAC.pas	FireDAC / AnyDAC library access classes
SynDBUniDAC.pas	UniDAC library access classes

26.2.5.3. SQLite3 folder

In the SQLite3/ folder, the files implementing the Synapse mORMot framework itself, i.e. its ORM and SOA features (using units from the Root folder):

File	Description
Documentation/	Sub folder containing the source of the framework documentation
Samples/	Sub folders containing some sample code
mORMot.pas	Main ORM / SOA unit of the framework
mORMotDB.pas	Virtual Tables for ORM external SynDB.pas access
mORMotFastCgiServer.pas	FastCGI server - not fully tested
mORMotHttpClient.pas	HTTP/1.1 Client
mORMotHttpServer.pas	HTTP/1.1 Server
mORMotReport.pas	Integrated Reporting engine
mORMotService.pas	Stand-alone Service
mORMotSQLite3.pas	SQLite3 kernel bridge between mORMot.pas and SynSQLite3.pas
mORMoti18n.pas	internationalization (i18n) routines and classes

mORMotMongoDB.pas	ODM integration of <i>MongoDB</i> NoSQL database
mORMotMVC.pas	MVC classes to develop high performance Web Applications
mORMotToolBar.pas	ORM ToolBar User Interface generation
mORMotUI.*	Grid to display Database content
mORMotUIEdit.*	Record edition dialog, used to edit record content on the screen
mORMotUILogin.*	some common User Interface functions and dialogs
mORMotUIOptions.*	General Options setting dialog, generated from code
mORMotUIQuery.*	Form handling queries to a User Interface Grid, using our ORM RTTI to define search parameters and algorithms
mORMotVCL.pas	DB VCL dataset using TSQLTable/TSQLTableJSON data access
*.bmp *.rc	Resource files, compiled into *.res files
TestSQL3.dpr mORMotSelfTests.pas	Main testing program of the Synapse <i>mORMot</i> framework
TestSQL3Register.dpr	Run as administrator for <i>TestSQL3</i> to use <i>http.sys</i> on Vista/Seven
c.bat sqlite3.c	Source code of the <i>SQLite3</i> embedded Database engine

26.2.5.4. CrossPlatform folder

In a CrossPlatform folder, some source code is available, to be used when creating *mORMot* clients for compilers or platforms not supported by the main branch:

File	Description
SynCrossPlatform.inc	Includes cross-platform and cross-compiler conditionals
SynCrossPlatformJSON.pas	Cross-platform JSON support for <i>Delphi</i> and FPC
SynCrossPlatformREST.pas	Main unit, handling secured ORM and SOA RESTful client
SynCrossPlatformCrypto.pas	SHA256 and crc32 algorithms, used for authentication
SynCrossPlatformSpecific.pas	System-specific functions, e.g. HTTP clients

See *Cross-Platform clients* (page 482) for more information.

26.3. Delphi Installation

Note: for FPC setup, see below (page 656).

To setup mORMot for *Delphi 6* up to the latest *Delphi* version, you have two ways: either download the framework from archives, or clone our *GitHub* repository at <https://github.com/synopse/mORMot..>

26.3.1. Manual download

Download and uncompress the framework archives, including all sub-folders, into a local directory of your computer (for instance, D:\Dev\mORMot).

Snapshot of the latest source code repository

<https://synopse.info/files/mORMotNightlyBuild.zip..>
into D:\Dev\mORMot\ (including all sub-folders)

for Delphi: static SQLite3 .obj/ .o files

<https://synopse.info/files/sqlite3obj.7z..>
into D:\Dev\mORMot\SQLite3\

for FPC: static .o files for Windows or Linux/BSD

<https://synopse.info/files/sqlite3fpc.7z..>
whole static folder into D:\Dev\mORMot\

optional 64-bit SQLite3 external library

<https://synopse.info/files/SQLite3-64.7z..>
into your Win64 .exe folders

32-bit SpiderMonkey library

<https://synopse.info/files/synsm.7z..>
into your .exe folders needing JavaScript

26.3.2. Get from GitHub

Or you may just clone our *GitHub* repository, from <https://github.com/synopse/mORMot..> e.g. via:

```
d:  
cd Dev  
git clone https://github.com/synopse/mORMot.git
```

It will create a d:\Dev\mORMot local folder, which will eventually be re-synchronized with the official sources. Advantage of cloning our *GitHub* repository is that it contains binaries for static linking, (*SQLite3* and FPC specific), in a single step.

Just take care that if you downloaded some other library from Synopse (e.g. from <https://github.com/synopse/SynPDF..> or [https://github.com/synopse/dmustache\)..](https://github.com/synopse/dmustache)..) you should better use the main <https://github.com/synopse/mORMot..> only, which contains other projects, to avoid any version confusion. We have seen a lot of installation problems reported in our forum due to source code file collision from several repositories, not in the same revision.

26.3.3. Setup the Delphi IDE

To let your IDE know about *mORMot* source code, add the following paths to your *Delphi* IDE (in

Tools/Environment/Library or *Tools/Options/Language/Delphi Options/Library* menu depending on your Delphi version):

- *Library path:*
(...existing path...);D:\Dev\mORMot;D:\Dev\mORMot\SQLite3;D:\Dev\mORMot\SynDBDataset
- *Search path:*
(...existing path...);D:\Dev\mORMot;D:\Dev\mORMot\SQLite3;D:\Dev\mORMot\SynDBDataset

For any cross-platform client, do not forget to include the D:\Dev\mORMot\CrossPlatform to the *Delphi* or *FreePascal* IDE paths of the corresponding targets.

For *Smart Mobile Studio*, execute *CopySynCrossPlatformUnits.bat* to set the needed units in the IDE repository.

Note that before *Delphi* 2006, you will need to download and install *FastMM4* heap memory manager - from <http://sourceforge.net/projects/fastmm..> or from the D:\Dev\mORMot\RTL7 sub folder of our repository - for some samples to work (without it, *mORMot* units will work, but will be slower). Starting with *Delphi* 2006, *FastMM4* is already included within the system RTL, so you do not need to download it.

Open the *TestSQL3.dpr* program from the *SQLite3* sub-folder. You should be able to compile it and run all regression tests on your computer.

If you want to run the tests with the fast *http.sys* kernel-based HTTP server, you'll need to compile and run (as administrator) *TestSQL3Register.dpr* once before launching *TestSQL3.dpr*.

Then open the *.dpr files, as available in the *SQLite3\Samples* sub-folder. You should be able to compile all sample programs, including *SynFile.dpr* in the *MainDemo* folder.

Enjoy!

26.4. FreePascal / Lazarus Installation

Note: see also Delphi Installation (page 654).

26.4.1. Possible targets

You can use the *FreePascal Compiler* (FPC) to (cross-)compile the *mORMot* framework source code, targeting the following CPU and OS combinations:

- i386-win32
- x86_64-win64
- i386-linux
- x86_64-linux
- i386-freebsd
- x86_64-freebsd
- i386-darwin
- x86_64-darwin
- arm-linux
- aarch64-linux

32-bit and 64-bit Windows and Linux platforms are the main supported targets, used in production since years. Others may need some enhancements, and you are free to contribute! *mORMot* has been reported to work on a Raspberry Pi running Linux, thanks to FPC abilities - and with good performance and stability.

Linux is a premium target for cheap and efficient server *Hosting* (page 537). Since *mORMot* has no dependency, installing a new *mORMot* server is as easy as copying its executable on a blank *Linux* host, then run it. No need to install any framework nor runtime. Even the *SQLite3* engine will be statically linked on most platforms, as we provide up-to-date binaries in our repository. You could even use diverse operating systems (several *Linux* or *Windows Server* versions) in your *mORMot* servers farm, with minimal system requirements, and updates.

For proper FPC compilation, ensure you have the following settings to your project:

- *Other unit files (-Fu):*
D:\Dev\mORMot;D:\Dev\mORMot\SQLite3;D:\Dev\mORMot\SQLite3\DDD\infra
- *Include files (-Fi):*
\$(ProjOutDir);D:\Dev\mORMot;D:\Dev\mORMot\SQLite3
- *Libraries (-fI):*
D:\Dev\mORMot\static\\$(TargetCPU)-\$(TargetOS)

Replace D:\Dev\mORMot path by the absolute/relative folder where you did install the framework. In practice, a relative path (e.g. ..\..\mORMot) is preferred.

26.4.2. Setup your dedicated FPC / Lazarus environment with fpcupdeluxe

We currently use the FPC 3.2 fixes branch compiler, and the corresponding *Lazarus* IDE.

If you want to use *TDocVariant custom variant type* (page 112), ensure that your revision includes the fix for <http://mantis.freepascal.org/view.php?id=26773..> bug, i.e. newer than revision 28995 from 2014-11-05T22:17:54. This bug was not fixed in 2.6.4 branch, but any newer 3.x revision should be enough.

But since the FPC trunk may be unstable, we will propose to put in place a stable development

environment based on the FPC 3.2 branch to work with your *mORMot*-based projects. It may ease support and debugging.

For this task, don't download an existing binary release of FPC / Lazarus, but use the *fpcupdeluxe* tool, as published at <http://wiki.freepascal.org/fpcupdeluxe..> - it will allow to build your environment directly from the sources, and install it in a dedicated folder. Several FPC / Lazarus installations, with dedicated revision numbers, may coexist on the same computer: just ensure you run Lazarus from the shortcut created by *fpcupdeluxe*.

- Download the latest release of the tool from <https://github.com/LongDirtyAnimAlf/fpcupdeluxe/releases..>
- Unpack it in a dedicated folder, and run its executable.
- On the main screen, locate on the left the two versions listboxes. Select "3.2" for *FPC version* and "2.1.0" for *Lazarus version*.
- Important note: if you want to cross-compile from Windows to other systems, e.g. install a Linux cross-compiler on Windows, ensure you installed the *Win32* FPC compiler and Lazarus, *not the Win64* version, which is known to have troubles with currency support;
- Then build the FPC and Lazarus binaries directly from the latest sources, by clicking on "Install/update FPC+Laz".

Those branches are currently used for building our production projects, so are expected to be properly tested and supported.

At the time of the writing of this documentation, our Lazarus IDE (on Linux) reports using:

- FPC SVN 45643 (3.2.0)
- Lazarus SVN 64940 (2.1.0).

One big advantage of *fpcupdeluxe* is that you can very easily install cross-compilers for the CPU / OS combinations enumerated at *Possible targets* (page 656).

Just go to the "Cross" tab, then select the target systems, and click on "Install compiler".

It may be needed to download the cross-compiler binaries (once): just select "Yes" when prompted.

You could install *mORMot* using *fpcupdeluxe*, but we recommend you clone our <https://github.com/synopse/mORMot..> repository, and setup the expected project paths, as detailed above at *Delphi Installation* (page 654).

If you don't want to define a given version, the current *trunk* should/could work, if it didn't include any regression at the time you get it - this is why we provide "supported" branches.

If you want to use the *FPC trunk*, please modify line #262 in *Synopse.inc* to enable the `FPC_PROVIDE_ATTR_TABLE` conditional and support the latest trunk RTTI changes:

```
{ $if not defined(VER3_0) and not defined(VER3_2) and not defined(VER2) }  
  { $define FPC_PROVIDE_ATTR_TABLE } // to be defined since SVN 42356-42411  
  // on compilation error in SynFPCTypeInfo, undefine the above conditional  
  // see https://lists.freepascal.org/pipermail/fpc-announce/2019-July/000612.html  
{ $ifend }
```

Sadly, there is no official conditional available to have this RTTI change detected. You need to define globally this conditional.

26.4.3. Missing RTTI for interfaces in old FPC 2.6

Sadly, if you use a somewhat old revision of FPC, you may have to face some long-time unresolved FPC compiler-level restriction/issue, which did not supply the needed interface RTTI, which was available since Delphi 6 - see <http://bugs.freepascal.org/view.php?id=26774..>

As a consequence, SOA, mock/stub and MVC framework features will not work directly with older FPC

revisions.

You could upgrade to a more recent FPC - we encourage you to *Setup your dedicated FPC / Lazarus environment with fpcupdeluxe* (page 656) - or we will propose here a workaround to compile such *mORMot* applications with oldest FPC. The trick is to use Delphi to generate one unit containing the needed information.

The `mORMotWrappers.pas` unit proposes a `ComputeFPCInterfacesUnit()` function, which could be used on Delphi to generate the RTTI unit for FPC, as such:

- Ensure that the application will use all its needed interface: for instance, run all your regression tests, and/or use all its SOA/MVC features if you are not confident about your test coverage;
- Just before the application exits, add a call to `ComputeFPCInterfacesUnit()` with the proper folders, e.g. at the very end of your `.dpr` code.

For instance, here is how `TestSQL3.dpr` has been modified:

```
program TestSQL3;
...
uses
...
  mORMotWrappers.pas,
...
begin
  SQLite3ConsoleTests;
  {$ifdef COMPUTEFPCINTERFACES}
  ChDir(ExtractFilePath(ParamStr(0)));
  ComputeFPCInterfacesUnit(
    ['..\CrossPlatform\templates', '..\..\CrossPlatform\templates'],
    ['..\..\SQLite3\TestSQL3FPCInterfaces.pas']);
  {$endif}
end.
```

If you define the `COMPUTEFPCINTERFACES` conditional, the `TestSQL3FPCInterfaces.pas` unit will be generated.

Of course, for your own application, you may use absolute path names: here we used relative naming, via `..\`, so that it will work on any development folder configuration.

Then, add it to any of your `uses` clause, as such:

```
uses
...
  TestSQL3FPCInterfaces, // will register RTTI for interfaces under FPC
...
```

This unit will do nothing when compiled under *Delphi*: it will register the RTTI only when compiled with *FPC*.

The rest of your code will be untouched, and could be shared between Delphi and FPC.

If you do not modify the interface methods definition, this generation step could be safely bypassed.

We hope that in a close future, the FPC team will fix the <http://bugs.freepascal.org/view.php?id=26774..> issue, but the ticket seems pretty inactive since its creation.

26.4.4. Writing your project for FPC

If you want your application to compile with FPC, some little patterns should be followed.

In all your source code file, the easiest is to including the following *mORMot* file, which will define all

compiler options and conditionals as expected:

```
{ $I Synopse.inc } // define HASINLINE USETYPEINFO CPU32 CPU64 OWNORMTOUPPER
```

Then in your .dpr file, you should write:

```
uses
  { $ifdef FPC } // we may be on Kylix or upcoming Delphi for Linux
  { $ifdef Linux }
  // if you use threads
  cthreads,
  // widestring manager for Linux if needed !!
  // could also be put in another unit ... but doc states: as early as possible
  cwstring, // optional
  { $endif }
  { $endif }
```

In fact, these above lines have been added to SynDprUses.inc, so you may just write the following:

```
uses
  { $I SynDprUses.inc } // will enable FastMM4 prior to Delphi 2006, and enable FPC on Linux
```

As a side benefit, you will be able to share the same .dpr with Delphi, and it will enable *FastMM4* for older versions which do not include it as default heap manager.

For instance a minimal FPC project to run the regression tests may be:

```
program LinuxSynTestFPCLinuxI386;

{ $I Synopse.inc }
{ $APPTYPE CONSOLE }

uses
  { $I SynDprUses.inc }
  mORMotSelfTests;

begin
  SQLite3ConsoleTests;
end.
```

In your user code, ensure you do not directly link to the Windows unit, but rely on the cross-platform classes and functions as defined in SysUtils.pas, Classes.pas and SynCommons.pas. You could find in SynFPCTypInfo.pas and SynFPCLinux.pas some low-level functions dedicated to FPC and *Linux* compilation, to be used with legacy units - your new code should better rely on higher level functions and classes.

If you rely on *mORMot* classes and types, e.g. use RawUTF8 for all your string process in the business logic, and do not use Delphi-specific features (like generics, or new syntax sugar), it will be very easy to let your application compile with FPC.

26.4.5. Linux VM installation tips

Here are a few informal notes about getting running a FPC/Lazarus virtual machine running *XUbuntu*, on a *Windows* host. They are published as a general guideline, and we will not provide any reference procedure, nor support it. As stated in *Setup your dedicated FPC / Lazarus environment with fpcupdeluxe* (page 656), instead of using a virtual machine, you could just install the needed cross-compilers, then generate your Linux/BSD executables from your Windows Lazarus.

- Install the latest *VirtualBox* version from <http://www.virtualbox.org/> to Windows;
- Download the latest .iso version published at <http://xubuntu.org/> or any other place - we use XFCE since it is a very lightweight desktop, perfect to run *Lazarus*, and we selected an Ubuntu LTS revision (14.04 at the time of this writing), which will be the same used on Internet servers;

- Create a new virtual machine (VM) in *VirtualBox*, with 1 or 2 CPUs, more than 512 MB of RAM (we use 777 MB), and an automatic-growing disk storage, with a maximal size of 15 GB; ensure that the disk storage is marked as SSD if your real host storage is a SSD;
- Let the CDROM storage point to the .iso you downloaded;
- Start the VM and install *Linux* locally, as usual - you may select to download the updated packages during the installation, for safety;
- When the system restarts, if it asks for software updates, accept and wait for the update installation to finish - it is a good idea to have the latest version of the kernel and libraries before installing the *VirtualBox* drivers;
- Restart your VM when asked to;
- Under a *Ubuntu/Debian* terminal, write the following commands:

```
sudo apt-get update
sudo apt-get upgrade
sudo apt-get install dkms
```

- Restart the VM, then select "Insert Guest Additions CD image" from the VM "Devices" menu: a virtual CD will be mounted on your system and appear on your desktop;
- Run the following command, according to your current user name and *VirtualBox* version:

```
sudo sh /media/...user.../VBOXADDITIONS_.../VBoxLinuxAdditions.run
```

- Restart the VM, then add a permanent shared folder in the VM configuration, named Lib, and pointing to your local *mORMot* installation (e.g. d:\Dev\mORMot);
- Create a void folder, e.g. in your home:

```
mkdir lib
```

- Create a launcher for the following command, to mount the shared folder as expected:

```
sudo mount -t vboxsf lib /home/...user.../lib
```

- Execute the following commands:

```
sudo apt-get install build-essential mingw32-binutils subversion libgtk2.0-dev
sudo ln -s /usr/bin/i586-mingw32msvc-windres /usr/bin/windres
```

- Then install FPC / Lazarus as detailed in *Setup your dedicated FPC / Lazarus environment with fpcupdeluxe* (page 656)
- If you have issues during SVN retrieval, go the development/fpc folder, then run the following before trying again the fpcup_linux_x86 command:

```
svn cleanup
svn update
```

If you followed the above steps, you should now have the expected Lazarus IDE and the corresponding FPC compiler. It is amazing seeing the whole compiler + IDE being compiled from the official sources, for free, and in a few minutes.

26.5. CrossKylix support

26.5.1. What is Cross-Kylix?

The framework source code can also be cross-compiled under Delphi into a *Linux* executable, using *CrossKylix*.

<https://crosskylix.undergrund.net..> is a free toolkit to integrate the Borland *Kylix* (*Delphi* for *Linux*) compiler into the Delphi Windows IDE.

CrossKylix has indeed several known drawbacks:

- It is a dead project, but an alive product. It still works!
- You can not buy it any more. *Kylix* 3 was shipped with Delphi 7.

- You need an actual *Kylix* CD (or an ISO image) to install it, since *CrossKylix* is just a wrapper around the official compiler, to let it run under Windows.
- Visual applications (based on the CLX framework - the predecessor of FMX) may still compile, but should not be used. But for server applications, it is still a pretty viable solution.
- The debugger and IDE is unusable. But thanks to our `SynLog.pas`, you can debug your applications, with a full stack trace in the log, in case of any exception.

We added *CrossKylix* support for several reasons:

- We use it since years, with great success, so we know it better than FPC.
- It has still a better compiler than FPC, e.g. for the RTTI we need on interfaces, or even for executable size and memory use.
- Its compilation is instant - whereas FPC is long to compile.
- It supports `FastMM4`, which performs better than the FPC memory manager, from our tests.
- Resulting executables, for *mORMot* purpose, are faster than FPC - timing based on the regression tests.
- If the code works with Delphi 7, it will certainly work with *Kylix* (since it shares the same compiler and RTL), whereas FPC is compatible, but not the same. In particular, it does not suffer from limited RTTI or other FPC limitations. So it sounds safer to be used on production than FPC, even today.
- There is not a lot of `IFDEF`, but in `SynCommons.pas`. Then there is a `SynKylix.pas` unit for several functions. User code will be the same than Delphi and FPC.
- There is a *Linux* compiler just released by *Embarcadero* since latest Delphi, but an *Enterprise* license is required, so we currently skip its support, and focus on FPC...

Currently, we use FPC with success for building `i386` and `x86_64` executables. FPC is therefore recommended for production work targeting *Linux*. See *FreePascal / Lazarus Installation* (page 656) and *Setup your dedicated FPC / Lazarus environment with fpcupdeluxe* (page 656).

Once you have installed *CrossKylix*, and set up its search path to the same as Delphi - see *Delphi Installation* (page 654), you should be able to compile your project for *Linux*, directly from your *Delphi* IDE. Then you need an actual *Linux* system to test it - please check the *Linux VM installation tips* (page 659).

A minimal console application which will compile for both *Delphi* and *CrossKylix*, running all our regression tests, may be:

```
program Test;

{$APPTYPE CONSOLE}

uses
  FastMM4, // optional - only for CrossKylix or Delphi < 2006
  mORMotSelfTests;

begin
  SQLite3ConsoleTests;
end.
```

Similar guidelines as for *Writing your project for FPC* (page 658) do apply with *CrossKylix*. In particular, you should never use the Windows unit in your server code, but rely on the cross-platform classes and functions as defined in `SysUtils.pas`, `Classes.pas` and `SynCommons.pas`.

We did not succeed to have a static `SQLite3` library linked by the *Kylix* compiler. It compiles about the `.o` format - sounds like if its linker expects a `gcc2` format (which is nowadays deprecated), and does not accept the `gcc3` or `gcc4` generated binaries. So you need to install the `sqlite3` as external library on your *Linux*.

On a 32-bit system, it is just a one line - depending on your distribution, here *Ubuntu*:

```
sudo apt-get install sqlite3
```

For a 64-bit system, you need to explicitly install the x86 32-bit version of *SQLite3*:

```
sudo apt-get install sqlite3:i386
```

or download and install manually packages for both modes:

```
sudo dpkg -i libsqlite3-0_3.8.2-1ubuntu2_amd64.deb libsqlite3-0_3.8.2-1ubuntu2_i386.deb
```

You could try to get the latest .deb from <https://launchpad.net/ubuntu/vivid/i386/libsqlite3-0>.

If you want to download and install manually a .deb for x86, please install both *i386* and *amd64* revisions with the same exact version at once, otherwise dpkg will complain.

If it may be of any help, here are the static dependencies listed on a running 64-bit Ubuntu system, on a *CrossKylx* compiled executable:

```
user@server:~$ ldd Test
linux-gate.so.1 => (0xf77be000)
libz.so.1 => /usr/lib32/libz.so.1 (0xf779b000)
librt.so.1 => /lib/i386-linux-gnu/librt.so.1 (0xf7792000)
libpthread.so.0 => /lib/i386-linux-gnu/libpthread.so.0 (0xf7775000)
libdl.so.2 => /lib/i386-linux-gnu/libdl.so.2 (0xf7770000)
libc.so.6 => /lib/i386-linux-gnu/libc.so.6 (0xf75c1000)
/lib/ld-linux.so.2 (0xf77bf000)
```

As you can see, there is a very few dependencies - then same as FPC's executable in fact, with the addition of the external *libsqlite3.so.0*, which is statically linked to FPC's version.

26.5.2. Running Kylix 32-bit executables on 64-bit Linux

For Ubuntu versions above 13.10, if you installed a 64-bit distribution, 32-bit executables - as generated by *CrossKylx* - may not be recognized by the system. Of course, we recommend using FPC (cross-)compiler, and build your executable natively for the *x86_64-linux* target.

In order to install the 32-bit libraries needed by *mORMot* 32-bit executables compiled by *Kylix* on *Linux*, please execute:

```
sudo apt-get install lib32z1 lib32ncurses5 lib32bz2-1.0
```

If you want *SynCrtSock.pas* to be able to handle *https://* on a 64-bit system - e.g. if you want to run the *TestSQL3* regression tests which download some json reference file over *https* - you will need also to install *libcurl* (and *OpenSSL*) in 32-bit, as such:

```
sudo apt-get install libcurl3:i386
```

If it may be for any help, here are the static dependencies listed on a running 64-bit Ubuntu system, on a *FPC 3.2* compiled executable:

```
user@xubuntu:~/lib/SQLite3/fpc/i386-linux$ ldd TestSQL3
linux-gate.so.1 => (0xb774c000)
libpthread.so.0 => /lib/i386-linux-gnu/libpthread.so.0 (0xb7718000)
libz.so.1 => /lib/i386-linux-gnu/libz.so.1 (0xb76fe000)
libdl.so.2 => /lib/i386-linux-gnu/libdl.so.2 (0xb76f8000)
libc.so.6 => /lib/i386-linux-gnu/libc.so.6 (0xb7549000)
/lib/ld-linux.so.2 (0xb774d000)
```

There is almost no dependency: installing a *mORMot* server under *Linux* is just as simple as copying an executable on a minimal blank *Linux* server. You do not need any LAMP runtime, virtual machine, installing other services, or execution environment.

Of course, you may better add a reverse proxy like *nginx* in front of your *mORMot* servers when connected on the Internet, but for a cloud-based solution, or a self-hosted office server, software

requirements are pretty low.

26.6. Upgrading from a 1.17 revision

If you are upgrading from an older revision of the framework, your own source code should be updated.

For instance, some units were renamed, and some breaking changes introduced by enhanced features. As a consequence, a direct update is not possible.

To properly upgrade to the latest revision:

1. Erase or rename your whole previous #\mORMot directory.
2. Download latest 1.18 revision files as stated just above.
3. Change your references to *mORMot* units:
 - Add in your uses clause `SynTests.pas` if you use testing features;
 - Add in your uses clause `SynLog.pas` if you use logging features;
 - Rename in your uses clauses any `SQLite3Commons` reference into `mORMot.pas`;
 - Rename in your uses clauses any `SQLite3` reference into `mORMotSQLite3.pas`;
 - Rename in your uses clauses any other `SQLite3*` reference into `mORMot*`;
 - Add in one of your uses clause a reference to the `SynSQLite3Static.pas` unit (for *Win32* or *Linux*).
4. Consult the units' headers about 1.18 for breaking changes, mainly:
 - Introducing `TID = type Int64` as `TSQLRecord.ID` primary key, `TIDDynArray` as an array, and `TRecordReference` now declared as `Int64` instead of plain `PtrInt / integer`;
 - Renamed `Iso8601` low-level structure as `TTimeLogBits`;
 - `TJSONSerializerCustomWriter` and `TJSONSerializerCustomReader` callbacks changed;
 - `TSQLRestServerCallBackParams` which is replaced by the `TSQLRestServerURIContext` class;
 - `rmJSON*` enumerates replaced by `TSQLRestRoutingREST` and `TSQLRestRoutingJSON_RPC` classes;
 - Changed 'x' into '~' character for `mORMoti18n.pas` (formerly `SQLite3i18n.pas`) language files.

Most of those changes will be easily identified at compile time. But a quick code review, and proper regression tests at application level is worth considering.

Feel free to get support from our forum, if needed.

27. mORMot Framework source

27.1. mORMot Framework used Units

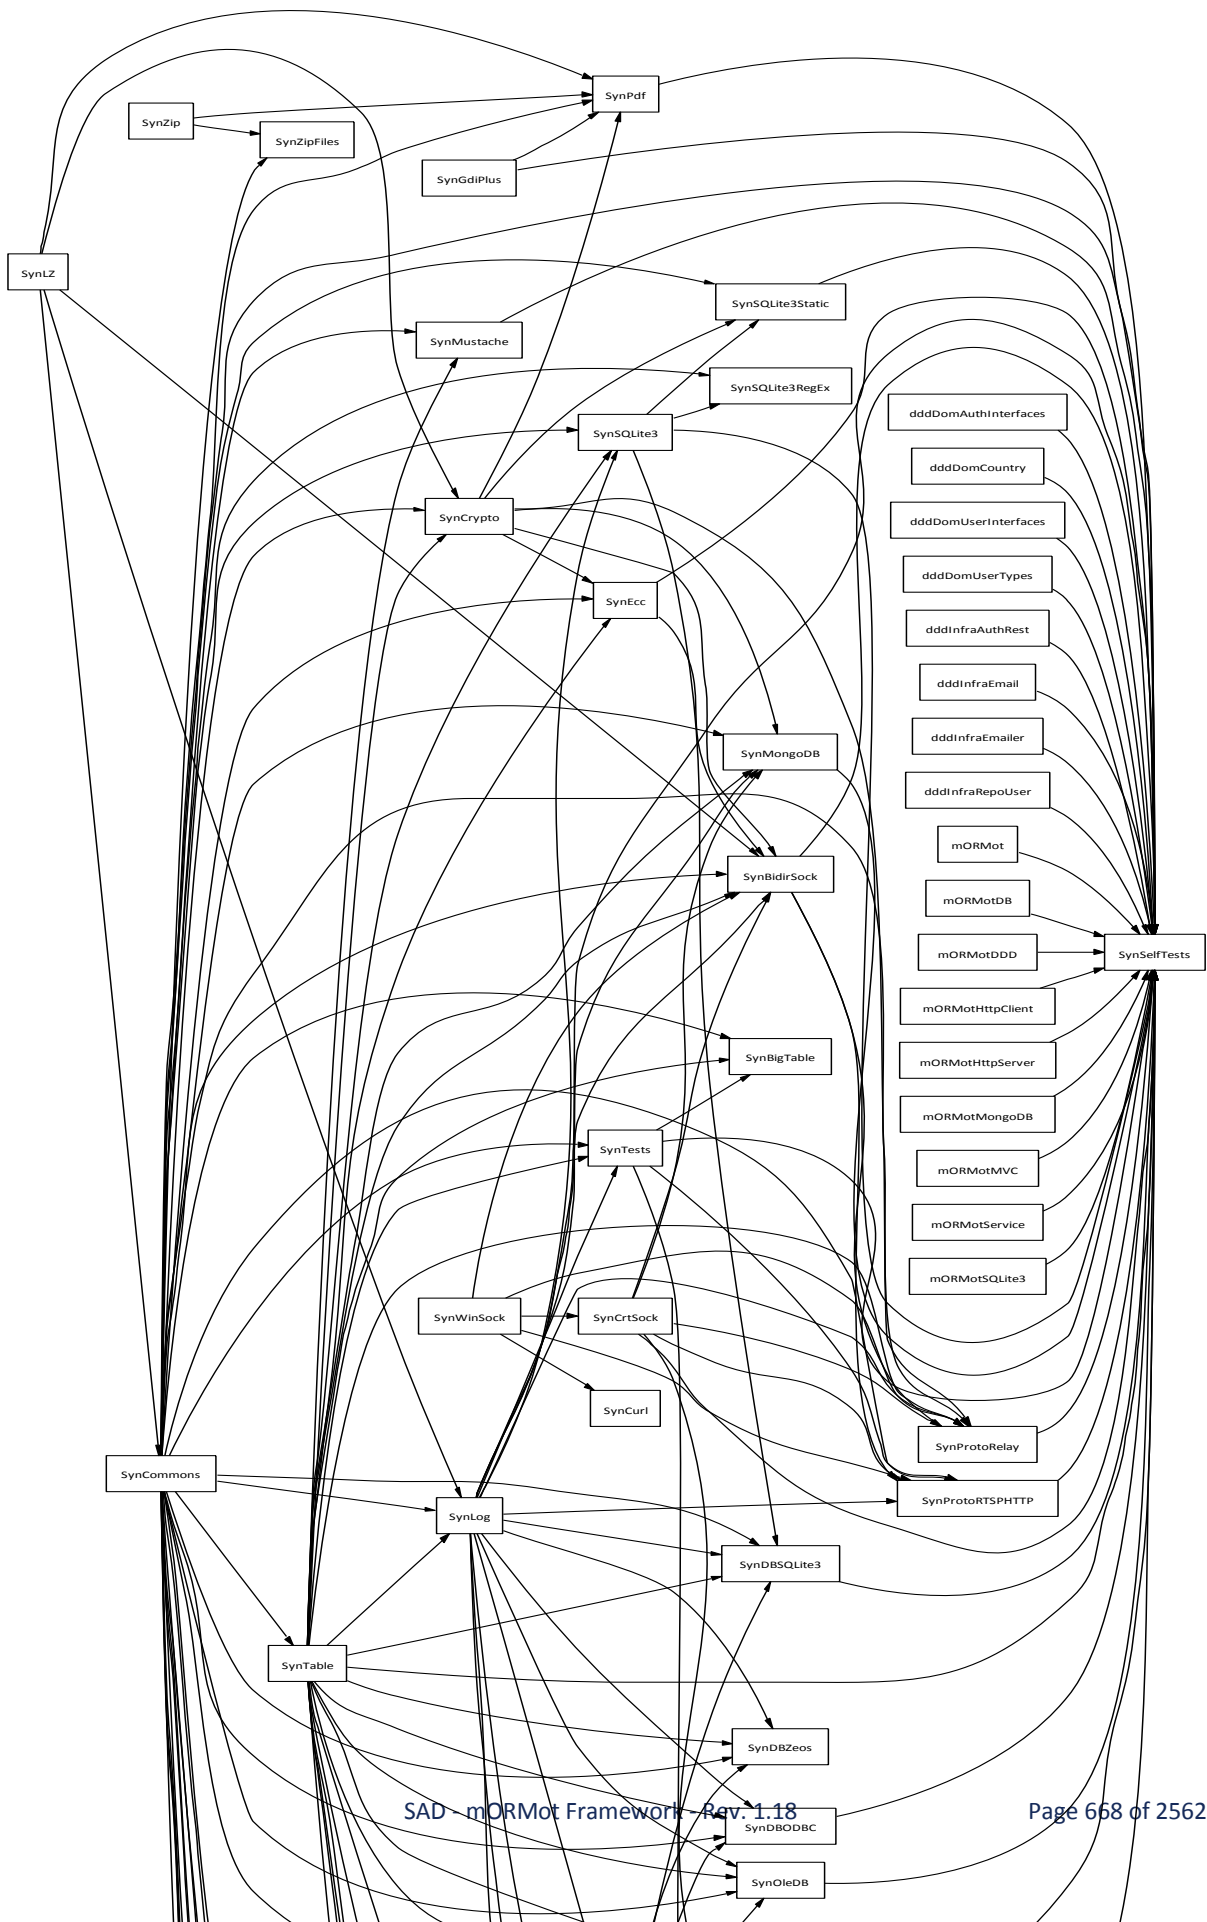

The mORMot Framework makes use of the following units.

Units located in the "Lib\" directory:

Source File Name	Description	Page
<i>PasZip</i>	ZIP/LZ77 Deflate/Inflate Compression in pure pascal	675
<i>SynBidirSock</i>	Implements bidirectional client and server protocol, e.g. WebSockets	681
<i>SynBigTable</i>	Class used to store huge amount of data with fast retrieval	705
<i>SynCommons</i>	Common functions used by most Synopse projects	718
<i>SynCrtSock</i>	Classes implementing TCP/UDP/HTTP client and server protocol	1086
<i>SynCrypto</i>	Fast cryptographic routines (hashing and cypher)	1143
<i>SynCurl</i>	Curl library direct access classes	1204
<i>SynDB</i>	Abstract database direct access classes	1208
<i>SynDBDataset</i>	DB.pas TDataset-based direct access classes (abstract TQuery-like)	1271
<i>SynDBMidasVCL</i>	Fill a VCL TClientDataset from SynDB data access	1275
<i>SynDBODBC</i>	ODBC 3.x library direct access classes to be used with our SynDB architecture	1278
<i>SynDBOracle</i>	Oracle DB direct access classes (via OCI)	1284
<i>SynDBPostgres</i>	PostgreSQL direct access classes for SynDB units (not DB.pas based)	1293
<i>SynDBRemote</i>	Remote access to any RDBMS via HTTP using our SynDB architecture	1297

Source File Name	Description	Page
<i>SynDBSQLite3</i>	SQLite3 direct access classes to be used with our SynDB architecture	1302
<i>SynDBVCL</i>	DB VCL read/only dataset from SynDB data access	1308
<i>SynDBZeos</i>	ZEOS 7.x direct access classes for SynDB units (not DB.pas based)	1312
<i>SynEcc</i>	Certificate-based public-key cryptography using ECC-secp256r1	1318
<i>SynFastWideString</i>	This unit will patch the System.pas RTL to use a custom NON OLE COMPATIBLE WideString type, NOT using the slow Windows API, but FastMM4 (without COW)	1354
<i>SynGdiPlus</i>	GDI+ library API access	1355
<i>SynLizard</i>	Lizard (LZ5) compression routines (statically linked for FPC)	1364
<i>SynLog</i>	Logging functions used by Synopse projects	1368
<i>SynLZ</i>	SynLZ Compression routines	1399
<i>SynLZO</i>	Fast LZO Compression routines	1401
<i>SynMongoDB</i>	MongoDB document-oriented database direct access classes	1402
<i>SynMustache</i>	Logic-less mustache template rendering	1456
<i>SynOleDB</i>	Fast OleDB direct access classes	1464
<i>SynPdf</i>	PDF file generation	1479
<i>SynProtoRelay</i>	Implements asynchronous safe WebSockets tunnelling	1528
<i>SynProtoRTSPHTTP</i>	Implements asynchronous RTSP stream tunnelling over HTTP	1533
<i>SynSelfTests</i>	Automated tests for common units of the Synopse mORMot Framework	1535
<i>SynSM</i>	Features JavaScript execution using the SpiderMonkey library	1561
<i>SynSMAPI</i>	SpiderMonkey *.h header port to Delphi	1580
<i>SynSQLite3</i>	SQLite3 Database engine direct access	1653
<i>SynSQLite3RegEx</i>	REGEXP function for SQLite3 Database using PCRE library	1717
<i>SynSQLite3Static</i>	SQLite3 3.38.2 Database engine - statically linked for Windows/Linux	1718

Source File Name	Description	Page
<i>SynSSPI</i>	Low level access to Windows SSPI/SChannel API for the Win32/Win64 platform	1721
<i>SynSSPIAuth</i>	Low level access to Windows Authentication for the Win32/Win64 platform	1725
<i>SynTable</i>	Filter/database/cache/buffer/security/search/multithread/OS features	1728
<i>SynTaskDialog</i>	Implement TaskDialog window (native on Vista/Seven, emulated on XP)	1832
<i>SynTests</i>	Unit test functions used by Synopse projects	1840
<i>SynVirtualDataSet</i>	DB VCL read-only virtual dataset	1848
<i>SynWinSock</i>	Low level access to network Sockets for the Win32 platform	1851
<i>SynZip</i>	Low-level access to ZLib compression (1.2.5 engine version)	1853
<i>SynZipFiles</i>	High-level access to .zip archive file compression	1864

Unit dependencies in the "Lib" directory

Units located in the "Lib\CrossPlatform\" directory:

Source File Name	Description	Page
<i>SynCrossPlatformCrypto</i>	Cryptographic cross-platform units	1867
<i>SynCrossPlatformJSON</i>	Minimum stand-alone cross-platform JSON process using variants	1869
<i>SynCrossPlatformREST</i>	Minimum stand-alone cross-platform REST process for mORMot client	1878
<i>SynCrossPlatformSpecific</i>	System-specific cross-platform units	1900
<i>SynCrossPlatformTests</i>	Regression tests for mORMot's cross-platform units	1905

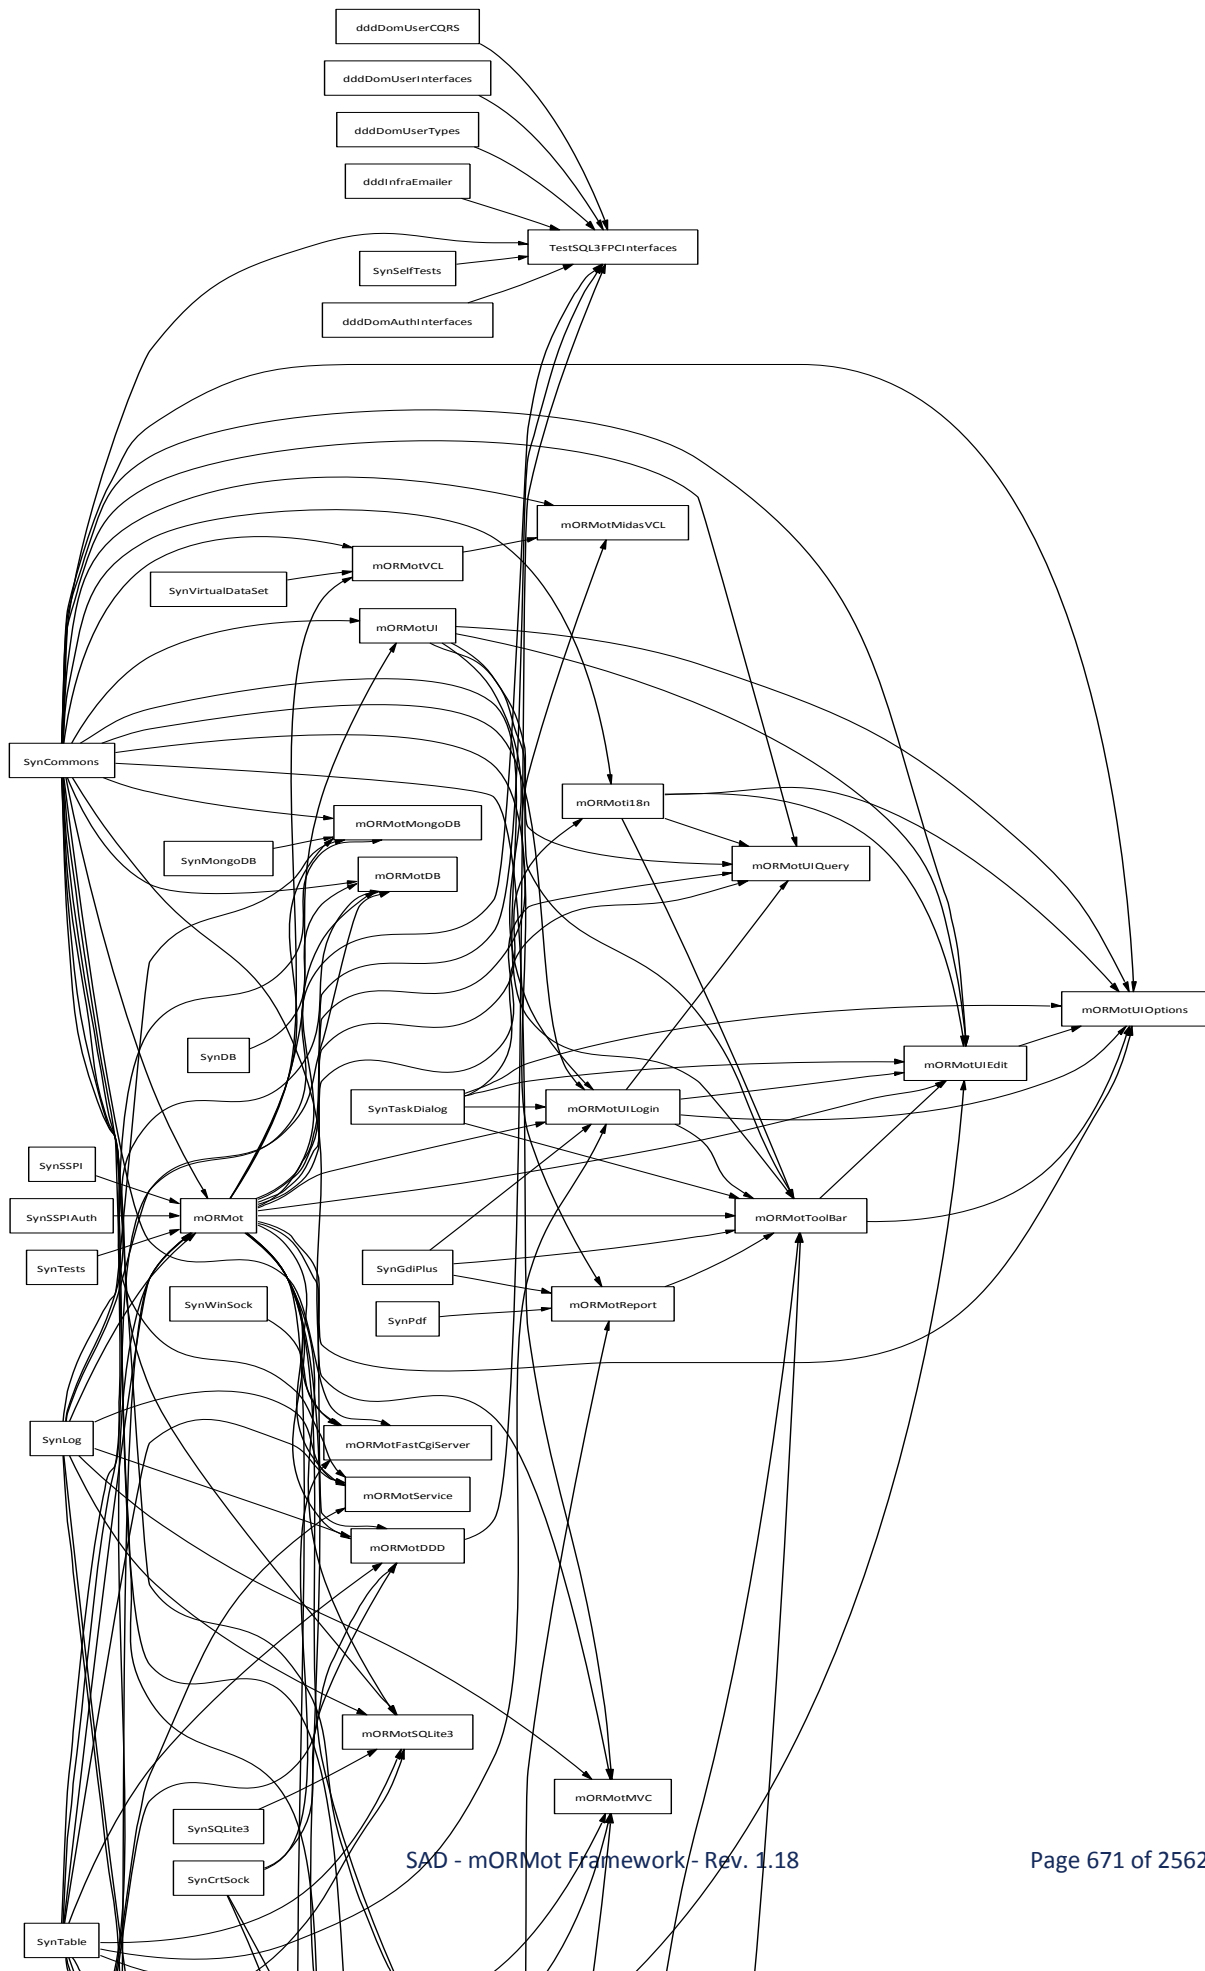

Unit dependencies in the "Lib\CrossPlatform" directory

Units located in the "Lib\SQLite3\" directory:

Source File Name	Description	Page
<i>mORMot</i>	Common ORM and SOA classes for mORMot	1907
<i>mORMotDB</i>	Virtual Tables for external DB access for mORMot	2286
<i>mORMotDDD</i>	Domain-Driven-Design toolbox for mORMot	2295
<i>mORMotFastCgiServer</i>	FastCGI HTTP/1.1 Server implementation for mORMot	2312
<i>mORMotHttpClient</i>	HTTP/1.1 RESTful JSON Client classes for mORMot	2316
<i>mORMotHttpServer</i>	HTTP/1.1 RESTFUL JSON Server classes for mORMot	2323
<i>mORMoti18n</i>	Internationalization (i18n) routines and classes for mORMot	2332
<i>mORMotMidasVCL</i>	Fill a VCL TClientDataset from TSQLTable/TSQLTableJSON data	2342
<i>mORMotMongoDB</i>	Direct optimized MongoDB access for mORMot's ORM	2344
<i>mORMotMVC</i>	Implements MVC patterns over mORMot's ORM/SOA and SynMustache	2349

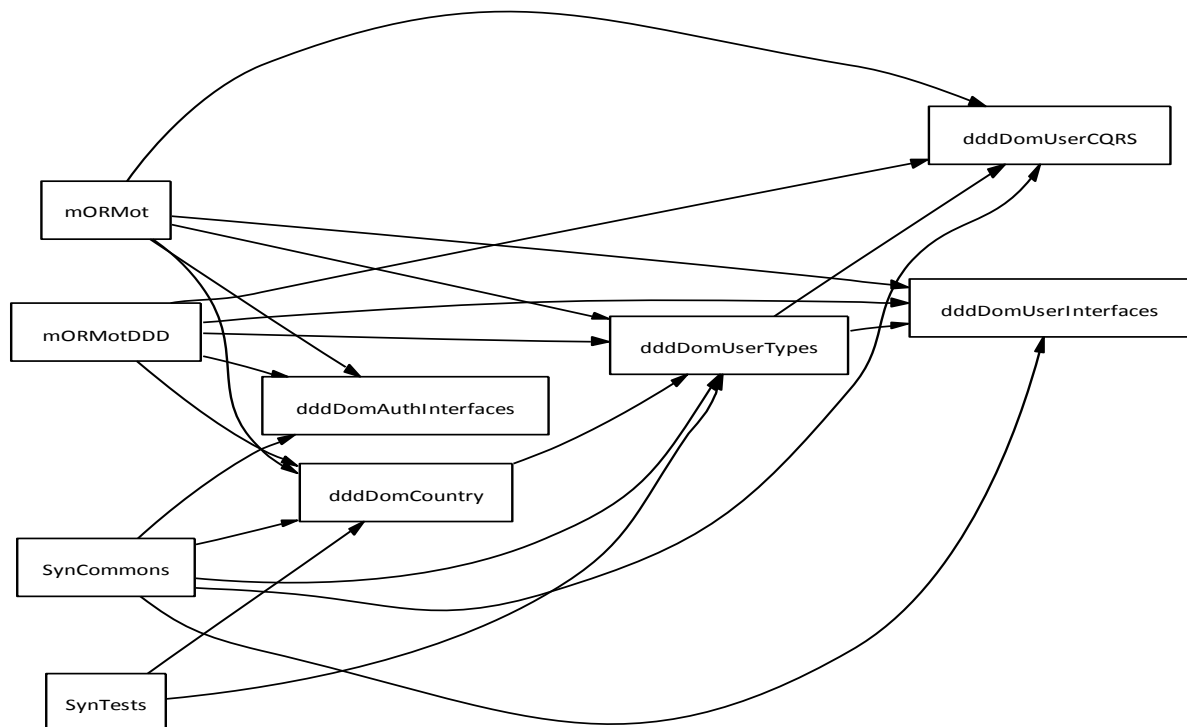

Source File Name	Description	Page
<i>mORMotReport</i>	Reporting unit	2362
<i>mORMotSelfTests</i>	Automated tests for common units of the Synapse mORMot Framework	2379
<i>mORMotService</i>	Daemon managment classes for mORMot, including low-level Win NT Service	2380
<i>mORMotSQLite3</i>	SQLite3 embedded Database engine used as the mORMot SQL kernel	2392
<i>mORMotToolBar</i>	ORM-driven Office 2007 Toolbar for mORMot	2400
<i>mORMotUI</i>	Grid to display database content for mORMot	2414
<i>mORMotUIEdit</i>	Record edition dialog, used to edit record content with mORMot	2425
<i>mORMotUILogin</i>	Some common User Interface functions and dialogs for mORMot	2428
<i>mORMotUIOptions</i>	General Options setting dialog for mORMot	2432
<i>mORMotUIQuery</i>	Form handling queries to a User Interface Grid for mORMot	2434
<i>mORMotVCL</i>	DB VCL dataset using TSQLTable/TSQLTableJSON data access	2436
<i>mORMotWrappers</i>	Generate cross-platform clients code and documentation from a mORMot server	2440
<i>TestSQL3FPCInterfaces</i>	SOA interface methods definition to circumvent FPC missing RTTI	2446

Unit dependencies in the "Lib\SQLite3" directory

Units located in the "Lib\SQLite3\DDD\dom\" directory:

Source File Name	Description	Page
<i>dddDomAuthInterfaces</i>	Shared DDD Domains: Authentication objects and interfaces	2447
<i>dddDomCountry</i>	Shared DDD Domains: TCountry object definition	2449
<i>dddDomUserCQRS</i>	Shared DDD Domains: User CQRS Repository interfaces	2452
<i>dddDomUserInterfaces</i>	Shared DDD Domains: User interfaces definition	2455
<i>dddDomUserTypes</i>	Shared DDD Domains: User objects definition	2457

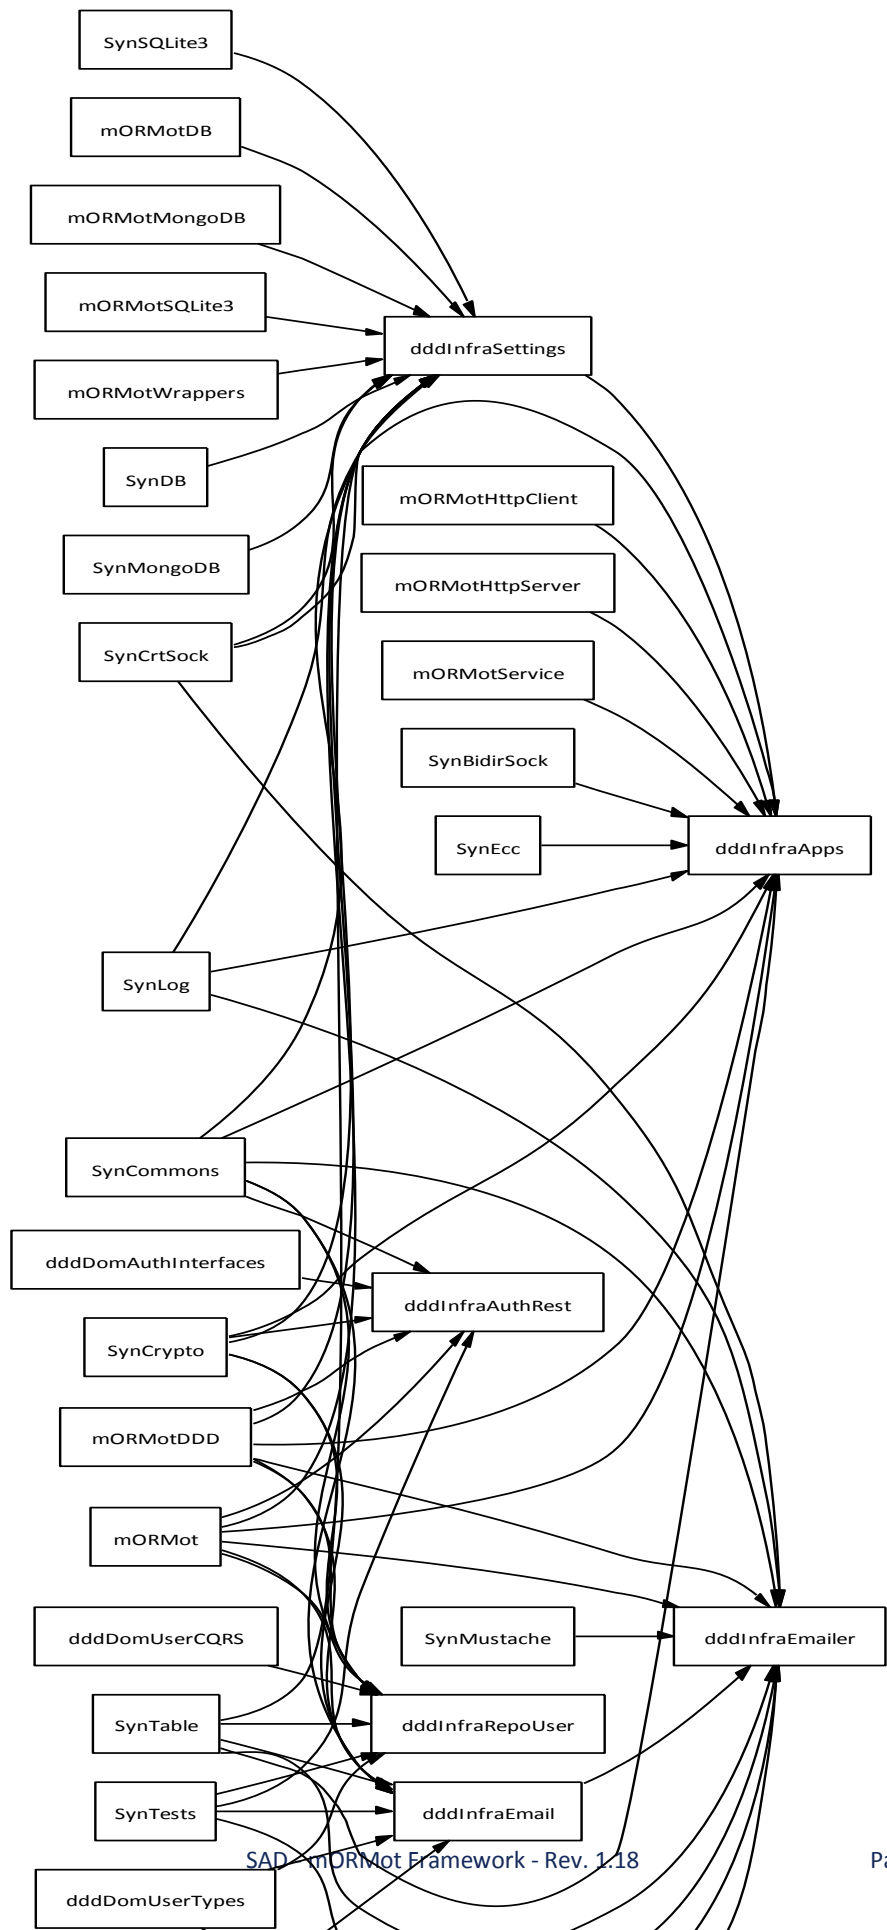

Unit dependencies in the "Lib\SQLite3\DDD\infra" directory

Units located in the "Lib\SQLite3\DDD\infra\" directory:

Source File Name	Description	Page
<i>dddInfraApps</i>	Shared DDD Infrastructure: Application/Daemon implementation classes	2460
<i>dddInfraAuthRest</i>	Shared DDD Infrastructure: Authentication implementation	2473

Source File Name	Description	Page
<i>dddInfraEmail</i>	Shared DDD Infrastructure: implement an email validation service	2477
<i>dddInfraEmailer</i>	Shared DDD Infrastructure: generic emailing service	2481
<i>dddInfraRepoUser</i>	Shared DDD Infrastructure: User CQRS Repository via ORM	2485
<i>dddInfraSettings</i>	Shared DDD Infrastructure: Application/Daemon settings classes	2487

Unit dependencies in the "Lib\SQLite3\DDD\infra" directory

Units located in the "Lib\SynDBDataset\" directory:

Source File Name	Description	Page
SynDBBDE	BDE access classes for SynDB units	2500
SynDBFireDAC	FireDAC/AnyDAC-based classes for SynDB units	2503
SynDBNexusDB	NexusDB 3.x direct access classes (embedded engine only)	2507
SynDBUniDAC	UniDAC-based classes for SynDB units	2511

Unit dependencies in the "Lib\SynDBDataset" directory

27.2. PasZip.pas unit

Purpose: ZIP/LZ77 Deflate/Inflate Compression in pure pascal

- this unit is a part of the freeware Synopse framework, licensed in the LGPL v3; version 1.18

PasZip class hierarchy

Objects implemented in the *PasZip* unit

Objects	Description	Page
TFileHeader	Directory file information structure, as used in .zip file format	676
TFileInfo	Generic file information structure, as used in .zip file format	675
TLastHeader	@TLocalFileHeader last header structure, as used in .zip file format	676
TLocalFileHeader	Internal file information structure, as used in .zip file format	676
TZipEntry	0 stores an entry of a file inside a .zip archive	677
TZipRead	Read-only access to a .zip archive file	677
TZipWrite	Write-only access for creating a .zip archive file	678

TFileInfo = packed record

Generic file information structure, as used in .zip file format

- used in any header, contains info about following block

extraLen: word;

Length(name)

flags: word;

14

zcrc32: dword;

Dos format

zlastModDate: word;

Dos format

zlastModTime: word;

8 (deflate)

zzipMethod: word;

0

TLocalFileHeader = packed record

Internal file information structure, as used in .zip file format

- used locally inside the file stream, followed by the name and then the data

```
fileInfo: TFileInfo;  
  04034b50
```

TFileHeader = packed record

Directory file information structure, as used in .zip file format

- used at the end of the zip file to recap all entries

```
extFileAttr: dword;  
  0 = binary; 1 = text
```

```
fileInfo: TFileInfo;  
  14
```

```
firstDiskNo: word;  
  0
```

```
intFileAttr: word;  
  0
```

```
localHeadOff: dword;  
  Dos file attributes
```

```
madeBy: word;  
  02014b50
```

TLastHeader = packed record

@TLocalFileHeader last header structure, as used in .zip file format

- this header ends the file and is used to find the TFileHeader entries

```
commentLen: word;  
  @TFileHeader
```

```
headerDisk: word;  
  0
```

```
headerOffset: dword;  
  SizeOf(TFileHeaders + names)
```

```
headerSize: dword;  
  1
```

```
thisDisk: word;  
  06054b50
```

thisFiles: word;

0

totalFiles: word;

1

TZipEntry = packed record

0 stores an entry of a file inside a .zip archive

data: PAnsiChar;

Points to the compressed data in the .zip archive, mapped in memory

info: PFileInfo;

The information of this file, as stored in the .zip archive

Name: array[0..127 - SizeOf(pointer)*2] of AnsiChar;

ASCIIZ name of the file inside the .zip archive
 - not a string, but a fixed-length array of char

TZipRead = class(TObject)

Read-only access to a .zip archive file

- can open directly a specified .zip file (will be memory mapped for fast access)
- can open a .zip archive file content from a resource (embedded in the executable)
- can open a .zip archive file content from memory

Count: integer;

The number of files inside a .zip archive

Entry: array of TZipEntry;

The files inside the .zip archive

constructor Create(BufZip: pByteArray; Size: cardinal); overload;

Open a .zip archive file directly from memory

constructor Create(Instance: THandle; const ResName: string; ResType: PChar); overload;

Open a .zip archive file directly from a resource

constructor Create(const aFileName: TFileName; ZipStartOffset: cardinal = 0; Size: cardinal = 0; ShowMessageBoxOnError: boolean = true); overload;

Open a .zip archive file as Read Only

destructor Destroy; override;

Release associated memory

function CheckFile(aIndex: integer; DestPath: TFileName): boolean;

Read the file from the supplied folder, and check its content according to the crc32 stored inside the .zip archive header (no decompression is made)

function GetInitialExeContent: RawByteZip;

Get any initial .exe file

function NameToIndex(**const** aZipName: TZipName): integer;

Get the index of a file inside the .zip archive

function UnZip(aIndex: integer): RawByteZip; overload;

Uncompress a file stored inside the .zip archive into memory

function UnZipFile(aIndex: integer; DestPath: TFileName; ForceWriteFlush: boolean): boolean;

Uncompress a file stored inside the .zip archive into a destination folder

property ZipStartOffset: cardinal **read** fZipStartOffset;

*The starting offset of the .zip content, after the initial .exe, if any
- can be used to copy the initial .exe file*

TZipWrite = **class**(TObject)

Write-only access for creating a .zip archive file

- not to be used to update a .zip file, but to create a new one
- update can be done manually by using a TZipRead instance and the AddFromZip() method

Count: integer;

The total number of entries

Entry: **array of record** name: TZipName; fhr: TFileHeader; **end**;

The resulting file entries

Handle: integer;

The associated file handle

constructor Create(**const** aFileName: TFileName); overload;

The file name the corresponding file header initialize the .zip file

destructor Destroy; **override**;

Release associated memory, and close destination file

procedure AddDeflated(**const** aFileName: TFileName; RemovePath: boolean = true; CompressLevel: integer = 6); overload;

Compress (using the deflate method) a file, and add it to the zip file

procedure AddDeflated(**const** aZipName: TZipName; Buf: pointer; Size: integer; CompressLevel: integer = 6; FileAge: integer = 1 + 1 shl 5 + 30 shl 9); overload;

*Compress (using the deflate method) a memory buffer, and add it to the zip file
- by default, the 1st of January, 2010 is used if not date is supplied*

procedure AddFromZip(**const** ZipEntry: TZipEntry);

Add a file from an already compressed zip entry

procedure AddStored(**const** aZipName: TZipName; Buf: pointer; Size: integer; FileAge: integer = 1 + 1 shl 5 + 30 shl 9);

*Add a memory buffer to the zip file, without compression
- content is stored, not deflated (in that case, no deflate code is added to the executable)
- by default, the 1st of January, 2010 is used if not date is supplied*

```
procedure Append(const Content: RawByteZip);
```

Append a file content into the destination file
- useful to add the initial Setup.exe file, e.g.

Types implemented in the *PasZip* unit

```
PFileInfo = ^TFileInfo;  
0
```

Functions or procedures implemented in the *PasZip* unit

Functions or procedures	Description	Page
CompressMem	Compress memory using the ZLib DEFLATE algorithm	679
CompressString	Compress memory using the ZLib DEFLATE algorithm with a crc32 checksum	679
CreateVoidZip	Create a void .zip file	679
GzCompress	Create a compatible .gz file (returns file size)	679
UnCompressMem	Uncompress memory using the ZLib INFLATE algorithm	679
UncompressString	Uncompress memory using the ZLib INFLATE algorithm, checking crc32 checksum	679
UpdateCrc32	Calculate the CRC32 hash of a specified memory buffer	679
Zip	You can create a "zip" compatible archive by calling the "Zip" function.	680

```
function CompressMem(src, dst: pointer; srcLen, dstLen: integer): integer;  
Compress memory using the ZLib DEFLATE algorithm
```

```
function CompressString(const data: RawByteZip; failIfGrow: boolean = false):  
RawByteZip;  
Compress memory using the ZLib DEFLATE algorithm with a crc32 checksum
```

```
procedure CreateVoidZip(const aFileName: TFileName);  
Create a void .zip file
```

```
function GzCompress(src: pointer; srcLen: integer; const fName: TFileName): cardinal;  
Create a compatible .gz file (returns file size)
```

```
function UnCompressMem(src, dst: pointer; srcLen, dstLen: integer): integer;  
Uncompress memory using the ZLib INFLATE algorithm
```

```
function UncompressString(const data: RawByteZip): RawByteZip;  
Uncompress memory using the ZLib INFLATE algorithm, checking crc32 checksum
```

```
function UpdateCrc32(aCRC32: cardinal; inBuf: pointer; inLen: integer): cardinal;  
Calculate the CRC32 hash of a specified memory buffer
```

```
function Zip(const zip: TFileName; const files, zipAs: array of TFileName;  
NoSubDirectories: boolean = false): boolean;
```

You can create a "zip" compatible archive by calling the "Zip" function.

- The first parameter is the full file path of the new zip archive.
- The second parameter must be an array of the files you want to have zipped into the archive (full file path again, please).
- The third array (only file names, please) allows you to store the files into the zip under a different name.
- Generally the resulting zip archive should not contain any directory structure: all zipped files are directly stored in the archive's root, if NoSubDirectories is set to TRUE.

Variables implemented in the *PasZip* unit

```
crc32Tab: TCRC32Tab;
```

The static buffer used for fast CRC32 hashing

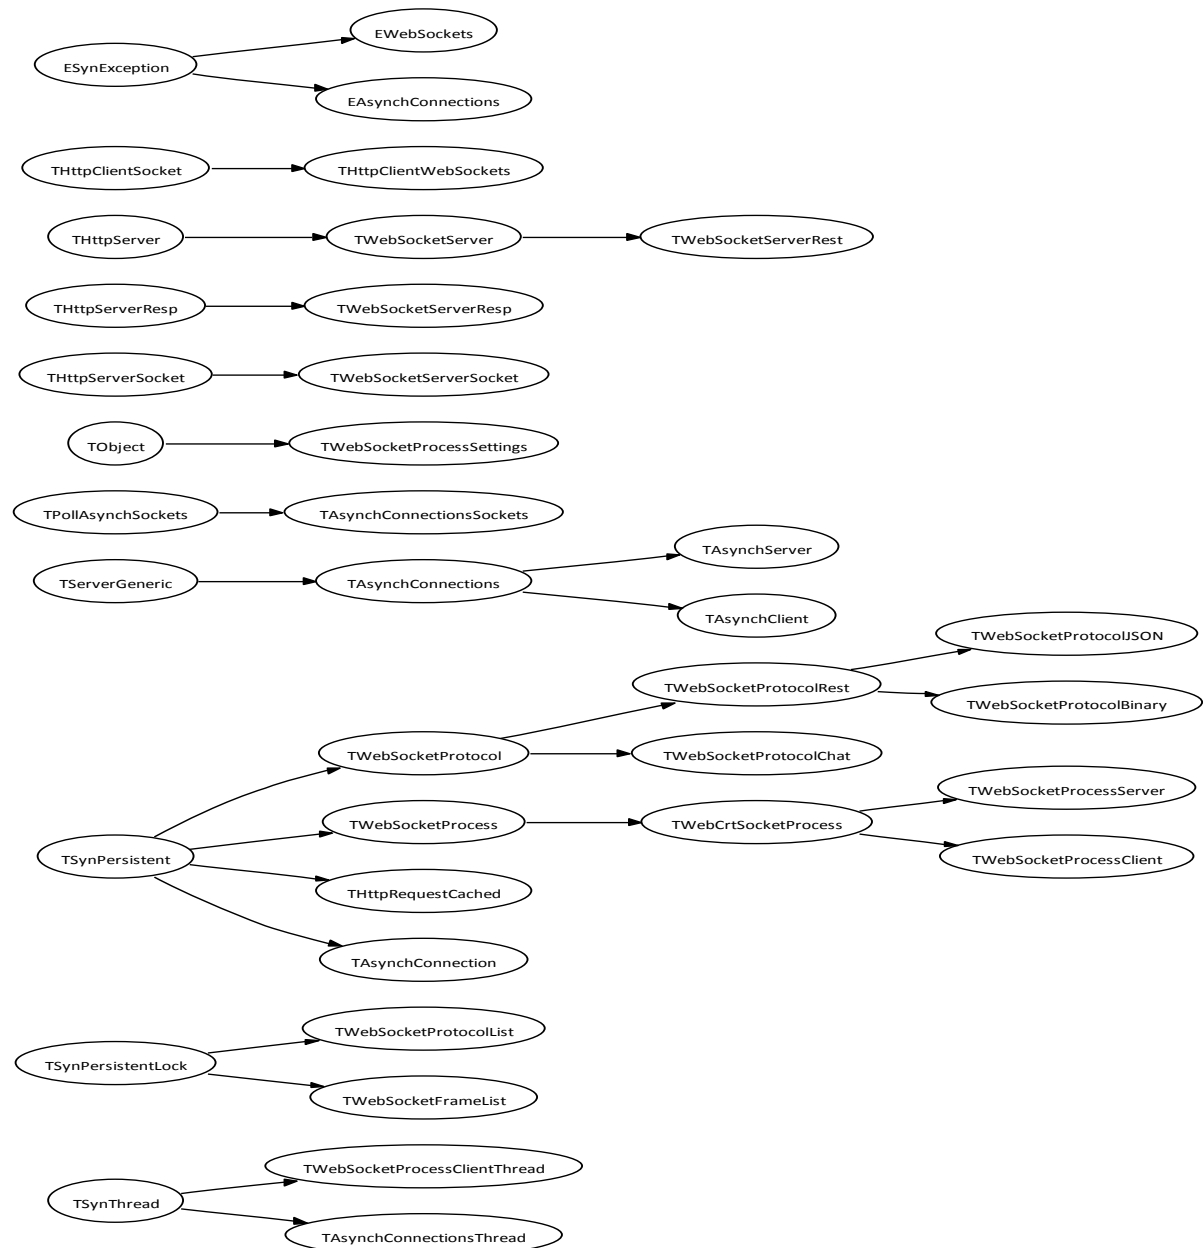

27.3. SynBidirSock.pas unit

Purpose: Implements bidirectional client and server protocol, e.g. WebSockets

- this unit is a part of the freeware Synopse mORMot framework, licensed under a MPL/GPL/LGPL tri-license; version 1.18

Units used in the *SynBidirSock* unit

Unit Name	Description	Page
<i>SynCommons</i>	Common functions used by most Synopse projects - this unit is a part of the freeware Synopse mORMot framework, licensed under a MPL/GPL/LGPL tri-license; version 1.18	718
<i>SynCrtSock</i>	Classes implementing TCP/UDP/HTTP client and server protocol - this unit is a part of the freeware Synopse mORMot framework, licensed under a MPL/GPL/LGPL tri-license; version 1.18	1086
<i>SynCrypto</i>	Fast cryptographic routines (hashing and cypher) - implements AES,XOR,ADLER32,MD5,RC4,SHA1,SHA256,SHA384,SHA512,SHA3 and JWT - optimized for speed (tuned assembler and SSE3/SSE4/AES-NI/PADLOCK support) - this unit is a part of the freeware Synopse mORMot framework, licensed under a MPL/GPL/LGPL tri-license; version 1.18	1143
<i>SynEcc</i>	Certificate-based public-key cryptography using ECC-secp256r1 - this unit is a part of the freeware Synopse mORMot framework, licensed under a MPL/GPL/LGPL tri-license; version 1.18	1318
<i>SynLog</i>	Logging functions used by Synopse projects - this unit is a part of the freeware Synopse mORMot framework, licensed under a MPL/GPL/LGPL tri-license; version 1.18	1368
<i>SynLZ</i>	SynLZ Compression routines - licensed under a MPL/GPL/LGPL tri-license; version 1.18	1399
<i>SynTable</i>	Filter/database/cache/buffer/security/search/multithread/OS features - as a complement to SynCommons, which tended to increase too much - licensed under a MPL/GPL/LGPL tri-license; version 1.18	1728
<i>SynWinSock</i>	Low level access to network Sockets for the Win32 platform - this unit is a part of the freeware Synopse framework, licensed under a MPL/GPL/LGPL tri-license; version 1.18	1851

SynBidirSock class hierarchy

Objects implemented in the *SynBidirSock* unit

Objects	Description	Page
EAsynchConnections	Exception associated with TAsynchConnection / TAsynchConnections process	685
EWebSockets	Exception raised when processing WebSockets	688
TAsynchClient	Implements thread-pooled high-performance TCP multiple clients	688
TAsynchConnection	Abstract class to store one TAsynchConnections connection	685

Objects	Description	Page
TAsynchConnections	Implements an abstract thread-pooled high-performance TCP clients or server	686
TAsynchConnectionsSockets	Handle multiple non-blocking connections using TAsynchConnection instances	685
TAsynchConnectionsThread	Used to implement a thread pool to process TAsynchConnection instances	685
TAsynchServer	Implements a thread-pooled high-performance TCP server	687
THttpClientWebSockets	Socket API based REST and HTTP/1.1 client, able to upgrade to WebSockets	700
THttpRequestCache	In-memory storage of one THttpRequestCached entry	684
THttpRequestCached	Handles cached HTTP connection to a remote server	684
TWebCrtSocketProcess	TCrtSocket-based WebSockets process, used on both client or server sides	697
TWebSocketFrame	Stores a WebSockets frame	688
TWebSocketFrameList	Used to manage a thread-safe list of WebSockets frames	693
TWebSocketProcess	Abstract WebSockets process, used on both client or server sides	695
TWebSocketProcessClient	Implements WebSockets process as used on client side	700
TWebSocketProcessClientThread	WebSockets processing thread used on client side	700
TWebSocketProcessServer	Implements WebSockets process as used on server side	697
TWebSocketProcessSettings	Parameters to be used for WebSockets process	694
TWebSocketProtocol	One instance implementing application-level WebSockets protocol	689
TWebSocketProtocolBinary	Handle a REST application-level WebSockets protocol using compressed and optionally AES-CFB encrypted binary	691
TWebSocketProtocolChat	Simple chatting protocol, allowing to receive and send WebSocket frames	690
TWebSocketProtocolJSON	Handle a REST application-level WebSockets protocol using JSON for transmission	691
TWebSocketProtocolList	Used to maintain a list of websocket protocols (for the server side)	692
TWebSocketProtocolRest	Handle a REST application-level bi-directional WebSockets protocol	691
TWebSocketServer	Main HTTP/WebSockets server Thread using the standard Sockets API (e.g. WinSock)	698

Objects	Description	Page
TWebSocketServerResp	An enhanced input/output structure used for HTTP and WebSockets requests	697
TWebSocketServerRest	Main HTTP/WebSockets server Thread using the standard Sockets API (e.g. WinSock)	699

THttpRequestCache = record

In-memory storage of one THttpRequestCached entry

THttpRequestCached = class(TSynPersistent)

Handles cached HTTP connection to a remote server

- use in-memory cached content when HTTP_NOTMODIFIED (304) is returned for an already known ETAG header value

constructor Create(**const** aURI: RawUTF8; aKeepAliveSeconds: integer=30; aTimeoutSeconds: integer=15*60; **const** aToken: RawUTF8=''; aHttpClass: THttpRequestClass=nil); **reintroduce**;

Initialize the cache for a given server

- once set, you can change the request URI using the Address property
- aKeepAliveSeconds = 0 will force "Connection: Close" HTTP/1.0 requests
- an internal cache will be maintained, and entries will be flushed after aTimeoutSeconds - i.e. 15 minutes per default - setting 0 will disable the client-side cache content
- aToken is an optional token which will be transmitted as HTTP header:
Authorization: Bearer <aToken>
- TWinHttp will be used by default under Windows, unless you specify another class

destructor Destroy; **override**;

Finalize the cache

function Flush(**const** aAddress: SockString): boolean;

Erase one resource from internal cache

function Get(**const** aAddress: SockString; aModified: PBoolean=nil; aStatus: PInteger=nil): SockString;

Retrieve a resource from the server, or internal cache

- aModified^ = true if server returned a HTTP_SUCCESS (200) with some new content, or
- aModified^ = false if HTTP_NOTMODIFIED (304) was returned

function LoadFromURI(**const** aURI: RawUTF8; **const** aToken: RawUTF8=''; aHttpClass: THttpRequestClass=nil): boolean;

Connect to a new server

- aToken is an optional token which will be transmitted as HTTP header:
Authorization: Bearer <aToken>
- TWinHttp will be used by default under Windows, unless you specify another class

procedure Clear;

Finalize the current connection and flush its in-memory cache

- you may use LoadFromURI() to connect to a new server

property URI: TURI read fURI;

Read-only access to the connected server

EAsynchConnections = **class**(ESynException)

Exception associated with TAsynchConnection / TAsynchConnections process

TAsynchConnection = **class**(TSynPersistent)

Abstract class to store one TAsynchConnections connection

- may implement e.g. WebSockets frames, or IoT binary protocol
- each connection will be identified by a TAsynchConnectionHandle integer
- idea is to minimize the resources used per connection, and allow full customization of the process by overriding the OnRead virtual method (and, if needed, AfterCreate/AfterWrite/BeforeDestroy/OnLastOperationIdle)

constructor Create(**const** aRemoteIP: RawUTF8); **reintroduce**; **virtual**;

Initialize this instance

property Handle: TAsynchConnectionHandle **read** fHandle;

Read-only access to the handle number associated with this connection

property RemoteIP: RawUTF8 **read** fRemoteIP;

The associated remote IP4/IP6, as text

property Socket: TSocket **read** fSlot.socket;

Read-only access to the socket number associated with this connection

TAsynchConnectionsSockets = **class**(TPollAsynchSockets)

Handle multiple non-blocking connections using TAsynchConnection instances

- OnRead will redirect to TAsynchConnection.OnRead virtual method
- OnClose will remove the instance from TAsynchConnections.fConnections[]
- OnError will return false to shutdown the connection (unless acoOnErrorContinue is defined in TAsynchConnections.Options)

function Write(connection: TObject; **const** data; datalen: integer; timeout: integer=5000): boolean; **override**;

Add some data to the asynchronous output buffer of a given connection

- this overridden method will refresh TAsynchConnection.LastOperation
- can be executed from an TAsynchConnection.OnRead method

property Total: integer **read** GetTotal;

How many clients have been handled by the poll, from the beginning

TAsynchConnectionsThread = **class**(TSynThread)

Used to implement a thread poll to process TAsynchConnection instances

constructor Create(aOwner: TAsynchConnections; aProcess: TPollSocketEvent); **reintroduce**;

Initialize the thread

TAsynchConnections = class(TServerGeneric)

Implements an abstract thread-pooled high-performance TCP clients or server

- internal TAsynchConnectionsSockets will handle high-performance process of a high number of long-living simultaneous connections
- will use a TAsynchConnection inherited class to maintain connection state
- don't use this abstract class but either TAsynchServer or TAsynchClients
- under Linux/POSIX, check your "ulimit -H -n" value: one socket consumes two file descriptors: you may better add the following line to your /etc/limits.conf or /etc/security/limits.conf system file:

```
* hard nofile 65535
```

constructor Create(OnStart,OnStop: TNotifyThreadEvent; aStreamClass: TAsynchConnectionClass; **const** ProcessName: SockString; aLog: TSynLogClass; aOptions: TAsynchConnectionsOptions; aThreadPoolCount: integer); **reintroduce;**
virtual;

From fThreadClients initialize the multiple connections

- warning: currently reliable only with aThreadPoolCount=1

destructor Destroy; **override;**

Shut down the instance, releasing all associated threads and sockets

function ConnectionFindLocked(aHandle: TAsynchConnectionHandle; aIndex: PInteger=nil): TAsynchConnection;

High-level access to a connection instance, from its handle

- could be executed e.g. from a TAsynchConnection.OnRead method
- returns nil if the handle was not found
- returns the matching instance, and caller should release the lock as:
 try ... finally UnLock; end;

function ConnectionRemove(aHandle: TAsynchConnectionHandle): boolean;

Remove an handle from the internal list, and close its connection

- could be executed e.g. from a TAsynchConnection.OnRead method

function Write(connection: TAsynchConnection; **const** data; datalen: integer): boolean; **overload;**

Add some data to the asynchronous output buffer of a given connection

- could be executed e.g. from a TAsynchConnection.OnRead method

function Write(connection: TAsynchConnection; **const** data: SockString): boolean; **overload;**

Add some data to the asynchronous output buffer of a given connection

- could be executed e.g. from a TAsynchConnection.OnRead method

procedure Lock;

Just a wrapper around fConnectionLock.Lock

```
procedure LogVerbose(connection: TAsynchConnection; const ident: RawUTF8; frame:  
pointer; framelen: integer); overload;
```

Log some binary data with proper escape

- can be executed from an TAsynchConnection.OnRead method to track content:
if acoVerboseLog in Sender.Options then Sender.LogVerbose(self,...);

```
procedure LogVerbose(connection: TAsynchConnection; const ident: RawUTF8; const  
frame: RawByteString); overload;
```

Log some binary data with proper escape

- can be executed from an TAsynchConnection.OnRead method to track content:
if acoVerboseLog in Sender.Options then Sender.LogVerbose(...);

```
procedure Unlock;
```

Just a wrapper around fConnectionLock.Unlock

```
property Clients: TAsynchConnectionsSockets read fClients;
```

Access to the TCP client sockets poll

- TAsynchConnection.OnRead should rather use Write() and LogVerbose() methods of this
TAsynchConnections class instead of using Clients

```
property Connection: TAsynchConnectionObjArray read fConnection;
```

Low-level unsafe direct access to the connection instances

- ensure this property is used in a thread-safe manner, i.e. via
Lock; try ... finally Unlock; end;

```
property ConnectionCount: integer read fConnectionCount;
```

Low-level unsafe direct access to the connection count

- ensure this property is used in a thread-safe manner, i.e. via
Lock; try ... finally Unlock; end;

```
property LastOperationIdleSeconds: cardinal read fLastOperationIdleSeconds write  
fLastOperationIdleSeconds;
```

Will execute TAsynchConnection.OnLastOperationIdle after an idle period

- could be used to send heartbeats after read/write inactivity
- equals 0 (i.e. disabled) by default

```
property Log: TSynLogClass read fLog;
```

Access to the associated log class

```
property Options: TAsynchConnectionsOptions read fOptions write fOptions;
```

Allow to customize low-level options for processing

```
TAsynchServer = class(TAsynchConnections)
```

Implements a thread-pooled high-performance TCP server

- will use a TAsynchConnection inherited class to maintain connection state for server process

constructor Create(const aPort: SockString; OnStart,OnStop: TNotifyThreadEvent; aStreamClass: TAsynchConnectionClass; const ProcessName: SockString; aLog: TSynLogClass; aOptions: TAsynchConnectionsOptions; aThreadPoolCount: integer=1); reintroduce; virtual;

Run the TCP server, listening on a supplied IP port

destructor Destroy; override;

Shut down the server, releasing all associated threads and sockets

property Server: TCrtSocket read fServer;

Access to the TCP server socket

TAsynchClient = **class**(TAsynchConnections)

Implements thread-pooled high-performance TCP multiple clients

- e.g. to run some load stress tests with optimized resource use
- will use a TAsynchConnection inherited class to maintain connection state of each connected client

constructor Create(const aServer,aPort: SockString; aClientsCount,aClientsTimeoutSecs: integer; OnStart,OnStop: TNotifyThreadEvent; aStreamClass: TAsynchConnectionClass; const ProcessName: SockString; aLog: TSynLogClass; aOptions: TAsynchConnectionsOptions; aThreadPoolCount: integer=1); reintroduce; virtual;

Start the TCP client connections, connecting to the supplied IP server

property Port: SockString read fThreadClients.Port;

Server IP port

property Server: SockString read fThreadClients.Address;

Server IP address

EWebSockets = **class**(ESynException)

Exception raised when processing WebSockets

TWebSocketFrame = **record**

Stores a WebSockets frame

- see <http://tools.ietf.org/html/rfc6455> for reference

content: TWebSocketFramePayloads;

What is stored in the frame data, i.e. in payload field

opcode: TWebSocketFrameOpCode;

The interpretation of the frame data

payload: RawByteString;

The frame data itself

- is plain UTF-8 for focText kind of frame
- is raw binary for focBinary or any other frames
- warning: the content will be masked in-place so caller should ensure this buffer can be modified (e.g. do not fill from a constant)

tix: cardinal;

Equals GetTickCount64 shr 10, as used for TWebSocketFrameList timeout

TWebSocketProtocol = class(TSynPersistent)

One instance implementing application-level WebSockets protocol

- shared by TWebSocketServer and TWebSocketClient classes
- once upgraded to WebSockets, a HTTP link could be used e.g. to transmit our proprietary 'synopsejson' or 'synopsebin' application content, as stated by this typical handshake:

```
GET /myservice HTTP/1.1
Host: server.example.com
Upgrade: websocket
Connection: Upgrade
Sec-WebSocket-Key: x3JJHMbDL1EzLkh9GBhXDw==
Sec-WebSocket-Protocol: synopsejson
Sec-WebSocket-Version: 13
Origin: http://example.com
```

```
HTTP/1.1 101 Switching Protocols
Upgrade: websocket
Connection: Upgrade
Sec-WebSocket-Accept: H5mrc0sM1YUkAGmm50PpG2HaGWk=
Sec-WebSocket-Protocol: synopsejson
```

- the TWebSocketProtocolJSON inherited class will implement
Sec-WebSocket-Protocol: synopsejson
- the TWebSocketProtocolBinary inherited class will implement
Sec-WebSocket-Protocol: synopsebin

constructor Create(**const** aName, aURI: RawUTF8); **reintroduce;**

Abstract constructor to initialize the protocol

- the protocol should be named, so that the client may be able to request for a given protocol
- if aURI is '', any URI would potentially upgrade to this protocol; you can specify an URI to limit the protocol upgrade to a single resource

function Clone(**const** aClientURI: RawUTF8): TWebSocketProtocol; **virtual; abstract;**

Compute a new instance of the WebSockets protocol, with same parameters

procedure SetEncryptKey(aServer: boolean; **const** aKey: RawUTF8);

Set the fEncryption: IProtocol according to the supplied key

- any asymmetric algorithm need to know which side (client/server) to work on
- try TECDHEProtocol.FromKey(aKey) and fallback to TProtocolAES.Create(TAESCFB) using SHA256Weak(aKey)

procedure SetEncryptKeyAES(**const** aKey; aKeySize: cardinal);

Set the fEncryption: IProtocol as TProtocolAES.Create(TAESCFB)

property Encrypted: boolean **read** GetEncrypted;

Returns TRUE if encryption is enabled during the transmission

- is currently only available for TWebSocketProtocolBinary

property Encryption: IProtocol **read** fEncryption;

Access low-level frame encryption

property FramesInBytes: QWord read fFramesInBytes;
How many (uncompressed) bytes have been received by this instance

property FramesInCount: integer read fFramesInCount;
How many frames have been received by this instance

property FramesOutBytes: QWord read fFramesOutBytes;
How many (uncompressed) bytes have been sent by this instance

property FramesOutCount: integer read fFramesOutCount;
How many frames have been sent by this instance

property LastError: string read fLastError;
The last error message, during frame processing

property Name: RawUTF8 read fName;
The Sec-WebSocket-Protocol application name currently involved
- e.g. 'synapsejson', 'synapsebin' or 'synapsebinary'

property OnBeforeIncomingFrame: TOnWebSocketProtocolIncomingFrame read fOnBeforeIncomingFrame write fOnBeforeIncomingFrame;
Allow low-level interception before ProcessIncomingFrame is done

property RemoteIP: SockString read GetRemoteIP;
The associated 'Remote-IP' HTTP header value
- returns '' if self=nil or RemoteLocalhost=true

property UpgradeURI: RawUTF8 read fUpgradeURI;
The URI on which this protocol has been upgraded

property URI: RawUTF8 read fURI;
The optional URI on which this protocol would be enabled
- leave to '' if any URI should match

TWebSocketProtocolChat = class(TWebSocketProtocol)

Simple chatting protocol, allowing to receive and send WebSocket frames
- you can use this protocol to implement simple asynchronous communication with events expecting no answers, e.g. with AJAX applications
- see TWebSocketProtocolRest for bi-directional events expecting answers

constructor Create(const aName, aURI: RawUTF8; const aOnIncomingFrame: TOnWebSocketProtocolChatIncomingFrame); overload;
Initialize the chat protocol with an incoming frame callback

function Clone(const aClientURI: RawUTF8): TWebSocketProtocol; override;
Compute a new instance of the WebSockets protocol, with same parameters

function SendFrame(Sender: THttpServerResp; const Frame: TWebSocketFrame): boolean;
On the server side, allows to send a message over the wire to a specified client connection
- a temporary copy of the Frame content will be made for safety

function SendFrameJson(Sender: THttpServerResp; var JSON: RawUTF8): boolean;

On the server side, allows to send a JSON message over the wire to a specified client connection
 - the supplied JSON content is supplied as "var", since it may be modified during execution, e.g. XORed for frame masking

property OnIncomingFrame: TOnWebSocketProtocolChatIncomingFrame read
 fOnIncomingFrame write fOnIncomingFrame;

You can assign an event to this property to be notified of incoming messages

TWebSocketProtocolRest = **class**(TWebSocketProtocol)

Handle a REST application-level bi-directional WebSockets protocol

- will emulate a bi-directional REST process, using THttpRequest to store and handle the request parameters: clients would be able to send regular REST requests to the server, but the server could use the same communication channel to push REST requests to the client
- a local THttpRequest will be used on both client and server sides, to store REST parameters and compute the corresponding WebSockets frames

TWebSocketProtocolJSON = **class**(TWebSocketProtocolRest)

Handle a REST application-level WebSockets protocol using JSON for transmission

- could be used e.g. for AJAX or non Delphi remote access
- this class will implement then following application-level protocol:
 Sec-WebSocket-Protocol: synapsejson

constructor Create(const aURI: RawUTF8); reintroduce;

Initialize the WebSockets JSON protocol

- if aURI is "", any URI would potentially upgrade to this protocol; you can specify an URI to limit the protocol upgrade to a single resource

function Clone(const aClientURI: RawUTF8): TWebSocketProtocol; override;

Compute a new instance of the WebSockets protocol, with same parameters

TWebSocketProtocolBinary = **class**(TWebSocketProtocolRest)

Handle a REST application-level WebSockets protocol using compressed and optionally AES-CFB encrypted binary

- this class will implement then following application-level protocol:
 Sec-WebSocket-Protocol: synapsebin

or fallback to the previous subprotocol

Sec-WebSocket-Protocol: synapsebinary

- 'synapsebin' will expect requests sequenced as 'r000001','r000002',... headers matching 'a000001','a000002',... instead of 'request'/'answer'

constructor Create(const aURI: RawUTF8; aServer: boolean; const aKey: RawUTF8; aCompressed: boolean=true); reintroduce; overload;

Initialize the WebSockets binary protocol from a textual key

- if aURI is "", any URI would potentially upgrade to this protocol; you can specify an URI to limit the protocol upgrade to a single resource
- will create a TProtocolAES or TECDHEProtocol instance, corresponding to the supplied aKey and aServer values, to secure the transmission using a symmetric or assymetric algorithm
- SynLZ compression is enabled by default, unless aCompressed is false

constructor Create(const aURI: RawUTF8; const aKey; aKeySize: cardinal; aCompressed: boolean=true); reintroduce; overload;

Initialize the WebSockets binary protocol with a symmetric AES key

- if aURI is "", any URI would potentially upgrade to this protocol; you can specify an URI to limit the protocol upgrade to a single resource
- if aKeySize if 128, 192 or 256, TProtocolAES (i.e. AES-CFB encryption) will be used to secure the transmission
- SynLZ compression is enabled by default, unless aCompressed is false

constructor Create(const aURI: RawUTF8; aCompressed: boolean=true); reintroduce; overload; virtual;

Initialize the WebSockets binary protocol with no encryption

- if aURI is "", any URI would potentially upgrade to this protocol; you can specify an URI to limit the protocol upgrade to a single resource
- SynLZ compression is enabled by default, unless aCompressed is false

function Clone(const aClientURI: RawUTF8): TWebSocketProtocol; override;

Compute a new instance of the WebSockets protocol, with same parameters

property Compressed: boolean read fCompressed write fCompressed;

Defines if SynLZ compression is enabled during the transmission

- is set to TRUE by default

property FramesInBytesSocket: QWord read fFramesInBytesSocket;

How many bytes have been received by this instance from the wire

property FramesInCompression: integer read GetFramesInCompression;

Compression ratio of frames received by this instance

property FramesOutBytesSocket: QWord read fFramesOutBytesSocket;

How many bytes have been sent by this instance to the wire

property FramesOutCompression: integer read GetFramesOutCompression;

Compression ratio of frames Sent by this instance

TWebSocketProtocolList = class(TSynPersistentLock)

Used to maintain a list of websocket protocols (for the server side)

destructor Destroy; override;

Finalize the list storage

function Add(aProtocol: TWebSocketProtocol): boolean;

Add a protocol to the internal list

- returns TRUE on success
- if this protocol is already existing for this given name and URI, returns FALSE: it is up to the caller to release aProtocol if needed

function AddOnce(aProtocol: TWebSocketProtocol): boolean;

Add once a protocol to the internal list

- if this protocol is already existing for this given name and URI, any previous one will be released - so it may be confusing on a running server
- returns TRUE if the protocol was added for the first time, or FALSE if the protocol has been replaced or is invalid (e.g. aProtocol=nil)

function CloneByName(const aProtocolName, aClientURI: RawUTF8):
TWebSocketProtocol;

Create a new protocol instance, from the internal list

function CloneByURI(const aClientURI: RawUTF8): TWebSocketProtocol;

Create a new protocol instance, from the internal list

function Count: integer;

How many protocols are stored

function Remove(const aProtocolName, aURI: RawUTF8): boolean;

Erase a protocol from the internal list, specified by its name

TWebSocketFrameList = **class**(TSynPersistentLock)

Used to manage a thread-safe list of WebSockets frames

Count: integer;

Current number of WebSocket frames in the list

List: TWebSocketFrameDynArray;

Low-level access to the WebSocket frames list

constructor Create(timeoutsec: integer); **reintroduce**;

Initialize the list

function AnswerToIgnore(incr: integer=0): integer;

How many 'answer' frames are to be ignored
- this method is thread-safe

function Pop(protocol: TWebSocketProtocol; const head: RawUTF8; out frame:
TWebSocketFrame): boolean;

Retrieve a WebSocket frame from the list, oldest first

- you should specify a frame type to search for, according to the specified WebSockets protocol
- this method is thread-safe

procedure Push(const frame: TWebSocketFrame);

Add a WebSocket frame in the list
- this method is thread-safe

procedure PushVoidFrame(opcode: TWebSocketFrameOpCode);

Add a void WebSocket frame in the list
- this method is thread-safe

TWebSocketProcessSettings = object(TObject)

Parameters to be used for WebSockets process

CallbackAcquireTimeOutMS: cardinal;

How many milliseconds the callback notification should wait acquiring the connection before failing
- default is 5000, i.e. 5 seconds

CallbackAnswerTimeOutMS: cardinal;

How many milliseconds the callback notification should wait for the client to return its answer
- default is 30000, i.e. 30 seconds

DisconnectAfterInvalidHeartbeatCount: cardinal;

Will close the connection after a given number of invalid Heartbeat sent
- when a Heartbeat is failed to be transmitted, the class will start counting how many ping/pong did fail: when this property value is reached, it will release and close the connection
- default value is 5

HeartbeatDelay: cardinal;

Time in milli seconds between each focPing commands sent to the other end
- default is 0, i.e. no automatic ping sending on client side, and 20000, i.e. 20 seconds, on server side

LogDetails: set of (logHeartbeat, logTextFrameContent, logBinaryFrameContent);

By default, contains [] to minimize the logged information
- set logHeartbeat if you want the ping/pong frames to be logged
- set logTextFrameContent if you want the text frame content to be logged
- set logBinaryFrameContent if you want the binary frame content to be logged
- used only if WebSocketLog global variable is set to a TSynLog class

LoopDelay: cardinal;

Maximum period time in milli seconds when ProcessLoop thread will stay idle before checking for the next pending requests
- default is 500 ms, but you may put a lower value, if you expects e.g. REST commands or NotifyCallback(wscNonBlockWithoutAnswer) to be processed with a lower delay

OnClientConnected: TNotifyEvent;

Callback run when a WebSockets client is just connected
- triggered by TWebSocketProcess.ProcessStart

OnClientDisconnected: TNotifyEvent;

Callback run when a WebSockets client is just disconnected
- triggered by TWebSocketProcess.ProcessStop

SendDelay: cardinal;

Ms between sending - allow to gather output frames
- GetTickCount resolution is around 16ms under Windows, so default 10ms seems fine for a cross-platform similar behavior

procedure SetDefaults;

Will set the default values

procedure SetFullLog;

Will set LogDetails to its highest level of verbosity

- used only if WebSocketLog global variable is set

TWebSocketProcess = class(TSynPersistent)

Abstract WebSockets process, used on both client or server sides

- CanGetFrame/ReceiveBytes/SendBytes abstract methods should be overridden with actual communication, and fState and ProcessStart/ProcessStop should be updated from the actual processing thread (e.g. as in TWebCrtSocketProcess)

constructor Create(aProtocol: TWebSocketProtocol; aOwnerConnection: THttpServerConnectionID; aOwnerThread: TSynThread; **const** aSettings: TWebSocketProcessSettings; **const** aProcessName: RawUTF8); **reintroduce**;

Initialize the WebSockets process on a given connection

- the supplied TWebSocketProtocol will be owned by this instance
- other parameters should reflect the client or server expectations

destructor Destroy; **override**;

Finalize the context

- if needed, will notify the other end with a fConnectionClose frame
- will release the TWebSocketProtocol associated instance

function CanGetFrame(TimeOut: cardinal; ErrorWithoutException: PInteger): boolean; **virtual**; **abstract**;

Abstract low-level method to check if there is some pending input data in the input Socket ready for GetFrame/ReceiveBytes

- is defined separated to allow multi-thread pooling

function GetFrame(**out** Frame: TWebSocketFrame; ErrorWithoutException: PInteger): boolean;

Blocking process incoming WebSockets framing protocol

- CanGetFrame should have been called and returned true before
- will call overridden ReceiveBytes() for the actual communication

function NotifyCallback(aRequest: THttpRequest; aMode: TWebSocketProcessNotifyCallback): cardinal; **virtual**;

Will push a request or notification to the other end of the connection

- caller should set the aRequest with the outgoing parameters, and optionally receive a response from the other end
- the request may be sent in blocking or non blocking mode
- returns the HTTP Status code (e.g. HTTP_SUCCESS=200 for success)

function ReceiveBytes(P: PAnsiChar; count: integer): integer; **virtual**; **abstract**;

Abstract low-level method to retrieve pending input data

- should return the number of bytes (<=count) received and written to P
- is defined separated to allow multi-thread pooling

function RemoteIP: SockString;

The associated 'Remote-IP' HTTP header value

- returns '' if Protocol=nil or Protocol.RemoteLocalhost=true

function SendBytes(P: pointer; Len: integer): boolean; **virtual; abstract;**

Abstract low-level method to send pending output data

- returns false on any error, true on success

- is defined separated to allow multi-thread pooling

function SendFrame(var Frame: TWebSocketFrame): boolean;

Process outgoing WebSockets framing protocol -> to be overridden

- will call overridden SendBytes() for the actual communication

- use Outgoing.Push() to send frames asynchronously

function Settings: PWebSocketProcessSettings;

The settings currently used during the WebSockets process

- defined as a pointer so that you may be able to change the values

function State: TWebSocketProcessState;

Returns the current state of the underlying connection

property Incoming: TWebSocketFrameList **read** fIncoming;

Direct access to the low-level incoming frame stack

property InvalidPingSendCount: cardinal **read** fInvalidPingSendCount;

How many invalid heartbeat frames have been sent

- a non 0 value indicates a connection problem

property NoConnectionCloseAtDestroy: boolean **read** fNoConnectionCloseAtDestroy
write fNoConnectionCloseAtDestroy;

May be set to TRUE before Destroy to force raw socket disconnection

property Outgoing: TWebSocketFrameList **read** fOutgoing;

Direct access to the low-level outgoing frame stack

- call Outgoing.Push() to send frames asynchronously, with optional jumboframe gathering (if supported by the protocol)

property OwnerConnection: THttpServerConnectionID **read** fOwnerConnection;

The associated low-level WebSocket connection opaque identifier

property OwnerThread: TSynThread **read** fOwnerThread;

The associated low-level processing thread

property ProcessCount: integer **read** fProcessCount;

How many frames are currently processed by this connection

property ProcessName: RawUTF8 **read** fProcessName **write** fProcessName;

The associated process name

property Protocol: TWebSocketProtocol **read** fProtocol;

The Sec-WebSocket-Protocol application protocol currently involved

- TWebSocketProtocolJSON or TWebSocketProtocolBinary in the mORMot context

- could be nil if the connection is in standard HTTP/1.1 mode

TWebCrtSocketProcess = class(TWebSocketProcess)

TCrtSocket-based WebSockets process, used on both client or server sides

- will use the socket in blocking mode, so expects its own processing thread

constructor Create(aSocket: TCrtSocket; aProtocol: TWebSocketProtocol; aOwnerConnection: THttpServerConnectionID; aOwnerThread: TSynThread; **const** aSettings: TWebSocketProcessSettings; **const** aProcessName: RawUTF8); **reintroduce; virtual;**

Initialize the WebSockets process on a given TCrtSocket connection

- the supplied TWebSocketProtocol will be owned by this instance
 - other parameters should reflect the client or server expectations

function CanGetFrame(TimeOut: cardinal; ErrorWithoutException: PInteger): boolean; **override;**

First step of the low level incoming WebSockets framing protocol over TCrtSocket

- in practice, just call fSocket.SocketInPending to check for pending data

function ReceiveBytes(P: PAnsiChar; count: integer): integer; **override;**

Low level receive incoming WebSockets frame data over TCrtSocket

- in practice, just call fSocket.SocketInRead to check for pending data

function SendBytes(P: pointer; Len: integer): boolean; **override;**

Low level receive incoming WebSockets frame data over TCrtSocket

- in practice, just call fSocket.TrySndLow to send pending data

property Socket: TCrtSocket **read** fSocket;

The associated communication socket

- on the server side, is a THttpServerSocket
 - access to this instance is protected by Safe.Lock/Unlock

TWebSocketProcessServer = class(TWebCrtSocketProcess)

Implements WebSockets process as used on server side

TWebSocketServerResp = class(THttpServerResp)

An enhanced input/output structure used for HTTP and WebSockets requests

- this class will contain additional parameters used to maintain the WebSockets execution context in overridden TWebSocketServer.Process method

constructor Create(aServerSock: THttpServerSocket; aServer: THttpServer); **override;**

Initialize the context, associated to a HTTP/WebSockets server instance

function NotifyCallback(Ctxt: THttpServerRequest; aMode: TWebSocketProcessNotifyCallback): cardinal; **virtual;**

Push a notification to the client

function WebSocketProtocol: TWebSocketProtocol;

The Sec-WebSocket-Protocol application protocol currently involved

- TWebSocketProtocolJSON or TWebSocketProtocolBinary in the mORMot context
 - could be nil if the connection is in standard HTTP/1.1 mode

property WebSocketProcess: TWebSocketProcessServer read fProcess;

Low-level WebSocket protocol processing instance

TWebSocketServer = **class**(THttpServer)

Main HTTP/WebSockets server Thread using the standard Sockets API (e.g. WinSock)

- once upgraded to WebSockets from the client, this class is able to serve any Sec-WebSocket-Protocol application content

constructor Create(**const** aPort: SockString; OnStart,OnStop: TNotifyThreadEvent; **const** ProcessName: SockString; ServerThreadPoolCount: integer=2; KeepAliveTimeOut: integer=30000; HeadersNotFiltered: boolean=false; CreateSuspended: boolean = false); **override**;

Create a Server Thread, binded and listening on a port

- this constructor will raise a EHttpServer exception if binding failed
- expects the port to be specified as string, e.g. '1234'; you can optionally specify a server address to bind to, e.g. '1.2.3.4:1234'
- due to the way how WebSockets works, one thread will be created for any incoming connection
- note that this constructor will not register any protocol, so is useless until you execute Protocols.Add()
- in the current implementation, the ServerThreadPoolCount parameter will use two threads by default to handle shortlived HTTP/1.0 "connection: close" requests, and one thread will be maintained per keep-alive/websockets client
- by design, the KeepAliveTimeOut value is ignored with this server once it has been upgraded to WebSockets

destructor Destroy; **override**;

Close the server

function IsActiveWebSocket(ConnectionID: THttpServerConnectionID): TWebSocketServerResp;

Give access to the underlying connection from its ID

- also identifies an incoming THttpServerResp as a valid TWebSocketServerResp

function IsActiveWebSocketThread(ConnectionThread: TSynThread): TWebSocketServerResp;

Give access to the underlying connection from its connection thread

- also identifies an incoming THttpServerResp as a valid TWebSocketServerResp

function Settings: PWebSocketProcessSettings;

The settings to be used for WebSockets process

- note that those parameters won't be propagated to existing connections
- defined as a pointer so that you may be able to change the values

function WebSocketConnections: integer;

How many WebSockets connections are currently maintained

procedure WebSocketBroadcast(**const** aFrame: TWebSocketFrame); overload;

Will send a given frame to all connected clients

- expect aFrame.opcode to be either focText or focBinary
- will call TWebSocketProcess.Outgoing.Push for asynchronous sending

procedure WebSocketBroadcast(**const** aFrame: TWebSocketFrame; **const** aClientsConnectionID: THttpServerConnectionIDDynArray); overload;

- Will send a given frame to clients matching the supplied connection IDs*
- expect aFrame.opcode to be either focText or focBinary
 - will call TWebSocketProcess.Outgoing.Push for asynchronous sending

property WebSocketProtocols: TWebSocketProtocolList **read** fProtocols;

Access to the protocol list handled by this server

TWebSocketServerRest = class(TWebSocketServer)

Main HTTP/WebSockets server Thread using the standard Sockets API (e.g. WinSock)

- once upgraded to WebSockets from the client, this class is able to serve our proprietary Sec-WebSocket-Protocol: 'synopsejson' or 'synopsebin' application content, managing regular REST client-side requests and also server-side push notifications
- once in 'synopse*' mode, the Request() method will be triggered from any incoming REST request from the client, and the OnCallback event will be available to push a request from the server to the client

constructor Create(**const** aPort: SockString; OnStart,OnStop: TNotifyThreadEvent; **const** aProcessName, aWebSocketsURI, aWebSocketsEncryptionKey: RawUTF8; aWebSocketsAJAX: boolean=false); **reintroduce**; overload;

Create a Server Thread, binded and listening on a port, with our 'synopsebin' and optionally 'synopsejson' modes

- if aWebSocketsURI is "", any URI would potentially upgrade; you can specify an URI to limit the protocol upgrade to a single resource
- TWebSocketProtocolBinary will always be registered by this constructor
- if the encryption key text is not "", TWebSocketProtocolBinary will use AES-CFB 256 bits encryption
- if aWebSocketsAJAX is TRUE, it will also register TWebSocketProtocolJSON so that AJAX applications would be able to connect to this server
- warning: WaitStarted should be called after Create() to check for actual port binding in the background thread

function Callback(Ctxt: THttpServerRequest; aNonBlocking: boolean): cardinal; **override**;

Server can send a request back to the client, when the connection has been upgraded to WebSocket

- InURL/InMethod/InContent properties are input parameters (InContentType is ignored)
- OutContent/OutContentType/OutCustomHeader are output parameters
- CallingThread should be set to the client's Ctxt.CallingThread value, so that the method could know which connection is to be used - it will return STATUS_NOTFOUND (404) if the connection is unknown
- result of the function is the HTTP error code (200 if OK, e.g.)

procedure WebSocketsEnable(**const** aWebSocketsURI, aWebSocketsEncryptionKey: RawUTF8; aWebSocketsAJAX: boolean=false; aWebSocketsCompressed: boolean=true);

Defines the WebSockets protocols to be used for this Server

- i.e. 'synopsebin' and optionally 'synopsejson' modes
- if aWebSocketsURI is "", any URI would potentially upgrade; you can specify an URI to limit the protocol upgrade to a single resource
- TWebSocketProtocolBinary will always be registered by this constructor
- if the encryption key text is not "", TWebSocketProtocolBinary will use AES-CFB 256 bits encryption
- if aWebSocketsAJAX is TRUE, it will also register TWebSocketProtocolJSON so that AJAX applications would be able to connect to this server

TWebSocketProcessClient = **class**(TWebCrtSocketProcess)

Implements WebSockets process as used on client side

constructor Create(aSender: THttpClientWebSockets; aProtocol: TWebSocketProtocol; **const** aProcessName: RawUTF8); **reintroduce**; **virtual**;

Initialize the client process for a given THttpClientWebSockets

destructor Destroy; **override**;

Finalize the process

TWebSocketProcessClientThread = **class**(TSynThread)

WebSockets processing thread used on client side

- will handle any incoming callback

THttpClientWebSockets = **class**(THttpClientSocket)

Socket API based REST and HTTP/1.1 client, able to upgrade to WebSockets

- will implement regular HTTP/1.1 until WebSocketsUpgrade() is called

constructor Create(aTimeOut: PtrInt=10000); **override**;

Common initialization of all constructors

- this overridden method will set the UserAgent with some default value

destructor Destroy; **override**;

Finalize the connection

function Request(**const** url, method: SockString; KeepAlive: cardinal; **const** header, Data, DataType: SockString; retry: boolean): integer; **override**;

Process low-level REST request, either on HTTP/1.1 or via WebSockets

- after WebSocketsUpgrade() call, will use WebSockets for the communication

function Settings: PWebSocketProcessSettings;

The settings to be used for WebSockets process

- note that those parameters won't be propagated to existing connections
- defined as a pointer so that you may be able to change the values

```
class function WebSocketsConnect(const aHost, aPort: SockString; aProtocol:
TWebSocketProtocol; aLog: TSynLogClass=nil; const aLogContext: RawUTF8=''; const
aURI: RawUTF8=''; const aCustomHeaders: RawUTF8=''): THttpClientWebSockets;
```

Low-level initialization of a client WebSockets connection

- calls Open() then WebSocketsUpgrade() for a given protocol
- with proper error interception and optional logging, returning nil

```
function WebSocketsUpgrade(const aWebSocketsURI, aWebSocketsEncryptionKey:
RawUTF8; aWebSocketsAJAX: boolean=false; aWebSocketsCompression: boolean=true;
aProtocol: TWebSocketProtocol=nil; const aCustomHeaders: RawUTF8=''): RawUTF8;
```

Upgrade the HTTP client connection to a specified WebSockets protocol

- i.e. 'synapsebin' and optionally 'synapsejson' modes
- you may specify an URI to as expected by the server for upgrade
- if aWebSocketsAJAX equals default FALSE, it will register the TWebSocketProtocolBinaryprotocol, with AES-CFB 256 bits encryption if the encryption key text is not "" and optional SynLZ compression
- if aWebSocketsAJAX is TRUE, it will register the slower and less secure TWebSocketProtocolJSON (to be used for AJAX debugging/test purposes only) and aWebSocketsEncryptionKey/aWebSocketsCompression parameters won't be used
- alternatively, you can specify your own custom TWebSocketProtocol instance (owned by this method and immediately released on error)
- will return "" on success, or an error message on failure

```
property OnBeforeIncomingFrame: TOnWebSocketProtocolIncomingFrame read
fOnBeforeIncomingFrame write fOnBeforeIncomingFrame;
```

Allow low-level interception before TWebSocketProcessClient.ProcessIncomingFrame is executed

```
property OnCallbackRequestProcess: TOnHttpRequest read
fOnCallbackRequestProcess write fOnCallbackRequestProcess;
```

This event handler will be executed for any incoming push notification

```
property OnWebSocketsClosed: TNotifyEvent read fOnWebSocketsClosed write
fOnWebSocketsClosed;
```

Event handler triggered when the WebSocket link is destroyed

- may happen e.g. after graceful close from the server side, or after DisconnectAfterInvalidHeartbeatCount is reached

```
property WebSockets: TWebSocketProcessClient read fProcess;
```

The current WebSockets processing class

- equals nil for plain HTTP/1.1 mode
- points to the current WebSockets process instance, after a successful WebSocketsUpgrade() call, so that you could use e.g. WebSockets.Protocol to retrieve the protocol currently used

Types implemented in the SynBidirSock unit

```
PWebSocketFrame = ^TWebSocketFrame;
```

Points to a WebSockets frame

```
PWebSocketProcessSettings = ^TWebSocketProcessSettings;
```

Points to parameters to be used for WebSockets process

- using a pointer/reference type will allow in-place modification of any TWebSocketProcess.Settings, TWebSocketServer.Settings or THttpClientWebSockets.Settings property

```
TAsynchConnectionClass = class of TAsynchConnection;
```

Meta-class of one TAsynchConnections connection

TAsynchConnectionHandle = type integer;

32-bit integer value used to identify an asynchronous connection

- will start from 1, and increase during the TAsynchConnections live-time

TAsynchConnectionObjArray = array of TAsynchConnection;

Used to store a dynamic array of TAsynchConnection

TAsynchConnectionsOptions = set of (acoOnErrorContinue, acoOnAcceptFailureStop, acoNoLogRead, acoNoLogWrite, acoVerboseLog, acoLastOperationNoRead, acoLastOperationNoWrite);

Low-level options for TAsynchConnections processing

- TAsynchConnectionsSockets.OnError will shutdown the connection on any error, unless acoOnErrorContinue is defined
- acoOnAcceptFailureStop will let failed Accept() finalize the process
- acoNoLogRead and acoNoLogWrite could reduce the log verbosity
- acoVerboseLog will log transmitted frames content, for debugging purposes
- acoLastOperationNoRead and acoLastOperationNoWrite could be used to avoid TAsynchConnection.fLastOperation reset at read or write

THttpRequestCacheDynArray = array of THttpRequestCache;

In-memory storage of all THttpRequestCached entries

TOnWebSocketProtocolChatIncomingFrame = procedure(Sender: THttpServerResp; const Frame: TWebSocketFrame) of object;

Callback event triggered by TWebSocketProtocolChat for any incoming message

- a first call with frame.opcode=focContinuation will take place when the connection will be upgraded to WebSockets
- then any incoming focText/focBinary events will trigger this callback
- eventually, a focConnectionClose will notify the connection ending

TOnWebSocketProtocolIncomingFrame = function(Sender: TWebSocketProcess; var Frame: TWebSocketFrame): boolean of object;

Callback event triggered by TWebSocketProtocol for any incoming message

- called before TWebSocketProtocol.ProcessIncomingFrame for incoming focText/focBinary frames
- should return true if the frame has been handled, or false if the regular processing should take place

TWebSocketFrameDynArray = array of TWebSocketFrame;

A dynamic list of WebSockets frames

TWebSocketFrameOpCode = (focContinuation, focText, focBinary, focReserved3, focReserved4, focReserved5, focReserved6, focReserved7, focConnectionClose, focPing, focPong, focReservedB, focReservedC, focReservedD, focReservedE, focReservedF);

Defines the interpretation of the WebSockets frame data

- match order expected by the WebSockets RFC

TWebSocketFrameOpCodes = set of TWebSocketFrameOpCode;

Set of WebSockets frame interpretation

TWebSocketFramePayload = (fopAlreadyCompressed);

Define one attribute of a WebSockets frame data

TWebSocketFramePayloads = set of TWebSocketFramePayload;

Define the attributes of a WebSockets frame data

```
TWebSocketProcessClientThreadState = ( sCreate, sRun, sFinished, sClosed );
```

The current state of the client side processing thread

```
TWebSocketProcessNotifyCallback = ( wscBlockWithAnswer, wscBlockWithoutAnswer, wscNonBlockWithoutAnswer );
```

Indicates how TWebSocketProcess.NotifyCallback() will work

```
TWebSocketProcessOne = ( wspNone, wspPing, wspDone, wspAnswer, wspError, wspClosed );
```

Indicates which kind of process did occur in the main WebSockets loop

```
TWebSocketProcessState = ( wpsCreate, wpsRun, wpsClose, wpsDestroy );
```

The current state of the WebSockets process

```
TWebSocketProtocolClass = class of TWebSocketProtocol;
```

Used to store the class of a TWebSocketProtocol type

Functions or procedures implemented in the SynBidirSock unit

Functions or procedures	Description	Page
FrameInit	Low-level initialization of a TWebSocketFrame for proper REST content	703
PurgeHeaders	Will remove most usual HTTP headers which are to be recomputed on sending	703
ToText	Used to return the text corresponding to a specified WebSockets frame data	703
ToText	Used to return the text corresponding to a specified WebSockets sending mode	703

```
procedure FrameInit(opcode: TWebSocketFrameOpCode; const Content, ContentType: RawByteString; out frame: TWebSocketFrame);
```

Low-level initialization of a TWebSocketFrame for proper REST content

```
function PurgeHeaders(P: PUTF8Char): RawUTF8;
```

Will remove most usual HTTP headers which are to be recomputed on sending

```
function ToText(mode: TWebSocketProcessNotifyCallback): PShortString; overload;
```

Used to return the text corresponding to a specified WebSockets sending mode

```
function ToText(opcode: TWebSocketFrameOpCode): PShortString; overload;
```

Used to return the text corresponding to a specified WebSockets frame data

Variables implemented in the SynBidirSock unit

WebSocketLog: TSynLogClass;

If set, will log all WebSockets raw information

- see also TWebSocketProcessSettings.LogDetails and TWebSocketProcessSettings.SetFullLog to setup even more verbose information, e.g. by setting HttpServerFullWebSocketsLog and HttpClientFullWebSocketsLog global variables to true (as defined in mORMotHttpServer/mORMotHttpClient)

WebSocketsBinarySynLzThreshold: integer = 450;

Number of bytes above which SynLZ compression may be done

- when working with TWebSocketProtocolBinary
- it is useless to compress smaller frames, which fits in network MTU

WebSocketsIVReplayAttackCheck: TAESIVReplayAttackCheck = repNoCheck;

How replay attacks will be handled in TWebSocketProtocolBinary encryption

- you may set this global value to repCheckedIfAvailable if you are really paranoid (but resulting security may be lower, since the IV is somewhat more predictable than plain random)

WebSocketsMaxFrameMB: cardinal = 256;

The allowed maximum size, in MB, of a WebSockets frame

27.4. SynBigTable.pas unit

Purpose: Class used to store huge amount of data with fast retrieval

- licensed under a MPL/GPL/LGPL tri-license; version 1.18

Units used in the *SynBigTable* unit

Unit Name	Description	Page
<i>SynCommons</i>	Common functions used by most Synopse projects - this unit is a part of the freeware Synopse mORMot framework, licensed under a MPL/GPL/LGPL tri-license; version 1.18	718
<i>SynTable</i>	Filter/database/cache/buffer/security/search/multithread/OS features - as a complement to SynCommons, which tended to increase too much - licensed under a MPL/GPL/LGPL tri-license; version 1.18	1728
<i>SynTests</i>	Unit test functions used by Synopse projects - this unit is a part of the freeware Synopse mORMot framework, licensed under a MPL/GPL/LGPL tri-license; version 1.18	1840

SynBigTable class hierarchy

Objects implemented in the *SynBigTable* unit

Objects	Description	Page
TSynBigTable	A class to store huge amount of data, just specified by an integer ID	706
TSynBigTableMetaData	A class to store huge data (like files content), with metadata fields associated with every record	713
TSynBigTableRecord	A class to store huge amount of data, with fields in every record	715
TSynBigTableString	A class to store huge amount of data, just specified by a string ID	709
TSynBigTableTable	An abstract class, associating a TSynTable to a Big Table	711
TTestBigTable	Unitary testing of the SynBigTable unit	716

TSynBigTable = class(TObject)

A class to store huge amount of data, just specified by an integer ID

- data is stored in a unique file
- retrieval is very fast (can't be faster IMHO)
- data is appended at the end of this file at adding (but use a caching mechanism for immediate adding)
- use a temporary in memory adding, till the UpdateToFile method is called
- data items can be deleted
- file can be packed using the Pack method in order to retrieve free space from deleted entries (sounds like a VACUUM command, but faster)
- total size of file has no limit (but your hard disk, of course)
- limit of one data block depends on RAM (RawByteString is used as storage for data block)
- before Delphi 2007, much faster when using FastMM4 memory manager
- after profiling, most of the time is spent in the Windows kernel, waiting from hard disk write of raw data; in all cases, this class is much faster than any SQL engine storing BLOB, and than plain Win32 files
- ACID behavior can be enforced by calling UpdateToFile(true)

constructor Create(**const** aFileName: TFileName; FileOpenMode: Cardinal = 0);
reintroduce;

Initialize the database engine with a supplied filename

- InternalCacheSize can be used to customize the internal cache count (set to 0 to disable caching; 128 is a good value, bigger makes no difference)
- you can specify a custom file open mode attributes on request, like fmShareDenyNone (not set by default, for safety reason)

destructor Destroy; **override;**

Finalize memory, and save all content

function Add(**const** aData: RawByteString; ForcedID: integer=0; PhysicalIndex: PInteger=nil; OldPhysicalIndex: integer=-1): integer; **virtual;**

Add a data to the database

- return the unique ID created to identify this data
- you can force a specified ID number, by setting a non null value to ForcedID (in this case, it MUST be added in increasing order)
- return 0 on error, otherwise the created Physical Index can be stored
- OldPhysicalIndex is to be used in case of constraint check (for TSynBigTableRecord and TSynBigTableMetaData)

function AddFile(**const** aFileName: TFileName): integer;

Add a file content to the database

- return the unique ID created to identify this data
- return 0 on error (e.g. specified file doesn't exist)

function Delete(aID: integer; PhysicalIndex: PInteger=nil): boolean; **virtual;**

Delete an ID

```
function Get(aIDFirst, aIDLast: integer; out aData: TRawByteStringDynArray):  
boolean; overload;
```

Retrieve a list of content, from a supplied ID range (including boundaries)

- return TRUE if all were found, FALSE if some ID were not existing (or deleted)
- return the data into aData[], or "" if one particular ID was not existing (or deleted); after call, length(aData)=aIDLast-aIDFirst+1

```
function Get(aID: integer; out aData: RawByteString): boolean; overload;
```

Retrieve a content, from a supplied ID

- return TRUE if found, FALSE if ID was not existing (or deleted)
- return the data into aData, or "" if ID was not existing (or deleted)

```
function GetAllIDs(var IDs: TIntegerDynArray; Order:  
TSynBigTableIterationOrder=ioPhysical): integer; virtual;
```

Fast retrieval of all IDs

- returned in physical or increasing ID value order
- returns the number of IDs stored in the integer array

```
function GetAllPhysicalIndexes(var Indexes: TIntegerDynArray): integer;
```

Fast retrieval of all used items physical indexes

- returned in physical order
- returns the number of Indexes stored in the integer array

```
function GetAsStream(aID: integer): TStream;
```

Retrieve a content, from a supplied ID, into a TStream

- this method is faster than Get() into a RawByteString, because the data is not moved from memory but mapped into a TCustomMemoryStream
- if the ID is not correct, returns nil
- if the ID is correct, returns a TStream instance, able to access to the associated content
- in most cases, this TStream is just a wrapper around the memory mapped buffer in memory
- the TStream must be consumed immediately, before any Pack or UpdateToFile method calls
- the caller must Free the returned TStream instance
- if the data is not already memory mapped (i.e. for files >= 2 GB) a custom TSynMemoryStreamMapped is used to access the data from disk

```
function GetLength(aID: integer): integer;
```

Retrieve the length of a content, from a supplied ID

- return -1 if the ID was not found, or the length (in bytes) of this ID content

```
function GetPart(aID: integer; Offset, Len: Integer; out aData: RawByteString):  
boolean;
```

Retrieve a part of a file content

- faster than Open/Seek/Read methods, which loads the whole content in memory before Seek and Read
- only the needed part of data is copied into aData

```
function GetPointer(aID: Integer; var aTempData: RawByteString; DataLen: PInteger=nil): pointer;
```

Retrieve a content, from a supplied ID, into a pointer

- returns nil on error
- returns a pointer to the data on success, directly from the memory mapped file on most cases; if the data is not in a memory mapped buffer (i.e. for files ≥ 2 GB) the aTempData variable is used to read the data from disk
- in case of success, if DataLen is not nil, it will be filled with the corresponding data length
- this method is therefore much faster than Get()

```
function GetPointerFromPhysicalIndex(aPhysicalIndex: integer; var aTempData: RawByteString): pointer;
```

Retrieve a content, from a supplied ID, into a pointer

- returns nil on error
- returns a pointer to the data on success, directly from the memory mapped file on most cases; if the data is not in a memory mapped buffer (i.e. for files ≥ 2 GB) the aTempData variable is used to read the data from disk
- this method is not thread-safe (but is therefore faster)

```
function Update(aID: Integer; const aData: RawByteString; PhysicalIndexOldNew: PInt64=nil): integer; virtual;
```

Update a record content in the database

- in fact, a new invisible record is created, and an alias will map this new record to the original ID
- the physical replacement will take place only during Pack method call
- returns the new content ID value on success
- returns 0 on error

```
procedure Clear; virtual;
```

Clear the whole table content and indexes

```
procedure GetIterating(aCallBack: TSynBigTableIterateEvent; Order: TSynBigTableIterationOrder=ioPhysical; Opaque: pointer=nil; DontRetrieveData: Boolean=false);
```

Call a supplied Event method by iterating through all table items

- Event will be called following the physical order of data in the disk file (somewhat faster), or incremental ID depending of Order parameter
- Event can set the result to TRUE to break the iteration loop
- the Opaque parameter will be supplied to the callback Event
- set DontRetrieveData to TRUE if you don't need any data to be set in the callback, but only the ID (faster)

```
procedure Pack(forceFlushOnDisk: boolean=false);
```

Pack the database, i.e. delete all formerly deleted ID from the disk

- if forceFlushOnDisk is TRUE, data is forced to be saved on the disk (slower but allow ACID behavior of the database file)

procedure UpdateToFile(forceFlushOnDisk: boolean=false; dontReopenReadBuffer: boolean=false);

Save last added entries into the files

- do nothing is nothing is to be written (if forceAlwaysWrite is false)
- can be called from time to time, after checking CurrentInMemoryDataSize
- if forceFlushOnDisk is TRUE, data is forced to be saved on the disk (slower but allow ACID behavior of the database file)

property Count: integer **read** GetCount;

The entries count

property CurrentInMemoryDataSize: Int64 **read** fCurrentInMemoryDataSize;

Returns the current in memory data size (in bytes)

- i.e. the data size not written yet to the disk
- can be used to flush regularly the data to disk by calling UpdateToFile method when this value reach a certain limit

property FileName: TFileName **read** fFileName;

The associated filename storing the database

property FileSizeOnDisk: Int64 **read** GetFileSizeOnDisk;

Returns the current data size stored on disk

property NumericalID[Index: integer]: integer **read** GetID;

Read-only access to a numerical ID, from its index

- index is from NumericalID[0] to NumericalID[Count-1]
- follows the numerical ID order for TSynBigTable, and the alphabetical order of UTF-8 keys for TSynBigTableString
- return 0 in case of out of range index
- this method can be slow with TSynBigTable (if they are some deleted or updated items - just call the Pack method to improve speed); but with a TSynBigTableString instance, it will be always fast
- don't use it to loop through all items, but rather the dedicated GetIterating() or GetAllIDs() fast methods

property Offset[Index: integer]: Int64 **read** GetOffset;

Retrieve an offset for a specified physical ID

- read from either fOffset32[] either fOffset64[]

property OnAfterPack: TSynBigTableAfterPackEvent **read** fOnAfterPack **write** fOnAfterPack;

Event called after a pack, just before the UpdateToFile() call

- can be used to synchronized the field indexes, e.g.

TSynBigTableString = class(TSynBigTable)

A class to store huge amount of data, just specified by a string ID

- string ID are case-sensitive (important warning)
- string ID are of RawUTF8 type, so you must make explicit conversion in your program to the native generic string type - you can use our Utf8ToString() and StringToUtf8() functions, which work for all version of Delphi (from Delphi 6 up to XE)

```
function Add(const aData: RawByteString; const aID: RawUTF8; ForcedID: integer=0): integer; reintroduce;
```

Add a data to the database, and its associated string ID

- return the unique numerical ID created to identify this data
- return 0 if the string ID is invalid (i.e. void or already used)

```
function Delete(aID: integer; PhysicalIndex: PInteger=nil): boolean; override;
```

Delete an entry from its numerical ID

```
function Delete(const aID: RawUTF8): boolean; reintroduce; override;
```

Delete an entry from its string ID

- return true if the record was successfully deleted

```
function Get(const aID: RawUTF8; out aData: RawByteString): boolean; override;
```

Retrieve a content, from a supplied string ID

- return TRUE if found, FALSE if this ID was not existing (or deleted)
- return the data into aData, or "" if ID was not existing (or deleted)

```
function GetAllIDs(var IDs: TIntegerDynArray; Order: TSynBigTableIterationOrder=ioPhysical): integer; override;
```

Fast retrieval of all IDs

- this overridden method handle ioFaster order, i.e; the fHeaderID[] content
- returns the number of IDs stored in the integer array

```
function GetAsStream(const aID: RawUTF8): TStream; override;
```

Retrieve a content, from a supplied ID, into a TStream

- if the ID is not correct, returns nil
- if the ID is correct, returns a TStream instance, able to access to the associated content
- in most cases, this TStream is just a wrapper around the memory mapped buffer in memory
- the TStream must be consumed immediately, before any Pack or UpdateToFile method calls
- the caller must Free the returned TStream instance
- if the data is not already memory mapped (i.e. for files >= 2 GB) a custom TSynMemoryStreamMapped is used to access the data from disk

```
function GetPointer(const aID: RawUTF8; var aTempData: RawByteString; DataLen: PInteger=nil): pointer; override;
```

Retrieve a content, from a supplied ID, into a pointer

- returns nil on error
- returns a pointer to the data on success, directly from the memory mapped file on most cases; if the data is not in a memory mapped buffer (i.e. for files >= 2 GB) the aTempData variable is used to read the data from disk
- in case of success, if DataLen is not nil, it will be filled with the corresponding data length
- this method is therefore much faster than Get() for big size of data

```
function IDToString(aID: integer): RawUTF8;
```

Retrieve the UTF-8 encoded string ID of a given numerical ID

- return "" if this ID was not found

```
function StringToID(const aID: RawUTF8): integer;
```

Retrieve a numerical ID from a UTF-8 encoded string ID

- return 0 if this string ID was not found

```
function Update(const aData: RawByteString; const aID: RawUTF8): boolean;  
reintroduce; override;
```

Update a record content in the database
- return true if the record was successfully updated

```
procedure Clear; override;
```

Clear the whole table content and indexes

```
property StringID[Index: integer]: RawUTF8 read GetStringID;
```

Read-only access to a string ID, from its index
- index is from StringID[0] to StringID[Count-1]
- string IDs are alphabetically sorted
- return "" in case of out of range index

```
TSynBigTableTable = class(TSynBigTable)
```

An abstract class, associating a TSynTable to a Big Table
- use optimized TSynTable logic for handling field values, using our SBF compact binary format (similar to BSON or Protocol Buffers)

```
constructor Create(const aFileName: TFileName; const aTableName: RawUTF8;  
GetRecordData: TSynTableGetRecordData; FileOpenMode: Cardinal = 0); reintroduce;
```

Initialize the database engine with a supplied filename
- you can specify an internal Table Name, similar to SQL table name
- you should better call either TSynBigTableMetaData or TSynBigTableRecord reintroduced constructor, which will set GetRecordData parameter as expected

```
destructor Destroy; override;
```

Finalize memory, and save all content

```
function AddField(const aName: RawUTF8; aType: TSynTableFieldType; aOptions:  
TSynTableFieldOptions=[]): boolean;
```

Add a field description to the table
- just a wrapper to the Table.AddField method
- warning: caller must call the AddFieldUpdate method when all AddField() methods have been called, in order to eventually process all already existing data to the resulting new field order
- physical order does not necessary follow the AddField() call order: for better performance, it will try to store fixed-sized record first, multiple of 4 bytes first (access is faster if data is 4 byte aligned), then variable-length after fixed-sized fields; in all case, a field indexed will be put first
- if tfoUnique is set in aOptions and there is already some data, this method will raise an exception: it's not possible to have multiple void data unique, so it will always fail the constraint

```
function RecordGet(aID: integer): TSynTableData; override;
```

Retrieve a record as a TSynTableData to access its properties
- using TSynTableData is faster than a TSynTableVariantType variant

function RecordUpdate(const aDataRecord: TSynTableData): boolean; **virtual; abstract;**

Update a Record from a given TSynTableData content

- using TSynTableData is faster than a TSynTableVariantType variant
- aRecord.ID is used to identify the record for calling raw Update()
- returns TRUE on success, FALSE on error (e.g. tftUnique constraint failure)
- for TSynBigTableMetaData, only update the metadata content, not the main record content

function Search(Field: TSynTableFieldProperties; const WhereValue: variant; var ResultID: TIntegerDynArray; var ResultIDCount: integer; Limit: Integer=0; ForceIterate: TSynBigTableIterationOrder=ioNone): boolean; overload;

Search for a matching value in a given field

- add the matching IDs in ResultID[] (in sorted order, with no duplicate)
- will use any existing index, or will iterate through all data (slower) if the ForceIterate parameter is either ioPhysical or ioID
- the Limit parameter is similar to the SQL LIMIT clause: if greater than 0, an upper bound on the number of rows returned is placed (e.g. set Limit=1 to only retrieve the first match)

function Search(Field: TSynTableFieldProperties; const WhereValue: TSBFString; var ResultID: TIntegerDynArray; var ResultIDCount: integer; Limit: Integer=0; ForceIterate: TSynBigTableIterationOrder=ioNone): boolean; overload;

Search for a matching value in a given field

- add the matching IDs in ResultID[] (in sorted order, with no duplicate), and update the number matching of elements in ResultIDCount (for performance reasons, the ResultID[] array remains filled with 0 until ResultID[ResultIDCount-1] itemk)
- will use any existing index, or will iterate through all data (slower) if the ForceIterate parameter is either ioPhysical or ioID
- the Limit parameter is similar to the SQL LIMIT clause: if greater than 0, an upper bound on the number of rows returned is placed (e.g. set Limit=1 to only retrieve the first match)

function VariantGet(aID: integer): Variant; **virtual; abstract;**

Retrieve a TSynTableVariantType variant to access a record properties

function VariantVoid: Variant;

Retrieve a void TSynTableVariantType variant instance

- similar to a call to Table.Data call

procedure AddFieldUpdate; **virtual; abstract;**

This method must be called after calls to AddField/Table.AddField methods

- this will launch the recreation of the database file content, if some field were effectively added (to map the new field layout): in this case some default void value is set for all newly added fields
- for TSynBigTableRecord, this method may recreate the field order then reload all field instances: you must retrieve all TSynTableFieldProperties instances after this method call via proper
 aField := Table.Table['FieldName'];

procedure Clear; **override;**

Clear the whole table content and indexes

- also delete the field layout

procedure RecordGet(aID: integer; var result: TSynTableData); overload; **virtual; abstract;**

Retrieve a record as a TSynTableData to access its properties

- using TSynTableData is faster than a TSynTableVariantType variant
- this overloaded function doesn't use a function return, therefore will avoid a Record copy content (faster)

property Table: TSynTable **read** fTable;

The associated field description

property TableName: RawUTF8 **read** fTableName;

The internal Table Name

TSynBigTableMetaData = class(TSynBigTableTable)

A class to store huge data (like files content), with metadata fields associated with every record

- this class will store the fields in memory, then uses TSynBigTable records to store some huge data blocks (e.g. file content), whereas TSynBigTableRecord will store the fields in the records: TSynBigTableRecord is preferred for huge number of records, and TSynBigTableMetaData is designed for less number of records, but will natively handle associated "blob-like" data. For instance, TSynBigTableRecord would be the right class to implement a logging table, whereas TSynBigTableMetaData would be ideal for storing pictures.
- use optimized TSynTable logic for handling metadata field values, using our SBF compact binary format (similar to BSON or Protocol Buffers)
- you can access to any metadata fields by using a custom TSynTableVariantType variant type, allowing late-binding in the code (this method is slower than direct access to the data due to the Variant overhead, but is perhaps more convenient)

constructor Create(const aFileName: TFileName; const aTableName: RawUTF8; FileOpenMode: Cardinal = 0); **reintroduce;**

Initialize the database engine with a supplied filename

- you can specify an internal Table Name, similar to SQL table name

function Add(const aData: RawByteString; const aMetaData: TSBFString): integer; **reintroduce;** overload;

Add a data item with its associated metadata record to the table

- the metadata record uses our SBF encoding, and is mandatory
- returns the unique ID created to identify this data
- returns 0 on adding error (e.g. if a tftUnique constraint failed, or if the supplied aMetaData is void)

function Delete(aID: integer; PhysicalIndex: PInteger=nil): boolean; **override;**

Overridden method to delete an entry from its numerical ID

- this method will handle the metadata fields synchronization

function GetMetaDataFromID(aID: integer): pointer;

Retrieve the metadata record of a given ID, encoded in our SBF format

- it could be more convenient to use VariantGet() or even the faster RecordGet() methods

```
function RecordAdd(const aData: RawByteString; const aMetaDataRecord: TSynTableData): integer;
```

Add a record to the table, with associated meta data

- using TSynTableData is faster than a TSynTableVariantType variant
- return the unique ID created to identify this data
- returns 0 on adding error (e.g. if a tftUnique constraint failed)

```
function RecordUpdate(const aMetaDataRecord: TSynTableData): boolean; override;
```

Update a Record from a given TSynTableData content

- using TSynTableData is faster than a TSynTableVariantType variant
- aRecord.ID is used to identify the record for calling raw Update()
- returns TRUE on success, FALSE on error (e.g. tftUnique constraint failure)
- this method will only update the meta data - the main record data must be updated with the inherited Update() method

```
function Update(aID: integer; const aMetaData: TSBFString): boolean; reintroduce;  
overload;
```

Update a metadata record using our SBF encoding

- returns TRUE on success, FALSE on error (e.g. tftUnique constraint failure)
- this method will only update the meta data - the main record data must be updated with the inherited Update() method

```
function VariantAdd(const aData: RawByteString; const aMetaDataRecord: Variant): integer;
```

Add a data item with its associated metadata record to the table

- the metadata record is a TSynTableVariantType variant
- returns the unique ID created to identify this data
- returns 0 on adding error (e.g. if a tftUnique constraint failed)

```
function VariantGet(aID: integer): Variant; override;
```

Retrieve a TSynTableVariantType variant to access a record metadata

```
function VariantUpdate(const aMetaDataRecord: Variant): boolean;
```

Update a metadata record as TSynTableVariantType variant

- aRecord.ID is used to identify the record for calling raw Update()
- returns TRUE on success, FALSE on error (e.g. tftUnique constraint failure, or wrong variant type)
- this method will only update the meta data - the main record data must be updated with the inherited Update() method

```
procedure AddFieldUpdate; override;
```

This method must be called after calls to AddField/Table.AddField methods

- this will launch the recreation of the database file content, if some field were effectively added (to map the new field layout): in this case some default void value is set for all newly added fields
- for TSynBigTableMeta, this method may recreate the field order, but won't change the TSynTableFieldProperties instances

procedure RecordGet(aID: integer; var result: TSynTableData); overload; **override**;

Retrieve a record as a TSynTableData to access its properties

- using TSynTableData is faster than a TSynTableVariantType variant
- this overloaded function doesn't use a function return, therefore will avoid a Record copy content (faster)

TSynBigTableRecord = class(TSynBigTableTable)

A class to store huge amount of data, with fields in every record

- this class will store the fields in the TSynBigTable records, whereas TSynBigTableMetaData will store the fields in memory, and will use records to store some huge data blocks (e.g. file content): TSynBigTableRecord is preferred for huge number of records, and TSynBigTableMetaData is designed for less records, but with associated "blob-like" data. For instance, TSynBigTableRecord would be the right class to implement a logging table, where TSynBigTableMetaData would be ideal for storing pictures.
- use optimized TSynTable logic for handling field values, using our SBF compact binary format (similar to BSON or Protocol Buffers)
- you can access to any record content fields by using a custom TSynTableVariantType variant type, allowing late-binding in the code (this method is slower than direct access to the data due to the Variant overhead, but is perhaps more convenient)

constructor Create(const aFileName: TFileName; const aTableName: RawUTF8; FileOpenMode: Cardinal = 0); **reintroduce**;

Initialize the database engine with a supplied filename

- you can specify an internal Table Name, similar to SQL table name

function Add(const aData: RawByteString; ForcedID: integer=0; PhysicalIndex: PInteger=nil; OldPhysicalIndex: integer=-1): integer; **override**;

Overridden method to add a record to the database

- this method will handle the field indexes synchronization
- returns 0 on adding error (e.g. if a tftUnique constraint failed)

function Delete(aID: integer; PhysicalIndex: PInteger=nil): boolean; **override**;

Overridden method to delete an entry from its numerical ID

- this method will handle the field indexes synchronization

function RecordAdd(const aRecord: TSynTableData; aForcedID: integer=0): integer;

Add a record to the table

- using TSynTableData is faster than a TSynTableVariantType variant
- return the unique ID created to identify this data
- you can specify an expected ID to be used in aForcedID parameter
- returns 0 on adding error (e.g. if a tftUnique constraint failed)

function RecordUpdate(const aRecord: TSynTableData): boolean; **override**;

Update a Record from a given TSynTableData content

- using TSynTableData is faster than a TSynTableVariantType variant
- aRecord.ID is used to identify the record for calling raw Update()
- returns TRUE on success, FALSE on error (e.g. tftUnique constraint failure)

```
function Update(aID: Integer; const aData: RawByteString; PhysicalIndexOldNew: PInt64=nil): integer; override;
```

Overridden method to update a record content in the database
- returns 0 on updating error (e.g. if a tftUnique constraint failed)

```
function VariantAdd(const aRecord: Variant): integer;
```

Add a record to the table
- the record is a TSynTableVariantType variant
- returns the unique ID created to identify this data
- returns 0 on adding error (e.g. if a tftUnique constraint failed)

```
function VariantGet(aID: integer): Variant; override;
```

Retrieve a TSynTableVariantType variant to access a record properties

```
function VariantUpdate(const aRecord: Variant): boolean;
```

Update a TSynTableVariantType variant
- aRecord.ID is used to identify the record for calling raw Update()
- returns TRUE on success, FALSE on error (e.g. tftUnique constraint failure)

```
procedure AddFieldUpdate; override;
```

This method must be called after calls to AddField/Table.AddField methods
- this will launch the recreation of the database file content, if some field were effectively added (to map the new field layout): in this case some default void value is set for all newly added fields
- for TSynBigTableRecord, this method may recreate the field order then reload all field instances: you must retrieve all TSynTableFieldProperties instances after this method call via proper
aField := Table.Table['FieldName'];

```
procedure RecordGet(aID: integer; var result: TSynTableData); overload; override;
```

Retrieve a record as a TSynTableData to access its properties
- using TSynTableData is faster than a TSynTableVariantType variant
- this overloaded function doesn't use a function return, therefore will avoid a Record copy content (faster)

```
TTestBigTable = class(TSynTestCase)
```

Unitary testing of the SynBigTable unit

```
procedure _TSynBigTable;
```

Test TSynBigTable class

```
procedure _TSynBigTableMetaData;
```

Test TSynBigTableMetaData class

```
procedure _TSynBigTableRecord;
```

Test TSynBigTableRecord class

```
procedure _TSynBigTableString;
```

Test TSynBigTableString class

Types implemented in the SynBigTable unit

TSynBigTableAfterPackEvent = procedure(var NewIndexs: TIntegerDynArray) of object;

Event called after a pack, just before the UpdateToFile()

- can be used to synchronized the field indexes, e.g.
- format of supplied parameter is NewIndexs[oldIndex] := newIndex

TSynBigTableCustomHeader = (sbtRead, sbtBeforeWrite, sbtWrite, sbtAfterRead);

Possible actions for CustomHeader() protected virtual method

TSynBigTableIterateEvent = function(Sender: TObject; Opaque: pointer; ID, DataIndex: integer; Data: pointer; DataLen: integer): boolean of object;

Prototype of a callback function for iterating through all items of a table

- will be called following the incremental ID order
- implementation can set the result to TRUE to break the iteration loop
- the Data pointer is either direct access to the direct mapped buffer, or a global temporary buffer: use the data between two iterations, but copy the content if you need some persistency
- the DataIndex parameter is the index of the data, physically on disk

TSynBigTableIterationOrder = (ioNone, ioPhysical, ioID, ioFaster, ioInternalID, ioInternalPhysical);

The way the GetIterating() method will loop through all items

- ioInternalID and ioInternalPhysical are internal codes used by GetID and GetAllPhysicalIndexes methods

Constants implemented in the *SynBigTable* unit

BIGTABLE_AUTOFLUSH_SIZE = 1 shl 28;

Will flush the in-memory data to disk when reached 256 MB of data in RAM

Functions or procedures implemented in the *SynBigTable* unit

Functions or procedures	Description	Page
TestBigTable	Unitary test function of the TSynBigTable class	717

function TestBigTable: boolean;

Unitary test function of the TSynBigTable class

- return TRUE if test was OK, FALSE on any error

27.5. SynCommons.pas unit

Purpose: Common functions used by most Synopse projects

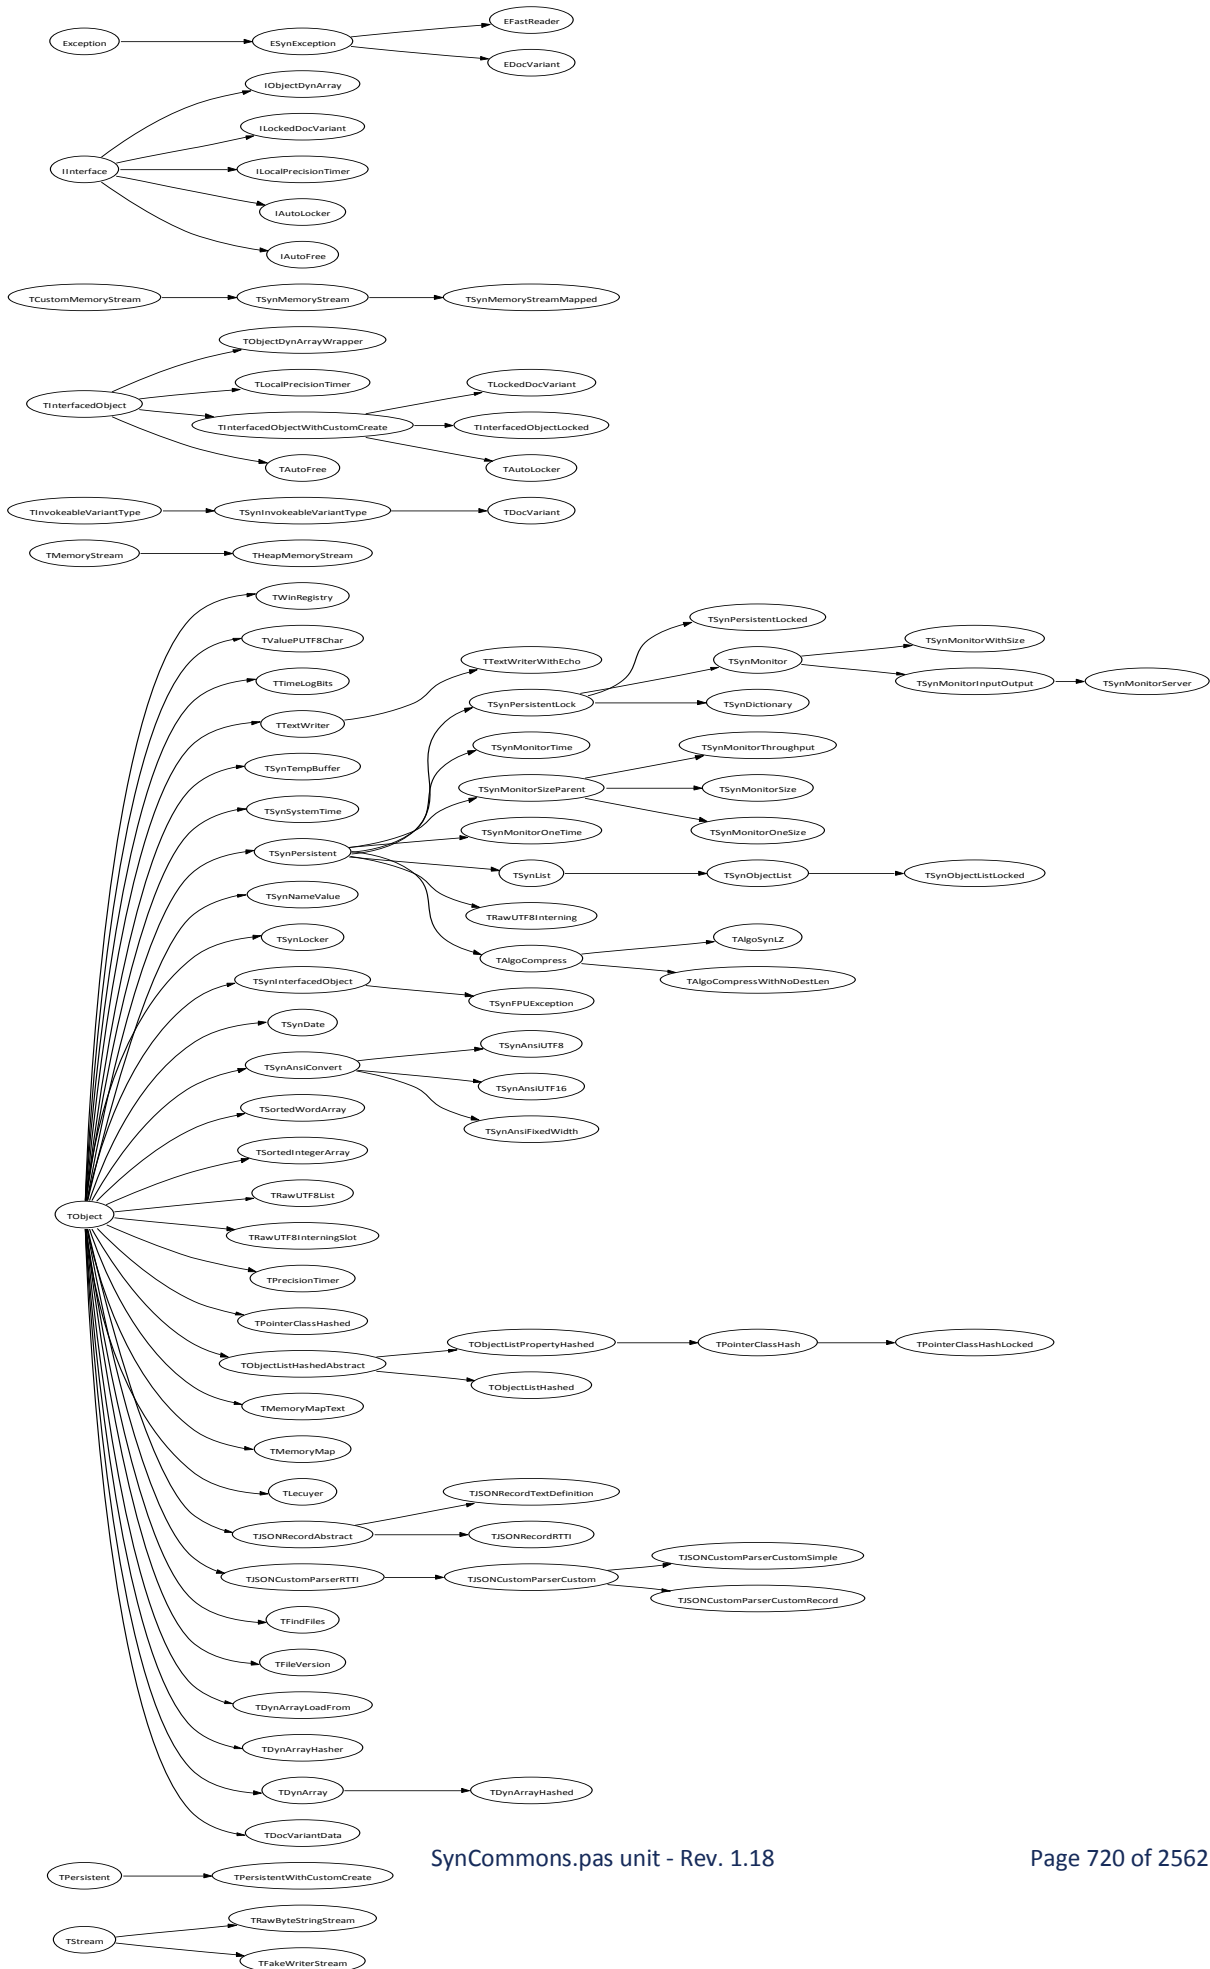

- this unit is a part of the freeware Synopse mORMot framework, licensed under a MPL/GPL/LGPL tri-license; version 1.18

The *SynCommons* unit is quoted in the following items

SWRS #	Description	Page
DI-2.1.2	UTF-8 JSON format shall be used to communicate	2555
DI-2.1.4	The framework shall provide some Cross-Cutting components	2557

Units used in the *SynCommons* unit

Unit Name	Description	Page
<i>SynLZ</i>	SynLZ Compression routines - licensed under a MPL/GPL/LGPL tri-license; version 1.18	1399

SynCommons class hierarchy

Objects implemented in the *SynCommons* unit

Objects	Description	Page
EDocVariant	Exception class associated to TDocVariant JSON/BSON document	813
EFastReader	Exception raised during TFastReader decoding	813
ESynException	Generic parent class of all custom Exception types of this unit	812
IAutoFree	Interface for TAutoFree to register another TObject instance to an existing IAutoFree local variable	856
IAutoLocker	An interface used by TAutoLocker to protect multi-thread execution	858
ILocalPrecisionTimer	Interface to a reference counted high resolution timer instance	849
ILockedDocVariant	Internal error C3517 under Delphi 5 :(ref-counted interface for thread-safe access to a TDocVariant document	861
IObjectDynArray	Defines a wrapper interface around a dynamic array of TObject	751
TAlgoCompress	Abstract low-level parent class for generic compression/decompression algorithms	797
TAlgoCompressWithNoDestLen	Abstract class storing the plain length before calling compression API	801
TAlgoSynLZ	Implement our fast SynLZ compression as a TAlgoCompress class	801
TAutoFree	Simple reference-counted storage for local objects	857
TAutoLocker	Reference-counted block code critical section	860
TDiv100Rec	Small structure used as convenient result to Div100() procedure	730
TDocVariant	A custom variant type used to store any JSON/BSON document-based content	824
TDocVariantData	Memory structure used for TDocVariant storage of any JSON/BSON document-based content as variant	829
TDWordRec	Binary access to an unsigned 32-bit value (4 bytes in memory)	813
TDynArray	A wrapper around a dynamic array with one dimension	732
TDynArrayHashed	Used to access any dynamic array elements using fast hash	747
TDynArrayHasher	Allow O(1) lookup to any dynamic array content	746
TDynArrayLoadFrom	Allows to iterate over a TDynArray.SaveTo binary buffer	745
TExeVersion	Stores some global information about the current executable and computer	821
TFakeWriterStream	A fake TStream, which will just count the number of bytes written	809

Objects	Description	Page
TFileVersion	To have existing RTTI for published properties used to retrieve version information from any EXE	818
TFindFiles	File found result item, as returned by FindFiles()	730
THash128Rec	Map a 128-bit hash as an array of lower bit size values	813
THash256Rec	Map a 256-bit hash as an array of lower bit size values	813
THash512Rec	Map a 512-bit hash as an array of lower bit size values	813
THeapMemoryStream	To be used instead of TMemoryStream, for speed	822
TInterfacedObjectLocked	Adding locking methods to a TInterfacedObject with virtual constructor	759
TInterfacedObjectWithCustomCreate	Abstract parent class with threadsafe implementation of IInterface and a virtual constructor	753
TJSONCustomParserCustom	Used to store additional RTTI as a ptCustom kind of property	767
TJSONCustomParserCustomRecord	Implement a reference to a registered record type	768
TJSONCustomParserCustomSimple	Used to store additional RTTI for simple type as a ptCustom kind	767
TJSONCustomParserRTTI	Used to store additional RTTI in TJSONCustomParser internal structures	765
TJSONRecordAbstract	Used to handle additional RTTI for JSON record serialization	768
TJSONRecordRTTI	Used to handle JSON record serialization using RTTI	769
TJSONRecordTextDefinition	Used to handle text-defined additional RTTI for JSON record serialization	769
TEcuyer	Low-level object implementing a 32-bit Pierre L'Ecuyer software generator	765
TLocalPrecisionTimer	Reference counted high resolution timer (for accurate speed statistics)	850
TLockedDocVariant	Allows thread-safe access to a TDocVariant document	863
TMemoryMap	Handle memory mapping of a file content	807
TMemoryMapText	Able to read a UTF-8 text file using memory map	807
TMultiPart	Used by MultiPartFormDataDecode() to return one item of its data	731
TNameValuePUTF8Char	Store one name/value pair of raw UTF-8 content, from a JSON buffer	811
TObjectDynArrayWrapper	A wrapper to own a dynamic array of TObject	752
TObjectListHashed	This class behaves like TList/TObjectList, but will use hashing for (much) faster IndexOf() method	790

Objects	Description	Page
TObjectListHashedAbstract	Abstract ancestor to manage a dynamic array of TObject	789
TObjectListPropertyHashed	This class will hash and search for a sub property of the stored objects	790
TOperatingSystemVersion	The running Operating System, encoded as a 32-bit integer	820
TOSVersionInfoEx	Low-level API structure, not defined in older Delphi versions	820
TPersistentWithCustomCreate	Abstract parent class with a virtual constructor, ready to be overridden to initialize the instance	753
TPointerClassHash	Handle a O(1) hashed-based storage of TPointerClassHashed, from a pointer	791
TPointerClassHashed	Abstract class stored by a TPointerClassHash list	790
TPointerClassHashLocked	Handle a O(1) hashed-based storage of TPointerClassHashed, from a pointer	791
TPrecisionTimer	High resolution timer (for accurate speed statistics)	847
TPublishedMethodInfo	Information about one method, as returned by GetPublishedMethods	731
TQWordRec	Binary access to an unsigned 64-bit value (8 bytes in memory)	813
TRawByteStringStream	A TStream using a RawByteString as internal storage	809
TRawUTF8Interning	Allow to store only one copy of distinct RawUTF8 values	760
TRawUTF8InterningSlot	Used to store one list of hashed RawUTF8 in TRawUTF8Interning pool	760
TRawUTF8List	TStringList-class optimized to work with our native UTF-8 string type	793
TSortedIntegerArray	Used to store and retrieve Integers in a sorted array	731
TSortedWordArray	Used to store and retrieve Words in a sorted array	731
TSynAnsiConvert	An abstract class to handle Ansi to/from Unicode translation	724
TSynAnsiFixedWidth	A class to handle Ansi to/from Unicode translation of fixed width encoding (i.e. non MBCS)	726
TSynAnsiUTF16	A class to handle UTF-16 to/from Unicode translation	728
TSynAnsiUTF8	A class to handle UTF-8 to/from Unicode translation	727
TSynDate	A simple way to store a date as Year/Month/Day	813
TSynDictionary	Thread-safe dictionary to store some values from associated keys	802
TSynFPUException	A simple class which will set FPU exception flags for a code block	856
TSynInterfacedObject	An abstract ancestor, for implementing a custom TInterfacedObject like class	856

Objects	Description	Page
TSynInvokeableVariantType	Custom variant handler with easier/faster access of variant properties, and JSON serialization support	822
TSynList	Simple and efficient TList, without any notification	754
TSynLocker	Allow to add cross-platform locking methods to any class instance	756
TSynLogExceptionContext	Calling context of TSynLogExceptionToStr callbacks	811
TSynMemoryStream	A TStream pointing to some in-memory data, for instance UTF-8 text	810
TSynMemoryStreamMapped	A TStream created from a file content, using fast memory mapping	810
TSynMonitor	A generic value object able to handle any task / process statistic	851
TSynMonitorInputOutput	Handle generic process statistic with a incoming and outgoing processing data size and bandwidth	854
TSynMonitorOneSize	Able to serialize any immediate size as bytes number	851
TSynMonitorOneTime	Able to serialize any immediate timing as raw micro-seconds number or text	850
TSynMonitorServer	Could monitor a standard Server	855
TSynMonitorSize	Able to serialize any cumulative size as bytes number	851
TSynMonitorThroughput	Able to serialize any bandwidth as bytes count per second	851
TSynMonitorTime	Able to serialize any cumulative timing as raw micro-seconds number or text	850
TSynMonitorWithSize	Handle generic process statistic with a processing data size and bandwidth	854
TSynNameValue	Pseudo-class used to store Name/Value RawUTF8 pairs	762
TSynNameValueItem	Store one Name/Value pair, as used by TSynNameValue class	762
TSynObjectList	Simple and efficient TObjectList, without any notification	755
TSynObjectListLocked	Add locking methods to a TSynObjectList	792
TSynPersistent	Our own empowered TPersistent-like parent class	754
TSynPersistentLock	Adding locking methods to a TSynPersistent with virtual constructor	759
TSynPersistentLocked	Used for backward compatibility only with existing code	759
TSynSystemTime	A cross-platform and cross-compiler TSystemTime 128-bit structure	814
TSynTempBuffer	Implements a stack-based storage of some (UTF-8 or binary) text	729
TTempUTF8	A memory structure which avoids a temporary RawUTF8 allocation	730
TTextWriter	Simple writer to a Stream, specialized for the TEXT format	770

Objects	Description	Page
TTextWriterWithEcho	Stream TEXT writer, with optional echoing of the lines	788
TTimeLogBits	Internal memory structure for direct access to a TTimeLog type value	816
TValuePUTF8Char	Points to one value of raw UTF-8 content, decoded from a JSON buffer	810
TValueResult	Kind of result returned by FromVarBlob() function	732
TwinRegistry	Direct access to the Windows Registry	820

TSynAnsiConvert = class(TObject)

An abstract class to handle Ansi to/from Unicode translation

- implementations of this class will handle efficiently all Code Pages
- this default implementation will use the Operating System APIs
- you should not create your own class instance by yourself, but should better retrieve an instance using TSynAnsiConvert.Engine(), which will initialize either a TSynAnsiFixedWidth or a TSynAnsiConvert instance on need

constructor Create(aCodePage: cardinal); reintroduce; virtual;

Initialize the internal conversion engine

function AnsiBufferToRawUTF8(Source: PAnsiChar; SourceChars: Cardinal): RawUTF8; overload; virtual;

Direct conversion of a PAnsiChar buffer into a UTF-8 encoded string

- will call AnsiBufferToUnicode() overloaded virtual method

function AnsiBufferToUnicode(Dest: PWideChar; Source: PAnsiChar; SourceChars: Cardinal; NoTrailingZero: boolean=false): PWideChar; overload; virtual;

Direct conversion of a PAnsiChar buffer into an Unicode buffer

- Dest^ buffer must be reserved with at least SourceChars*2 bytes
- this default implementation will use the Operating System APIs
- will append a trailing #0 to the returned PWideChar, unless NoTrailingZero is set

function AnsiBufferToUTF8(Dest: PUTF8Char; Source: PAnsiChar; SourceChars: Cardinal; NoTrailingZero: boolean=false): PUTF8Char; overload; virtual;

Direct conversion of a PAnsiChar buffer into a UTF-8 encoded buffer

- Dest^ buffer must be reserved with at least SourceChars*3 bytes
- will append a trailing #0 to the returned PUTF8Char, unless NoTrailingZero is set
- this default implementation will use the Operating System APIs

function AnsiToAnsi(From: TSynAnsiConvert; const Source: RawByteString): RawByteString; overload;

Convert any Ansi Text (providing a From converted) into Ansi Text

function AnsiToAnsi(From: TSynAnsiConvert; Source: PAnsiChar; SourceChars: cardinal): RawByteString; overload;

Convert any Ansi buffer (providing a From converted) into Ansi Text

function AnsiToRawUnicode(const AnsiText: RawByteString): RawUnicode; overload;

Convert any Ansi Text into an UTF-16 Unicode String

- returns a value using our RawUnicode kind of string

```
function AnsiToRawUnicode(Source: PAnsiChar; SourceChars: Cardinal): RawUnicode;  
overload; virtual;
```

Convert any Ansi buffer into an Unicode String
- returns a value using our RawUnicode kind of string

```
function AnsiToUnicodeString(const Source: RawByteString): SynUnicode; overload;
```

Convert any Ansi buffer into an Unicode String
- returns a SynUnicode, i.e. Delphi 2009+ UnicodeString or a WideString

```
function AnsiToUnicodeString(Source: PAnsiChar; SourceChars: Cardinal):  
SynUnicode; overload;
```

Convert any Ansi buffer into an Unicode String
- returns a SynUnicode, i.e. Delphi 2009+ UnicodeString or a WideString

```
function AnsiToUTF8(const AnsiText: RawByteString): RawUTF8; virtual;
```

Convert any Ansi Text into an UTF-8 encoded String
- internally calls AnsiBufferToUTF8 virtual method

```
class function Engine(aCodePage: cardinal): TSynAnsiConvert;
```

Returns the engine corresponding to a given code page
- a global list of TSynAnsiConvert instances is handled by the unit - therefore, caller should not release the returned instance
- will return nil in case of unhandled code page
- is aCodePage is 0, will return CurrentAnsiConvert value

```
function RawUnicodeToAnsi(const Source: RawUnicode): RawByteString;
```

Convert any Unicode-encoded String into Ansi Text
- internally calls UnicodeBufferToAnsi virtual method

```
function UnicodeBufferToAnsi(Dest: PAnsiChar; Source: PWideChar; SourceChars:  
Cardinal): PAnsiChar; overload; virtual;
```

Direct conversion of an Unicode buffer into a PAnsiChar buffer
- Dest^ buffer must be reserved with at least SourceChars*3 bytes
- this default implementation will rely on the Operating System for all non ASCII-7 chars

```
function UnicodeBufferToAnsi(Source: PWideChar; SourceChars: Cardinal):  
RawByteString; overload; virtual;
```

Direct conversion of an Unicode buffer into an Ansi Text

```
function UTF8BufferToAnsi(Dest: PAnsiChar; Source: PUTF8Char; SourceChars:  
Cardinal): PAnsiChar; overload; virtual;
```

Direct conversion of an UTF-8 encoded buffer into a PAnsiChar buffer
- Dest^ buffer must be reserved with at least SourceChars bytes
- no trailing #0 is appended to the buffer

```
function UTF8BufferToAnsi(Source: PUTF8Char; SourceChars: Cardinal):  
RawByteString; overload;
```

Convert any UTF-8 encoded buffer into Ansi Text
- internally calls UTF8BufferToAnsi virtual method

```
function UTF8ToAnsi(const UTF8: RawUTF8): RawByteString; virtual;
```

Convert any UTF-8 encoded String into Ansi Text
- internally calls UTF8BufferToAnsi virtual method

function Utf8ToAnsiBuffer(const S: RawUTF8; Dest: PAnsiChar; DestSize: integer): integer;

Direct conversion of a UTF-8 encoded string into a WinAnsi buffer

- will truncate the destination string to DestSize bytes (including the trailing #0), with a maximum handled size of 2048 bytes
- returns the number of bytes stored in Dest^ (i.e. the position of #0)

procedure UTF8BufferToAnsi(Source: PUTF8Char; SourceChars: Cardinal; var result: RawByteString); overload; **virtual**;

Convert any UTF-8 encoded buffer into Ansi Text

- internally calls UTF8BufferToAnsi virtual method

property CodePage: Cardinal **read** fCodePage;

Corresponding code page

TSynAnsiFixedWidth = class(TSynAnsiConvert)

A class to handle Ansi to/from Unicode translation of fixed width encoding (i.e. non MBCS)

- this class will handle efficiently all Code Page availables without MBCS encoding - like WinAnsi (1252) or Russian (1251)
- it will use internal fast look-up tables for such encodings
- this class could take some time to generate, and will consume more than 64 KB of memory: you should not create your own class instance by yourself, but should better retrieve an instance using TSynAnsiConvert.Engine(), which will initialize either a TSynAnsiFixedWidth or a TSynAnsiConvert instance on need
- this class has some additional methods (e.g. IsValid*) which take advantage of the internal lookup tables to provide some fast process

constructor Create(aCodePage: cardinal); **override**;

Initialize the internal conversion engine

function AnsiBufferToUnicode(Dest: PWideChar; Source: PAnsiChar; SourceChars: Cardinal; NoTrailingZero: boolean=false): PWideChar; **override**;

Direct conversion of a PAnsiChar buffer into an Unicode buffer

- Dest^ buffer must be reserved with at least SourceChars*2 bytes
- will append a trailing #0 to the returned PWideChar, unless NoTrailingZero is set

function AnsiBufferToUTF8(Dest: PUTF8Char; Source: PAnsiChar; SourceChars: Cardinal; NoTrailingZero: boolean=false): PUTF8Char; **override**;

Direct conversion of a PAnsiChar buffer into a UTF-8 encoded buffer

- Dest^ buffer must be reserved with at least SourceChars*3 bytes
- will append a trailing #0 to the returned PUTF8Char, unless NoTrailingZero is set

function AnsiToRawUnicode(Source: PAnsiChar; SourceChars: Cardinal): RawUnicode; **override**;

Convert any Ansi buffer into an Unicode String

- returns a value using our RawUnicode kind of string

function IsValidAnsi(WideText: PWideChar; Length: PtrInt): boolean; overload;

Return TRUE if the supplied unicode buffer only contains characters of the corresponding Ansi code page

- i.e. if the text can be displayed using this code page

function IsValidAnsi(WideText: PWideChar): boolean; overload;

Return TRUE if the supplied unicode buffer only contains characters of the corresponding Ansi code page

- i.e. if the text can be displayed using this code page

function IsValidAnsiU(UTF8Text: PUTF8Char): boolean;

Return TRUE if the supplied UTF-8 buffer only contains characters of the corresponding Ansi code page

- i.e. if the text can be displayed using this code page

function IsValidAnsiU8Bit(UTF8Text: PUTF8Char): boolean;

Return TRUE if the supplied UTF-8 buffer only contains 8 bits characters of the corresponding Ansi code page

- i.e. if the text can be displayed with only 8 bit unicode characters (e.g. no "tm" or such) within this code page

function UnicodeBufferToAnsi(Dest: PAnsiChar; Source: PWideChar; SourceChars: Cardinal): PAnsiChar; **override**;

Direct conversion of an Unicode buffer into a PAnsiChar buffer

- Dest^ buffer must be reserved with at least SourceChars*3 bytes

- this overridden version will use internal lookup tables for fast process

function UTF8BufferToAnsi(Dest: PAnsiChar; Source: PUTF8Char; SourceChars: Cardinal): PAnsiChar; **override**;

Direct conversion of an UTF-8 encoded buffer into a PAnsiChar buffer

- Dest^ buffer must be reserved with at least SourceChars bytes

- no trailing #0 is appended to the buffer

function WideCharToAnsiChar(wc: cardinal): integer;

Conversion of a wide char into the corresponding Ansi character

- return -1 for an unknown WideChar in the current code page

property AnsiToWide: TWordDynArray **read** fAnsiToWide;

Direct access to the Ansi-To-Unicode lookup table

- use this array like AnsiToWide: array[byte] of word

property WideToAnsi: TByteDynArray **read** fWideToAnsi;

Direct access to the Unicode-To-Ansi lookup table

- use this array like WideToAnsi: array[word] of byte

- any unhandled WideChar will return ord('?')

TSynAnsiUTF8 = class(TSynAnsiConvert)

A class to handle UTF-8 to/from Unicode translation

- match the TSynAnsiConvert signature, for code page CP_UTF8

- this class is mostly a non-operation for conversion to/from UTF-8

constructor Create(aCodePage: cardinal); **override**;

Initialize the internal conversion engine

function AnsiBufferToRawUTF8(Source: PAnsiChar; SourceChars: Cardinal): RawUTF8; **override**;

Direct conversion of a PAnsiChar buffer into a UTF-8 encoded string

function AnsiBufferToUnicode(Dest: PWideChar; Source: PAnsiChar; SourceChars: Cardinal; NoTrailingZero: boolean=false): PWideChar; **override**;

Direct conversion of a PAnsiChar UTF-8 buffer into an Unicode buffer

- Dest^ buffer must be reserved with at least SourceChars*2 bytes
- will append a trailing #0 to the returned PWideChar, unless NoTrailingZero is set

function AnsiBufferToUTF8(Dest: PUTF8Char; Source: PAnsiChar; SourceChars: Cardinal; NoTrailingZero: boolean=false): PUTF8Char; **override**;

Direct conversion of a PAnsiChar UTF-8 buffer into a UTF-8 encoded buffer

- Dest^ buffer must be reserved with at least SourceChars*3 bytes
- will append a trailing #0 to the returned PUTF8Char, unless NoTrailingZero is set

function AnsiToRawUnicode(Source: PAnsiChar; SourceChars: Cardinal): RawUnicode; **override**;

Convert any UTF-8 Ansi buffer into an Unicode String

- returns a value using our RawUnicode kind of string

function AnsiToUTF8(const AnsiText: RawByteString): RawUTF8; **override**;

Convert any Ansi Text into an UTF-8 encoded String

- directly assign the input as result, since no conversion is needed

function UnicodeBufferToAnsi(Source: PWideChar; SourceChars: Cardinal): RawByteString; **override**;

Direct conversion of an Unicode buffer into an Ansi Text

function UnicodeBufferToAnsi(Dest: PAnsiChar; Source: PWideChar; SourceChars: Cardinal): PAnsiChar; **override**;

Direct conversion of an Unicode buffer into a PAnsiChar UTF-8 buffer

- Dest^ buffer must be reserved with at least SourceChars*3 bytes

function UTF8BufferToAnsi(Dest: PAnsiChar; Source: PUTF8Char; SourceChars: Cardinal): PAnsiChar; **override**;

Direct conversion of an UTF-8 encoded buffer into a PAnsiChar UTF-8 buffer

- Dest^ buffer must be reserved with at least SourceChars bytes
- no trailing #0 is appended to the buffer

function UTF8ToAnsi(const UTF8: RawUTF8): RawByteString; **override**;

Convert any UTF-8 encoded String into Ansi Text

- directly assign the input as result, since no conversion is needed

procedure UTF8BufferToAnsi(Source: PUTF8Char; SourceChars: Cardinal; var result: RawByteString); **override**;

Convert any UTF-8 encoded buffer into Ansi Text

TSynAnsiUTF16 = class(TSynAnsiConvert)

A class to handle UTF-16 to/from Unicode translation

- match the TSynAnsiConvert signature, for code page CP_UTF16
- even if UTF-16 is not an Ansi format, code page CP_UTF16 may have been used to store UTF-16 encoded binary content
- this class is mostly a non-operation for conversion to/from Unicode

constructor Create(aCodePage: cardinal); **override**;

Initialize the internal conversion engine

function AnsiBufferToUnicode(Dest: PWideChar; Source: PAnsiChar; SourceChars: Cardinal; NoTrailingZero: boolean=false): PWideChar; **override**;

Direct conversion of a PAnsiChar UTF-16 buffer into an Unicode buffer

- Dest^ buffer must be reserved with at least SourceChars*2 bytes
- will append a trailing #0 to the returned PWideChar, unless NoTrailingZero is set

function AnsiBufferToUTF8(Dest: PUTF8Char; Source: PAnsiChar; SourceChars: Cardinal; NoTrailingZero: boolean=false): PUTF8Char; **override**;

Direct conversion of a PAnsiChar UTF-16 buffer into a UTF-8 encoded buffer

- Dest^ buffer must be reserved with at least SourceChars*3 bytes
- will append a trailing #0 to the returned PUTF8Char, unless NoTrailingZero is set

function AnsiToRawUnicode(Source: PAnsiChar; SourceChars: Cardinal): RawUnicode; **override**;

Convert any UTF-16 Ansi buffer into an Unicode String

- returns a value using our RawUnicode kind of string

function UnicodeBufferToAnsi(Dest: PAnsiChar; Source: PWideChar; SourceChars: Cardinal): PAnsiChar; **override**;

Direct conversion of an Unicode buffer into a PAnsiChar UTF-16 buffer

- Dest^ buffer must be reserved with at least SourceChars*3 bytes

function UTF8BufferToAnsi(Dest: PAnsiChar; Source: PUTF8Char; SourceChars: Cardinal): PAnsiChar; **override**;

Direct conversion of an UTF-8 encoded buffer into a PAnsiChar UTF-16 buffer

- Dest^ buffer must be reserved with at least SourceChars bytes
- no trailing #0 is appended to the buffer

TSynTempBuffer = object(TObject)

Implements a stack-based storage of some (UTF-8 or binary) text

- avoid temporary memory allocation via the heap for up to 4KB of data
- could be used e.g. to make a temporary copy when JSON is parsed in-place
- call one of the Init() overloaded methods, then Done to release its memory
- all Init() methods will allocate 16 more bytes, for a trailing #0 and to ensure our fast JSON parsing won't trigger any GPF (since it may read up to 4 bytes ahead via its PInteger() trick) or any SSE4.2 function

buf: pointer;

Where the text/binary is available (and any Source has been copied)

- equals nil if len=0

len: PtrInt;

The text/binary length, in bytes, excluding the trailing #0

function Init(SourceLen: PtrInt): pointer; **overload**;

Initialize a new temporary buffer of a given number of bytes

function Init: integer; **overload**;

Initialize the buffer returning the internal buffer size (4095 bytes)

- could be used e.g. for an API call, first trying with plain temp.Init and using temp.buf and temp.len safely in the call, only calling temp.Init(expectedsize) if the API returned an error about an insufficient buffer space

function Init(Source: PUTF8Char): PUTF8Char; overload;

Initialize a temporary copy of the supplied text buffer, ending with #0

function InitIncreasing(Count: PtrInt; Start: PtrInt=0): PIntegerArray;

Initialize a new temporary buffer filled with 32-bit integer increasing values

function InitOnStack: pointer;

Initialize a temporary buffer with the length of the internal stack

function InitRandom(RandomLen: integer; forcecsl: boolean=true): pointer;

Initialize a new temporary buffer of a given number of random bytes

- will fill the buffer via FillRandom() calls

- forcecsl is true by default, since Lecuyer's generator has no HW bug

function InitZero(ZeroLen: PtrInt): pointer;

Initialize a new temporary buffer of a given number of zero bytes

procedure Done; overload;

Finalize the temporary storage

procedure Done(EndBuf: pointer; var Dest: RawUTF8); overload;

Finalize the temporary storage, and create a RawUTF8 string from it

procedure Init(Source: pointer; SourceLen: PtrInt); overload;

Initialize a temporary copy of the supplied text buffer

procedure Init(const Source: RawByteString); overload;

Initialize a temporary copy of the content supplied as RawByteString

- will also allocate and copy the ending #0 (even for binary)

TTempUTF8 = record

A memory structure which avoids a temporary RawUTF8 allocation

- used by VarRecToTempUTF8() and FormatUTF8()/FormatShort()

TDiv100Rec = packed record

Small structure used as convenient result to Div100() procedure

D: cardinal;

Contains V div 100 after Div100(V)

M: cardinal;

Contains V mod 100 after Div100(V)

TFindFiles = object(TObject)

File found result item, as returned by FindFiles()

- Delphi "object" is buggy on stack -> also defined as record with methods

Attr: Integer;

The matching file attributes

Name: TFileName;

The matching file name, including its folder name

Size: Int64;

The matching file size

Timestamp: TDateTime;

The matching file date/time

function ToText: shortstring;

Returns some ready-to-be-logged text

procedure FromSearchRec(const Directory: TFileName; const F: TSearchRec);

Fill the item properties from a FindFirst/FindNext's TSearchRec

TPublishedMethodInfo = record

Information about one method, as returned by GetPublishedMethods

Method: TMethod;

A callback to the method, for the given class instance

Name: RawUTF8;

The method name

TMultiPart = record

Used by MultiPartFormDataDecode() to return one item of its data

TSortedWordArray = object(TObject)

Used to store and retrieve Words in a sorted array

- Delphi "object" is buggy on stack -> also defined as record with methods

Count: PtrInt;

How many items are currently in Values[]

Values: TWordDynArray;

The actual 16-bit word storage

function Add(aValue: Word): PtrInt;

Add a value into the sorted array

- return the index of the new inserted value into the Values[] array

- return -(foundindex+1) if this value is already in the Values[] array

function IndexOf(aValue: Word): PtrInt;

Return the index if the supplied value in the Values[] array

- return -1 if not found

TSortedIntegerArray = object(TObject)

Used to store and retrieve Integers in a sorted array

- Delphi "object" is buggy on stack -> also defined as record with methods

Count: PtrInt;

How many items are currently in Values[]

Values: TIntegerDynArray;

The actual 32-bit integers storage

function Add(aValue: integer): PtrInt;

Add a value into the sorted array

- return the index of the new inserted value into the Values[] array
- return -(foundindex+1) if this value is already in the Values[] array

function IndexOf(aValue: integer): PtrInt;

Return the index if the supplied value in the Values[] array

- return -1 if not found

TValueResult = record

Kind of result returned by FromVarBlob() function

Len: PtrInt;

Value length (in bytes)

Ptr: PAnsiChar;

Start of data value

TDynArray = object(TObject)

A wrapper around a dynamic array with one dimension

- provide TList-like methods using fast RTTI information
- can be used to fast save/retrieve all memory content to a TStream
- note that the "const Elem" is not checked at compile time nor runtime: you must ensure that Elem matches the element type of the dynamic array
- can use external Count storage to make Add() and Delete() much faster (avoid most reallocation of the memory buffer)
- Note that TDynArray is just a wrapper around an existing dynamic array: methods can modify the content of the associated variable but the TDynArray doesn't contain any data by itself. It is therefore aimed to initialize a TDynArray wrapper on need, to access any existing dynamic array.
- is defined as an object or as a record, due to a bug in Delphi 2009/2010 compiler (at least): this structure is not initialized if defined as an object on the stack, but will be as a record :(

function Add(const Elem): PtrInt;

Add an element to the dynamic array

- warning: Elem must be of the same exact type than the dynamic array, and must be a reference to a variable (you can't write Add(i+10) e.g.)
- returns the index of the added element in the dynamic array
- note that because of dynamic array internal memory management, adding may reallocate the list every time a record is added, unless an external count variable has been specified in Init(...,@Count) method

function AddArray(**const** DynArrayVar; aStartIndex: integer=0; aCount: integer=-1): integer;

Add elements from a given dynamic array variable

- the supplied source DynArray MUST be of the same exact type as the current used for this TDynArray - warning: pass here a reference to a "array of ..." variable, not another TDynArray instance; if you want to add another TDynArray, use AddDynArray() method
- you can specify the start index and the number of items to take from the source dynamic array (leave as -1 to add till the end)
- returns the number of items added to the array

function ClearSafe: boolean;

Delete the whole dynamic array content, ignoring exceptions

- returns true if no exception occurred when calling Clear, false otherwise
- you should better not call this method, which will catch and ignore all exceptions - but it may somewhat make sense in a destructor
- this method will recognize T*ObjArray types and free all instances

function Delete(aIndex: PtrInt): boolean;

Delete one item inside the dynamic array

- the deleted element is finalized if necessary
- this method will recognize T*ObjArray types and free all instances

function ElemCopyFirstField(Source, Dest: Pointer): boolean;

Will copy the first field value of an array element

- will use the array KnownType to guess the copy routine to use
- returns false if the type information is not enough for a safe copy

function ElemEquals(**const** A,B): boolean;

Compare the content of two elements, returning TRUE if both values equal

- this method compares first using any supplied Compare property, then by content using the RTTI element description of the whole record

function ElemLoad(Source: PAnsiChar; SourceMax: PAnsiChar=nil): RawByteString; overload;

Load an array element as saved by the ElemSave method

- this overloaded method will retrieve the element as a memory buffer, which should be cleared by ElemLoadClear() before release

function ElemLoadFind(Source: PAnsiChar; SourceMax: PAnsiChar=nil): integer;

Search for an array element as saved by the ElemSave method

- same as ElemLoad() + Find()/IndexOf() + ElemLoadClear()
- will call Find() method if Compare property is set
- will call generic IndexOf() method if no Compare property is set

function ElemPtr(index: PtrInt): pointer;

Returns a pointer to an element of the array

- returns nil if aIndex is out of range
- since TDynArray is just a wrapper around an existing array, you should better use direct access to its wrapped variable, and not using this slower and more error prone method (such pointer access lacks of strong typing abilities), which was designed for TDynArray internal use

function ElemSave(**const** Elem): RawByteString;

Save an array element into a serialized binary content

- use the same layout as TDynArray.SaveTo, but for a single item
- you can use ElemLoad method later to retrieve its content
- warning: Elem must be of the same exact type than the dynamic array, and must be a reference to a variable (you can't write ElemSave(i+10) e.g.)

function Equals(**const** B: TDynArray; ignorecompare: boolean=false): boolean;

Compare the content of the two arrays, returning TRUE if both match

- this method compares using any supplied Compare property (unless ignorecompare=true), or by content using the RTTI element description of the whole array items
- will call SaveToJSON to compare T*ObjArray kind of arrays

function FastLocateOrAddSorted(**const** Elem; wasAdded: PBoolean=nil): integer;

Search and add an element value inside a sorted dynamic array

- this method will use the Compare property function for the search
- will be faster than a manual FindAndAddIfNotExisting+Sort process
- returns the index of the existing Elem and wasAdded^=false
- returns the sorted index of the inserted Elem and wasAdded^=true
- if the array is not sorted, returns -1 and wasAdded^=false
- is just a wrapper around FastLocateSorted+FastAddSorted

function FastLocateSorted(**const** Elem; **out** Index: Integer): boolean;

Search for an element value inside a sorted dynamic array

- this method will use the Compare property function for the search
- will be faster than a manual FindAndAddIfNotExisting+Sort process
- returns TRUE and the index of existing Elem, or FALSE and the index where the Elem is to be inserted so that the array remains sorted
- you should then call FastAddSorted() later with the returned Index
- if the array is not sorted, returns FALSE and Index=-1
- warning: Elem must be of the same exact type than the dynamic array, and must be a reference to a variable (no FastLocateSorted(i+10) e.g.)

function Find(**const** Elem; **const** aIndex: TIntegerDynArray; aCompare: TDynArraySortCompare): PtrInt; overload;

Search for an element value inside the dynamic array, from an external indexed lookup table

- return the index found (0..Count-1), or -1 if Elem was not found
- this method will use a custom comparison function, with an external integer table, as created by the CreateOrderedIndex() method: it allows multiple search orders in the same dynamic array content
- if an indexed lookup is supplied, it must already be sorted: this function will then use fast O(log(n)) binary search
- if an indexed lookup is not supplied (i.e aIndex=nil), this function will use slower but accurate O(n) iterating search
- warning; the lookup index should be synchronized if array content is modified (in case of adding or deletion)

function Find(const Elem): PtrInt; overload;

Search for an element value inside the dynamic array

- this method will use the Compare property function for the search
- return the index found (0..Count-1), or -1 if Elem was not found
- if the array is sorted, it will use fast $O(\log(n))$ binary search
- if the array is not sorted, it will use slower $O(n)$ iterating search
- warning: Elem must be of the same exact type than the dynamic array, and must be a reference to a variable (you can't write Find(i+10) e.g.)

function FindAllSorted(const Elem; out FirstIndex, LastIndex: Integer): boolean;

Search the elements range which match a given value in a sorted dynamic array

- this method will use the Compare property function for the search
- returns TRUE and the matching indexes, or FALSE if none found
- if the array is not sorted, returns FALSE

function FindAndAddIfNotExisting(const Elem; aIndex: PIntegerDynArray=nil; aCompare: TDynArraySortCompare=nil): integer;

Search for an element value, then add it if none matched

- this method will use the Compare property function for the search, or the supplied indexed lookup table and its associated compare function
- if no Elem content matches, the item will added to the array
- can be used e.g. as a simple dictionary: if Compare will match e.g. the first string field (i.e. set to SortDynArrayString), you can fill the first string field with the searched value (if returned index is ≥ 0)
- return the index found (0..Count-1), or -1 if Elem was not found and the supplied element has been succesfully added
- if the array is sorted, it will use fast $O(\log(n))$ binary search
- if the array is not sorted, it will use slower $O(n)$ iterating search
- warning: Elem must be of the same exact type than the dynamic array, and must be a reference to a variable (you can't write Find(i+10) e.g.)

function FindAndDelete(const Elem; aIndex: PIntegerDynArray=nil; aCompare: TDynArraySortCompare=nil): integer;

Search for an element value, then delete it if match

- this method will use the Compare property function for the search, or the supplied indexed lookup table and its associated compare function
- if Elem content matches, this item will be deleted from the array
- can be used e.g. as a simple dictionary: if Compare will match e.g. the first string field (i.e. set to SortDynArrayString), you can fill the first string field with the searched value (if returned index is ≥ 0)
- return the index deleted (0..Count-1), or -1 if Elem was not found
- if the array is sorted, it will use fast $O(\log(n))$ binary search
- if the array is not sorted, it will use slower $O(n)$ iterating search
- warning: Elem must be of the same exact type than the dynamic array, and must be a reference to a variable (you can't write Find(i+10) e.g.)

```
function FindAndFill(var Elem; aIndex: PIntegerDynArray=nil; aCompare:  
TDynArraySortCompare=nil): integer;
```

Search for an element value, then fill all properties if match

- this method will use the Compare property function for the search, or the supplied indexed lookup table and its associated compare function
- if Elem content matches, all Elem fields will be filled with the record
- can be used e.g. as a simple dictionary: if Compare will match e.g. the first string field (i.e. set to SortDynArrayString), you can fill the first string field with the searched value (if returned index is ≥ 0)
- return the index found (0..Count-1), or -1 if Elem was not found
- if the array is sorted, it will use fast $O(\log(n))$ binary search
- if the array is not sorted, it will use slower $O(n)$ iterating search
- warning: Elem must be of the same exact type than the dynamic array, and must be a reference to a variable (you can't write Find(i+10) e.g.)

```
function FindAndUpdate(const Elem; aIndex: PIntegerDynArray=nil; aCompare:  
TDynArraySortCompare=nil): integer;
```

Search for an element value, then update the item if match

- this method will use the Compare property function for the search, or the supplied indexed lookup table and its associated compare function
- if Elem content matches, this item will be updated with the supplied value
- can be used e.g. as a simple dictionary: if Compare will match e.g. the first string field (i.e. set to SortDynArrayString), you can fill the first string field with the searched value (if returned index is ≥ 0)
- return the index found (0..Count-1), or -1 if Elem was not found
- if the array is sorted, it will use fast $O(\log(n))$ binary search
- if the array is not sorted, it will use slower $O(n)$ iterating search
- warning: Elem must be of the same exact type than the dynamic array, and must be a reference to a variable (you can't write Find(i+10) e.g.)

```
function GuessKnownType(exactType: boolean=false): TDynArrayKind;
```

Low-level computation of KnownType and KnownSize fields from RTTI

- do nothing if has already been set at initialization, or already computed

```
function HasCustomJSONParser: boolean;
```

Check this dynamic array from the GlobalJSONCustomParsers list

- returns TRUE if this array has a custom JSON parser

function IndexOf(**const** Elem): PtrInt;

Search for an element value inside the dynamic array

- return the index found (0..Count-1), or -1 if Elem was not found
- will search for all properties content of the eLement: TList.IndexOf() searches by address, this method searches by content using the RTTI element description (and not the Compare property function)
- use the Find() method if you want the search via the Compare property function, or e.g. to search only with some part of the element content
- will work with simple types: binaries (byte, word, integer, Int64, Currency, array[0..255] of byte, packed records with no reference-counted type within...), string types (e.g. array of string), and packed records with binary and string types within (like TFileVersion)
- won't work with not packed types (like a shortstring, or a record with byte or word fields with {\$A+}): in this case, the padding data (i.e. the bytes between the aligned feeds can be filled as random, and there is no way with standard RTTI do know which they are)
- warning: Elem must be of the same exact type than the dynamic array, and must be a reference to a variable (you can't write IndexOf(i+10) e.g.)

function IsVoid: boolean;

Check if the wrapper points to a dynamic array

function LoadFrom(Source: PAnsiChar; AfterEach: TDynArrayAfterLoadFrom=**nil**;
NoCheckHash: boolean=false; SourceMax: PAnsiChar=**nil**): PAnsiChar;

Unserialize dynamic array content from binary written by TDynArray.SaveTo

- return nil if the Source buffer is incorrect: invalid type, wrong checksum, or optional SourceMax overflow
- return a non nil pointer just after the Source content on success
- this method will raise an ESynException for T*ObjArray types
- you can optionally call AfterEach callback for each row loaded
- if you don't want to allocate all items on memory, but just want to iterate over all items stored in a TDynArray.SaveTo memory buffer, consider using TDynArrayLoadFrom object

function LoadFromBinary(**const** Buffer: RawByteString; NoCheckHash: boolean=false): boolean;

Unserialize the dynamic array content from a TDynArray.SaveTo binary string

- same as LoadFrom, and will check for any buffer overflow since we know the actual end of input buffer

function LoadFromJSON(P: PUTF8Char; aEndOfObject: PUTF8Char=nil;
 CustomVariantOptions: PDocVariantOptions=nil): PUTF8Char;

Load the dynamic array content from an UTF-8 encoded JSON buffer

- expect the format as saved by TTextWriter.AddDynArrayJSON method, i.e. handling TBooleanDynArray, TIntegerDynArray, TInt64DynArray, TCardinalDynArray, TDoubleDynArray, TCurrencyDynArray, TWordDynArray, TByteDynArray, TRawUTF8DynArray, TWinAnsiDynArray, TRawByteStringDynArray, TStringDynArray, TWideStringDynArray, TSynUnicodeDynArray, TTimeLogDynArray and TDateTimeDynArray as JSON array - or any customized valid JSON serialization as set by TTextWriter.RegisterCustomJSONSerializer
- or any other kind of array as Base64 encoded binary stream preprocessed via JSON_BASE64_MAGIC (UTF-8 encoded \uFFFF0 special code)
- typical handled content could be
`'[1,2,3,4]' or '["\uFFFF0base64encodedbinary"]'`
- return a pointer at the end of the data read from P, nil in case of an invalid input buffer
- this method will recognize T*ObjArray types, and will first free any existing instance before unserializing, to avoid memory leak
- warning: the content of P^ will be modified during parsing: please make a local copy if it will be needed later (using e.g. TSynTempBufer)

function LoadFromVariant(const DocVariant: variant): boolean;

Load the dynamic array content from a TDocVariant instance

- will convert the TDocVariant into JSON, the call LoadFromJSON

function New: integer;

Add an element to the dynamic array

- this version add a void element to the array, and returns its index
- note: if you use this method to add a new item with a reference to the dynamic array, using a local variable is needed under FPC:

```
i := DynArray.New;
with Values[i] do begin // otherwise Values is nil -> GPF
  Field1 := 1;
  ...
end;
```

function Peek(var Dest): boolean;

Get the last element stored in the dynamic array

- Add + Pop/Peek will implement a LIFO (Last-In-First-Out) stack
- warning: Elem must be of the same exact type than the dynamic array
- returns true if the item was successfully copied into Dest
- use Pop() if you also want to remove the item

function Pop(var Dest): boolean;

Get and remove the last element stored in the dynamic array

- Add + Pop/Peek will implement a LIFO (Last-In-First-Out) stack
- warning: Elem must be of the same exact type than the dynamic array
- returns true if the item was successfully copied and removed
- use Peek() if you don't want to remove the item

function SaveTo: RawByteString; overload;

Save the dynamic array content into a RawByteString

- will use a proprietary binary format, with some variable-length encoding of the string length - note that if you change the type definition, any previously-serialized content will fail, maybe triggering unexpected GPF: use SaveToTypeInfoHash if you share this binary data accross executables
- this method will raise an ESynException for T*ObjArray types
- use TDynArray.LoadFrom or TDynArrayLoadFrom to decode the saved buffer

function SaveTo(Dest: PAnsiChar): PAnsiChar; overload;

Save the dynamic array content into an allocated memory buffer

- Dest buffer must have been allocated to contain at least the number of bytes returned by the SaveToLength method
- return a pointer at the end of the data written in Dest, nil in case of an invalid input buffer
- will use a proprietary binary format, with some variable-length encoding of the string length - note that if you change the type definition, any previously-serialized content will fail, maybe triggering unexpected GPF: use SaveToTypeInfoHash if you share this binary data accross executables
- this method will raise an ESynException for T*ObjArray types
- use TDynArray.LoadFrom or TDynArrayLoadFrom to decode the saved buffer

function SaveToJSON(EnumSetsAsText: boolean=false; reformat: TTextWriterJSONFormat=jsonCompact): RawUTF8; overload;

Serialize the dynamic array content as JSON

- is just a wrapper around TTextWriter.AddDynArrayJSON()
- this method will therefore recognize T*ObjArray types

function SaveToLength: integer;

Compute the number of bytes needed by SaveTo() to persist a dynamic array

- will use a proprietary binary format, with some variable-length encoding of the string length - note that if you change the type definition, any previously-serialized content will fail, maybe triggering unexpected GPF: use SaveToTypeInfoHash if you share this binary data accross executables
- this method will raise an ESynException for T*ObjArray types

function SaveToTypeInfoHash(crc: cardinal=0): cardinal;

Compute a crc32c-based hash of the RTTI for this dynamic array

- can be used to ensure that the TDynArray.SaveTo binary layout is compatible accross executables
- won't include the RTTI type kind, as TypeInfoToHash(), but only ElemSize or ElemType information, or any previously registered TTextWriter.RegisterCustomJSONSerializerFromText definition

procedure AddDynArray(const aSource: TDynArray; aStartIndex: integer=0; aCount: integer=-1);

Add elements from a given TDynArray

- the supplied source TDynArray MUST be of the same exact type as the current used for this TDynArray, otherwise it won't do anything
- you can specify the start index and the number of items to take from the source dynamic array (leave as -1 to add till the end)

procedure Clear;

Delete the whole dynamic array content

- this method will recognize T*ObjArray types and free all instances

procedure Copy(const Source: TDynArray; ObjArrayByRef: boolean=false);

Set all content of one dynamic array to the current array

- both must be of the same exact type
- T*ObjArray will be reallocated and copied by content (using a temporary JSON serialization), unless ObjArrayByRef is true and pointers are copied

procedure CopyFrom(const Source; MaxElem: integer; ObjArrayByRef: boolean=false);

Set all content of one dynamic array to the current array

- both must be of the same exact type
- T*ObjArray will be reallocated and copied by content (using a temporary JSON serialization), unless ObjArrayByRef is true and pointers are copied

procedure CopyTo(out Dest; ObjArrayByRef: boolean=false);

Set all content of the current dynamic array to another array variable

- both must be of the same exact type
- resulting length(Dest) will match the exact items count, even if an external Count integer variable is used by this instance
- T*ObjArray will be reallocated and copied by content (using a temporary JSON serialization), unless ObjArrayByRef is true and pointers are copied

procedure CreateOrderedIndex(var aIndex: TIntegerDynArray; aCompare: TDynArraySortCompare); overload;

Sort the dynamic array elements using a lookup array of indexes

- in comparison to the Sort method, this CreateOrderedIndex won't change the dynamic array content, but only create (or update) the supplied integer lookup array, using the specified comparison function
- if aCompare is not supplied, the method will use fCompare (if defined)
- you should provide either a void either a valid lookup table, that is a table with one to one lookup (e.g. created with FillIncreasing)
- if the lookup table has less elements than the main dynamic array, its content will be recreated

procedure CreateOrderedIndex(out aIndex: TSynTempBuffer; aCompare: TDynArraySortCompare); overload;

Sort the dynamic array elements using a lookup array of indexes

- this overloaded method will use the supplied TSynTempBuffer for index storage, so use PIntegerArray(aIndex.buf) to access the values
- caller should always make aIndex.Done once done

procedure CreateOrderedIndexAfterAdd(var aIndex: TIntegerDynArray; aCompare: TDynArraySortCompare);

Sort using a lookup array of indexes, after a Add()

- will resize aIndex if necessary, and set aIndex[Count-1] := Count-1

procedure ElemClear(var Elem);

Will reset the element content

procedure ElemCopy(const A; var B);

Will copy one element content

procedure ElemCopyAt(**index**: PtrInt; **var** Dest);

Will copy one element content from its index into another variable
- do nothing if index is out of range

procedure ElemCopyFrom(**const** Source; **index**: PtrInt; ClearBeforeCopy: boolean=false);

Will copy one variable content into an indexed element
- do nothing if index is out of range
- ClearBeforeCopy will call ElemClear() before the copy, which may be safer if the source item is a copy of Values[index] with some dynamic arrays

procedure ElemLoad(Source: PAnsiChar; **var** Elem; SourceMax: PAnsiChar=nil);
overload;

Load an array element as saved by the ElemSave method into Elem variable
- warning: Elem must be of the same exact type than the dynamic array, and must be a reference to a variable (you can't write ElemLoad(P,i+10) e.g.)

procedure ElemLoadClear(**var** ElemTemp: RawByteString);

Finalize a temporary buffer used to store an element via ElemLoad()
- will release any managed type referenced inside the RawByteString, then void the variable
- is just a wrapper around ElemClear(pointer(ElemTemp)) + ElemTemp := ""

procedure ElemMoveTo(**index**: PtrInt; **var** Dest);

Will move one element content from its index into another variable
- will erase the internal item after copy
- do nothing if index is out of range

procedure FastAddSorted(**Index**: Integer; **const** Elem);

Insert a sorted element value at the proper place
- the index should have been computed by FastLocateSorted(): false
- you may consider using FastLocateOrAddSorted() instead

procedure FastDeleteSorted(**Index**: Integer);

Delete a sorted element value at the proper place
- plain Delete(Index) would reset the fSorted flag to FALSE, so use this method with a FastLocateSorted/FastAddSorted array

procedure Init(aTypeInfo: pointer; var aValue; aCountPointer: PInteger=nil);

Initialize the wrapper with a one-dimension dynamic array

- the dynamic array must have been defined with its own type (e.g. TIntegerDynArray = array of Integer)
- if aCountPointer is set, it will be used instead of length() to store the dynamic array items count
- it will be much faster when adding elements to the array, because the dynamic array won't need to be resized each time - but in this case, you should use the Count property instead of length(array) or high(array) when accessing the data: in fact length(array) will store the memory size reserved, not the items count
- if aCountPointer is set, its content will be set to 0, whatever the array length is, or the current aCountPointer^ value is
- a sample usage may be:

```
var DA: TDynArray;
    A: TIntegerDynArray;
begin
  DA.Init(TypeInfo(TIntegerDynArray),A);
  (...)
```

- a sample usage may be (using a count variable):

```
var DA: TDynArray;
    A: TIntegerDynArray;
    ACount: integer;
    i: integer;
begin
  DA.Init(TypeInfo(TIntegerDynArray),A,@ACount);
  for i := 1 to 100000 do
    DA.Add(i); // MUCH faster using the ACount variable
  (...) // now you should use DA.Count or Count instead of Length(A)
```

procedure InitFrom(const aAnother: TDynArray; var aValue);

Fast initialize a wrapper for an existing dynamic array of the same type

- is slightly faster than
- ```
Init(aAnother.ArrayType,aValue,nil);
```

**procedure** InitSpecific(aTypeInfo: pointer; var aValue; aKind: TDynArrayKind; aCountPointer: PInteger=nil; aCaseInsensitive: boolean=false);

*Initialize the wrapper with a one-dimension dynamic array*

- this version accepts to specify how comparison should occur, using TDynArrayKind kind of first field
- djNone and djCustom are too vague, and will raise an exception
- no RTTI check is made over the corresponding array layout: you shall ensure that the aKind parameter matches the dynamic array element definition
- aCaseInsensitive will be used for djRawUTF8..djHash512 text comparison

**procedure** Insert(Index: PtrInt; const Elem);

*Add an element to the dynamic array at the position specified by Index*

- warning: Elem must be of the same exact type than the dynamic array, and must be a reference to a variable (you can't write Insert(10,i+10) e.g.)

**procedure** LoadFromStream(Stream: TCustomMemoryStream);

*Load the dynamic array content from a (memory) stream*

- stream content must have been created using SaveToStream method
- will handle array of binaries values (byte, word, integer...), array of strings or array of packed records, with binaries and string properties
- will use a proprietary binary format, with some variable-length encoding of the string length - note that if you change the type definition, any previously-serialized content will fail, maybe triggering unexpected GPF: use SaveToTypeInfoHash if you share this binary data accross executables

**procedure** Reverse;

*Will reverse all array elements, in place*

**procedure** SaveToJSON(out Result: RawUTF8; EnumSetsAsText: boolean=false; reformat: TTextWriterJSONFormat=jsonCompact); overload;

*Serialize the dynamic array content as JSON*

- is just a wrapper around TTextWriter.AddDynArrayJSON()
- this method will therefore recognize T\*ObjArray types

**procedure** SaveToStream(Stream: TStream);

*Save the dynamic array content into a (memory) stream*

- will handle array of binaries values (byte, word, integer...), array of strings or array of packed records, with binaries and string properties
- will use a proprietary binary format, with some variable-length encoding of the string length - note that if you change the type definition, any previously-serialized content will fail, maybe triggering unexpected GPF: use SaveToTypeInfoHash if you share this binary data accross executables
- Stream position will be set just after the added data
- is optimized for memory streams, but will work with any kind of TStream

**procedure** Slice(var Dest; aCount: Cardinal; aFirstIndex: cardinal=0);

*Select a sub-section (slice) of a dynamic array content*

**procedure** Sort(aCompare: TDynArraySortCompare=nil); overload;

*Sort the dynamic array elements, using the Compare property function*

- it will change the dynamic array content, and exchange all elements in order to be sorted in increasing order according to Compare function

**procedure** Sort(const aCompare: TEventDynArraySortCompare; aReverse: boolean=false); overload;

*Sort the dynamic array elements, using a Compare method (not function)*

- it will change the dynamic array content, and exchange all elements in order to be sorted in increasing order according to Compare function, unless aReverse is true
- it won't mark the array as Sorted, since the comparer is local

**procedure** SortRange(aStart, aStop: integer; aCompare: TDynArraySortCompare=nil);

*Sort some dynamic array elements, using the Compare property function*

- this method allows to sort only some part of the items
- it will change the dynamic array content, and exchange all elements in order to be sorted in increasing order according to Compare function

**procedure** UseExternalCount(**var** aCountPointer: Integer);

*Define the reference to an external count integer variable*

- Init and InitSpecific methods will reset the aCountPointer to 0: you can use this method to set the external count variable without overriding the current value

**procedure** Void;

*Initialize the wrapper to point to no dynamic array*

**property** ArrayType: pointer **read** fTypeInfo;

*The known RTTI information of the whole array*

**property** ArrayTypeName: RawUTF8 **read** GetArrayTypeName;

*The known type name of the whole array, as RawUTF8*

**property** ArrayTypeShort: PShortString **read** GetArrayTypeShort;

*The known type name of the whole array, as PShortString*

**property** Capacity: PtrInt **read** GetCapacity **write** SetCapacity;

*The internal buffer capacity*

- if no external Count pointer was set with Init, is the same as Count  
 - if an external Count pointer is set, you can set a value to this property before a massive use of the Add() method e.g.  
 - if no external Count pointer is set, set a value to this property will affect the Count value, i.e. Add() will append after this count  
 - this property will recognize T\*ObjArray types, so will free any stored instance if the array is sized down

**property** Compare: TDynArraySortCompare **read** fCompare **write** SetCompare;

*The compare function to be used for Sort and Find methods*

- by default, no comparison function is set  
 - common functions exist for base types: e.g. SortDynArrayByte, SortDynArrayBoolean, SortDynArrayWord, SortDynArrayInteger, SortDynArrayCardinal, SortDynArraySingle, SortDynArrayInt64, SortDynArrayDouble, SortDynArrayAnsiString, SortDynArrayAnsiStringI, SortDynArrayString, SortDynArrayStringI, SortDynArrayUnicodeString, SortDynArrayUnicodeStringI

**property** Count: PtrInt **read** GetCount **write** SetCount;

*Retrieve or set the number of elements of the dynamic array*

- same as length(DynArray) or SetLength(DynArray)  
 - this property will recognize T\*ObjArray types, so will free any stored instance if the array is sized down

**property** ElemSize: cardinal **read** fElemSize;

*The internal in-memory size of one element, as retrieved from RTTI*

**property** ElemType: pointer **read** fElemType;

*The internal type information of one element, as retrieved from RTTI*

**property** IsObjArray: boolean **read** GetIsObjArray **write** SetIsObjArray;

*If this dynamic array is a T\*ObjArray*

**property** KnownSize: integer **read** fKnownSize;

*The raw storage size of the first field KnownType*

**property** KnownType: TDynArrayKind **read** fKnownType;

*The first field recognized type*

- could have been set at initialization, or after a GuessKnownType call

**property** Sorted: boolean **read** fSorted **write** fSorted;

*Must be TRUE if the array is currently in sorted order according to the compare function*

- Add/Delete/Insert/Load\* methods will reset this property to false
- Sort method will set this property to true
- you MUST set this property to false if you modify the dynamic array content in your code, so that Find() won't try to wrongly use binary search in an unsorted array, and miss its purpose

**property** Value: PPointer **read** fValue;

*Low-level direct access to the storage variable*

**TDynArrayLoadFrom** = **object**(TObject)

*Allows to iterate over a TDynArray.SaveTo binary buffer*

- may be used as alternative to TDynArray.LoadFrom, if you don't want to allocate all items at once, but retrieve items one by one

**Count**: integer;

*How many items were saved in the TDynArray.SaveTo binary buffer*

- equals -1 if Init() failed to unserialize its header

**Current**: integer;

*The zero-based index of the current item pointed by next Step() call*

- is in range 0..Count-1 until Step() returns false

**Position**: PAnsiChar;

*Current position in the TDynArray.SaveTo binary buffer*

- after Step() returned false, points just after the binary buffer, like a regular TDynArray.LoadFrom

**function** CheckHash: boolean;

*After all items are read by Step(), validate the stored hash*

- returns true if items hash is correct, false otherwise

**function** FirstField(out Field): boolean;

*Extract the first field value of the current stored item*

- returns true if Field was filled with one value, or false if all items were read, and Position contains the end of the binary buffer
- could be called before Step(), to pre-allocate a new item instance, or update an existing instance

**function** Init(ArrayTypeInfo: pointer; Source: PAnsiChar; SourceMaxLen: PtrInt=0): boolean; overload;

*Initialize iteration over a TDynArray.SaveTo binary buffer*

- returns true on success, with Count and Position being set
- returns false if the supplied binary buffer is not correct
- you can specify an optional SourceMaxLen to avoid any buffer overflow

**function** Init(ArrayTypeInfo: pointer; **const** Source: RawByteString): boolean;  
 overload;

*Initialize iteration over a TDynArray.SaveTo binary buffer*  
 - returns true on success, with Count and Position being set  
 - returns false if the supplied binary buffer is not correct

**function** Step(**out** Elem): boolean;

*Iterate over the current stored item*  
 - Elem should point to a variable of the exact item type stored in this dynamic array  
 - returns true if Elem was filled with one value, or false if all items were read, and Position contains the end of the binary buffer

TDynArrayHasher = **object**(TObject)

*Allow O(1) lookup to any dynamic array content*  
 - this won't handle the storage process (like add/update), just efficiently maintain a hash table over an existing dynamic array: several TDynArrayHasher could be applied to a single TDynArray wrapper  
 - TDynArrayHashed will use a TDynArrayHasher for its own store

Compare: TDynArraySortCompare;

*Associated item comparison - may differ from DynArray^.Compare*

CountTrigger: integer;

*After how many FindBeforeAdd() or Scan() the hashing starts - default 32*

EventCompare: TEventDynArraySortCompare;

*Custom method-based comparison function*

**function** Find(Elem: pointer): integer; overload;

*Search for an element value inside the dynamic array with hashing*

**function** Find(Elem: pointer; aHashCode: cardinal): integer; overload;

*Search for a hashed element value inside the dynamic array with hashing*

**function** Find(aHashCode: cardinal; aForAdd: boolean): integer; overload;

*Search for a hash position inside the dynamic array with hashing*

**function** FindBeforeAdd(Elem: pointer; **out** wasAdded: boolean; aHashCode: cardinal): integer;

*Search an hashed element value for adding, updating the internal hash table*  
 - trigger hashing if Count reaches CountTrigger

**function** FindBeforeDelete(Elem: pointer): integer;

*Search and delete an element value, updating the internal hash table*

**function** FindOrNew(aHashCode: cardinal; Elem: pointer; aHashTableIndex: PInteger=nil): integer;

*Returns position in array, or next void index in HashTable[] as -(index+1)*

**function** GetHashFromIndex(aIndex: PtrInt): cardinal;

*Retrieve the low-level hash of a given item*

**function** HashOne(Elem: pointer): cardinal;

*Compute the hash of a given item*

**function** ReHash(forced: boolean): integer;

*Full computation of the internal hash table*

- returns the number of duplicated values found

**function** Scan(Elem: pointer): integer;

*Search for an element value inside the dynamic array without hashing*

- trigger hashing if ScanCounter reaches CountTrigger\*2

**procedure** Clear;

*Reset the hash table - no rehash yet*

**procedure** Init(aDynArray: PDynArray; aHashElement: TDynArrayHashOne; aEventHash: TEventDynArrayHashOne; aHasher: THasher; aCompare: TDynArraySortCompare; aEventCompare: TEventDynArraySortCompare; aCaseInsensitive: boolean);

*Initialize the hash table for a given dynamic array storage*

- you can call this method several times, e.g. if aCaseInsensitive changed

**procedure** InitSpecific(aDynArray: PDynArray; aKind: TDynArrayKind; aCaseInsensitive: boolean);

*Initialize a known hash table for a given dynamic array storage*

- you can call this method several times, e.g. if aCaseInsensitive changed

**procedure** SetEventHash(const event: TEventDynArrayHashOne);

*Allow custom hashing via a method event*

**TDynArrayHashed = object(TDynArray)**

*Used to access any dynamic array elements using fast hash*

- by default, binary sort could be used for searching items for TDynArray: using a hash is faster on huge arrays for implementing a dictionary

- in this current implementation, modification (update or delete) of an element is not handled yet: you should rehash all content - only TDynArrayHashed.FindHashedForAdding /

FindHashedAndUpdate / FindHashedAndDelete will refresh the internal hash

- this object extends the TDynArray type, since presence of Hashs[] dynamic array will increase code size if using TDynArrayHashed instead of TDynArray

- in order to have the better performance, you should use an external Count variable, AND set the Capacity property to the expected maximum count (this will avoid most ReHash calls for FindHashedForAdding+FindHashedAndUpdate)

**function** AddAndMakeUniqueName(aName: RawUTF8): pointer;

*Search for a given element name, make it unique, and add it to the array*

- expected element layout is to have a RawUTF8 field at first position

- the aName is searched (using hashing) to be unique, and if not the case, some suffix is added to make it unique

- use internal FindHashedForAdding method

- this version will set the field content with the unique value

- returns a pointer to the newly added element (to set other fields)

```
function AddUniqueName(const aName: RawUTF8; aNewIndex: PInteger=nil): pointer;
overload;
```

*Ensure a given element name is unique, then add it to the array*  
- just a wrapper to AddUniqueName(aName,"",[aNewIndex])

```
function AddUniqueName(const aName: RawUTF8; const ExceptionMsg: RawUTF8; const
ExceptionArgs: array of const; aNewIndex: PInteger=nil): pointer; overload;
```

*Ensure a given element name is unique, then add it to the array*  
- expected element layout is to have a RawUTF8 field at first position  
- the aName is searched (using hashing) to be unique, and if not the case, an  
ESynException.CreateUTF8() is raised with the supplied arguments  
- use internally FindHashedForAdding method  
- this version will set the field content with the unique value  
- returns a pointer to the newly added element (to set other fields)

```
function FindFromHash(const Elem; aHashCode: cardinal): integer;
```

*Search for an element value inside the dynamic array using its hash*  
- returns -1 if not found, or the index in the dynamic array if found  
- aHashCode parameter contains an already hashed value of the item, to be used e.g. after a  
call to HashFind()

```
function FindHashed(const Elem): integer;
```

*Search for an element value inside the dynamic array using hashing*  
- Elem should be of the type expected by both the hash function and Equals/Compare methods:  
e.g. if the searched/hashed field in a record is a string as first field, you can safely use a string  
variable as Elem  
- Elem must refer to a variable: e.g. you can't write FindHashed(i+10)  
- will call fHashElement(Elem,fHasher) to compute the needed hash  
- returns -1 if not found, or the index in the dynamic array if found

```
function FindHashedAndDelete(const Elem; FillDeleted: pointer=nil; noDeleteEntry:
boolean=false): integer;
```

*Search for an element value inside the dynamic array using hashing, and delete it if matches*  
- return the index deleted (0..Count-1), or -1 if Elem was not found  
- can optionally copy the deleted item to FillDeleted^ before erased  
- Elem should be of the type expected by both the hash function and Equals/Compare methods,  
and must refer to a variable: e.g. you can't write FindHashedAndDelete(i+10)  
- it won't call slow ReHash but refresh the hash table as needed

```
function FindHashedAndFill(var ElemToFill): integer;
```

*Search for an element value inside the dynamic array using hashing, and fill Elem with the found  
content*  
- return the index found (0..Count-1), or -1 if Elem was not found  
- ElemToFill should be of the type expected by the dynamic array, since all its fields will be set on  
match

**function** FindHashedAndUpdate(**const** Elem; AddIfNotExisting: boolean): integer;

*Search for an element value inside the dynamic array using hashing, then update any matching item, or add the item if none matched*

- by design, hashed field shouldn't have been modified by this update, otherwise the method won't be able to find and update the old hash: in this case, you should first call FindHashedAndDelete(OldElem) then FindHashedForAdding(NewElem) to properly handle the internal hash table
- if AddIfNotExisting is FALSE, returns the index found (0..Count-1), or -1 if Elem was not found - update will force slow rehash all content
- if AddIfNotExisting is TRUE, returns the index found (0..Count-1), or the index newly created/added is the Elem value was not matching - add won't rehash all content - for even faster process (avoid ReHash), please set the Capacity property
- Elem should be of the type expected by the dynamic array, since its content will be copied into the dynamic array, and it must refer to a variable: e.g. you can't write FindHashedAndUpdate(i+10)

**function** FindHashedForAdding(**const** Elem; **out** wasAdded: boolean; noAddEntry: boolean=false): integer; overload;

*Search for an element value inside the dynamic array using hashing, and add a void entry to the array if was not found (unless noAddEntry is set)*

- this method will use hashing for fast retrieval
- Elem should be of the type expected by both the hash function and Equals/Compare methods: e.g. if the searched/hashed field in a record is a string as first field, you can safely use a string variable as Elem
- returns either the index in the dynamic array if found (and set wasAdded to false), either the newly created index in the dynamic array (and set wasAdded to true)
- for faster process (avoid ReHash), please set the Capacity property
- warning: in contrast to the Add() method, if an entry is added to the array (wasAdded=true), the entry is left VOID: you must set the field content to expecting value - in short, Elem is used only for searching, not copied to the newly created entry in the array - check FindHashedAndUpdate() for a method actually copying Elem fields

**function** FindHashedForAdding(**const** Elem; **out** wasAdded: boolean; aHashCode: cardinal; noAddEntry: boolean=false): integer; overload;

*Search for an element value inside the dynamic array using hashing, and add a void entry to the array if was not found (unless noAddEntry is set)*

- overloaded method accepting an already hashed value of the item, to be used e.g. after a call to HashFind()

**function** ReHash(forAdd: boolean=false): integer;

*Will compute all hash from the current elements of the dynamic array*

- is called within the TDynArrayHashed.Init method to initialize the internal hash array
- can be called on purpose, when modifications have been performed on the dynamic array content (e.g. in case of element deletion or update, or after calling LoadFrom/Clear method) - this is not necessary after FindHashedForAdding / FindHashedAndUpdate / FindHashedAndDelete methods
- returns the number of duplicated items found - which won't be available by hashed FindHashed() by definition

**function** Scan(const Elem): integer;

*Will search for an element value inside the dynamic array without hashing*

- is used internally when Count < HashCountTrigger
- is preferred to Find(), since EventCompare would be used if defined
- Elem should be of the type expected by both the hash function and Equals/Compare methods, and must refer to a variable: e.g. you can't write Scan(i+10)
- returns -1 if not found, or the index in the dynamic array if found
- an internal algorithm can switch to hashing if Scan() is called often, even if the number of items is lower than HashCountTrigger

**procedure** Init(aTypeInfo: pointer; var aValue; aHashElement: TDynArrayHashOne=nil; aCompare: TDynArraySortCompare=nil; aHasher: THasher=nil; aCountPointer: PInteger=nil; aCaseInsensitive: boolean=false);

*Initialize the wrapper with a one-dimension dynamic array*

- this version accepts some hash-dedicated parameters: aHashElement to set how to hash each element, aCompare to handle hash collision
- if no aHashElement is supplied, it will hash according to the RTTI, i.e. strings or binary types, and the first field for records (strings included)
- if no aCompare is supplied, it will use default Equals() method
- if no THasher function is supplied, it will use the one supplied in DefaultHasher global variable, set to crc32c() by default - using SSE4.2 instruction if available
- if CaseInsensitive is set to TRUE, it will ignore difference in 7 bit alphabetic characters (e.g. compare 'a' and 'A' as equal)

**procedure** InitSpecific(aTypeInfo: pointer; var aValue; aKind: TDynArrayKind; aCountPointer: PInteger=nil; aCaseInsensitive: boolean=false);

*Initialize the wrapper with a one-dimension dynamic array*

- this version accepts to specify how both hashing and comparison should occur, setting the TDynArrayKind kind of first/hashed field
- djNone and djCustom are too vague, and will raise an exception
- no RTTI check is made over the corresponding array layout: you shall ensure that aKind matches the dynamic array element definition
- aCaseInsensitive will be used for djRawUTF8..djHash512 text comparison

**property** EventCompare: TEventDynArraySortCompare read fHash.EventCompare write fHash.EventCompare;

*Alternative event-oriented Compare function to be used for Sort and Find*

- will be used instead of Compare, to allow object-oriented callbacks

**property** EventHash: TEventDynArrayHashOne read fHash.EventHash write SetEventHash;

*Alternative event-oriented Hash function for ReHash*

- this object-oriented callback will be used instead of HashElement on each dynamic array entries - HashElement will still be used on const Elem values, since they may be just a sub part of the stored entry

**property** Hash[aIndex: PtrInt]: Cardinal read GetHashFromIndex;

*Retrieve the hash value of a given item, from its index*

**property** HashCountTrigger: integer **read** fHash.CountTrigger **write** fHash.CountTrigger;

*After how many items the hashing take place*

- for smallest arrays, O(n) search is faster than O(1) hashing, since maintaining internal hash table has some CPU and memory costs
- internal search is able to switch to hashing if it finds out that it may have some benefit, e.g. if Scan() is called 2\*HashCountTrigger times
- equals 32 by default, i.e. start hashing when Count reaches 32 or manual Scan() is called 64 times

**property** HashElement: TDynArrayHashOne **read** fHash.HashElement;

*Custom hash function to be used for hashing of a dynamic array element*

**property** Hasher: TDynArrayHasher **read** fHash;

*Access to the internal hash table*

- you can call e.g. Hasher.Clear to invalidate the whole hash table

**IObjectDynArray = interface(IInterface)**

*Defines a wrapper interface around a dynamic array of TObject*

- implemented by TObjectDynArrayWrapper for instance
- i.e. most common methods are available to work with a dynamic array
- warning: the IObjectDynArray MUST be defined in the stack, class or record BEFORE the dynamic array it is wrapping, otherwise you may leak memory - see for instance TSQLRestServer class:

```
fSessionAuthentications: IObjectDynArray; // defined before the array
fSessionAuthentication: TSQLRestServerAuthenticationDynArray;
```

note that allocation time as variable on the local stack may depend on the compiler, and its optimization

**function** Add(Instance: TObject): integer;

*Add one element to the dynamic array of TObject instances*

- once added, the Instance will be owned by this TObjectDynArray instance

**function** Capacity: integer;

*Returns the internal array capacity of TObject instances available*

- which is in fact the length() of the associated dynamic array

**function** Count: integer;

*Returns the number of TObject instances available*

- note that the length of the associated dynamic array is used to store the capacity of the list, so won't probably never match with this value

**function** Find(Instance: TObject): integer;

*Search one element within the TObject instances*

**procedure** Clear;

*Delete all TObject instances, and release the memory*

- is not to be called for most use, thanks to reference-counting memory handling, but can be handy for quick release

**procedure** Delete(Index: integer);

*Delete one element from the TObject dynamic array*

- deleted TObject instance will be freed as expected

#### **procedure** Slice;

*Ensure the internal list capacity is set to the current Count*

- may be used to publish the associated dynamic array with the expected final size, once IObjectDynArray is out of scope

#### **procedure** Sort(Compare: TDynArraySortCompare);

*Sort the dynamic array content according to a specified comparer*

### **TObjectDynArrayWrapper = class(TInterfacedObject)**

*A wrapper to own a dynamic array of TObject*

- this version behave list a TObjectList (i.e. owning the class instances)
- but the dynamic array is NOT owned by the instance
- will define an internal Count property, using the dynamic array length as capacity: adding and deleting will be much faster
- implements IObjectDynArray, so that most common methods are available to work with the dynamic array
- does not need any sub-classing of generic overhead to work, and will be reference counted
- warning: the IObjectDynArray MUST be defined in the stack, class or record BEFORE the dynamic array it is wrapping, otherwise you may leak memory, and TObjectDynArrayWrapper.Destroy will raise an ESynException
- warning: issues with Delphi 10.4 Sydney were reported, which seemed to change the order of fields finalization, so the whole purpose of this wrapper may have become incompatible with Delphi 10.4 and up
- a sample usage may be:

```
var DA: IObjectDynArray; // defined BEFORE the dynamic array itself
 A: array of TMyObject;
 i: integer;
begin
 DA := TObjectDynArrayWrapper.Create(A);
 DA.Add(TMyObject.Create('one'));
 DA.Add(TMyObject.Create('two'));
 DA.Delete(0);
 assert(DA.Count=1);
 assert(A[0].Name='two');
 DA.Clear;
 assert(DA.Count=0);
 DA.Add(TMyObject.Create('new'));
 assert(DA.Count=1);
end; // will auto-release DA (no need of try..finally DA.Free)
```

#### **constructor** Create(var aValue; aOwnObjects: boolean=true);

*Initialize the wrapper with a one-dimension dynamic array of TObject*

- by default, objects will be owned by this class, but you may set aOwnObjects=false if you expect the dynamic array to remain available

#### **destructor** Destroy; **override**;

*Will release all associated TObject instances*

#### **function** Add(Instance: TObject): integer;

*Add one element to the dynamic array of TObject instances*

- once added, the Instance will be owned by this TObjectDynArray instance (unless aOwnObjects was false in Create)

**function** Capacity: integer;

*Returns the internal array capacity of TObject instances available*  
- which is in fact the length() of the associated dynamic array

**function** Count: integer;

*Returns the number of TObject instances available*  
- note that the length() of the associated dynamic array is used to store the capacity of the list, so won't probably never match with this value

**function** Find(Instance: TObject): integer;

*Search one element within the TObject instances*

**procedure** Clear;

*Delete all TObject instances, and release the memory*  
- is not to be called for most use, thanks to reference-counting memory handling, but can be handy for quick release  
- warning: won't release the instances if aOwnObjects was false in Create

**procedure** Delete(Index: integer);

*Delete one element from the TObject dynamic array*  
- deleted TObject instance will be freed as expected (unless aOwnObjects was defined as false in Create)

**procedure** Slice;

*Ensure the internal list capacity is set to the current Count*  
- may be used to publish the associated dynamic array with the expected final size, once TObjectDynArray is out of scope

**procedure** Sort(Compare: TDynArraySortCompare);

*Sort the dynamic array content according to a specified comparer*

**TPersistentWithCustomCreate = class(TPersistent)**

*Abstract parent class with a virtual constructor, ready to be overridden to initialize the instance*  
- you can specify such a class if you need an object including published properties (like TPersistent) with a virtual constructor (e.g. to initialize some nested class properties)

**constructor** Create; virtual;

*This virtual constructor will be called at instance creation*  
- this constructor does nothing, but is declared as virtual so that inherited classes may safely override this default void implementation

**TInterfacedObjectWithCustomCreate = class(TInterfacedObject)**

*Abstract parent class with threadsafe implementation of IInterface and a virtual constructor*  
- you can specify e.g. such a class to TSQLRestServer.ServiceRegister() if you need an interfaced object with a virtual constructor, ready to be overridden to initialize the instance

**constructor** Create; virtual;

*This virtual constructor will be called at instance creation*  
- this constructor does nothing, but is declared as virtual so that inherited classes may safely override this default void implementation

**procedure** RefCountUpdate(Release: boolean); **virtual**;

*Used to mimic TInterfacedObject reference counting*

- Release=true will call TInterfacedObject.\_Release
- Release=false will call TInterfacedObject.\_AddRef
- could be used to emulate proper reference counting of the instance via interfaces variables, but still storing plain class instances (e.g. in a global list of instances)

**TSynPersistent** = **class**(TObject)

*Our own empowered TPersistent-like parent class*

- TPersistent has an unexpected speed overhead due a giant lock introduced to manage property name fixup resolution (which we won't use outside the VCL)
- this class has a virtual constructor, so is a preferred alternative to both TPersistent and TPersistentWithCustomCreate classes
- for best performance, any type inheriting from this class will bypass some regular steps: do not implement interfaces or use TMonitor with them!

**constructor** Create; **virtual**;

*This virtual constructor will be called at instance creation*

- this constructor does nothing, but is declared as virtual so that inherited classes may safely override this default void implementation

**class function** NewInstance: TObject; **override**;

*Optimized initialization code*

- somewhat faster than the regular RTL implementation - especially since rewritten in pure asm on Delphi/x86
- warning: this optimized version won't initialize the vmtIntfTable for this class hierarchy: as a result, you would NOT be able to implement an interface with a TSynPersistent descendent (but you should not need to, but inherit from TInterfacedObject)
- warning: under FPC, it won't initialize fields management operators

**procedure** Assign(Source: TSynPersistent); **virtual**;

*Allows to implement a TPersistent-like assignement mechanism*

- inherited class should override AssignTo() protected method to implement the proper assignment

**procedure** FreeInstance; **override**;

*Optimized x86 asm finalization code*

- warning: this version won't release either any allocated TMonitor (as available since Delphi 2009) - do not use TMonitor with TSynPersistent, but rather the faster TSynPersistentLock class

**TSynList** = **class**(TSynPersistent)

*Simple and efficient TList, without any notification*

- regular TList has an internal notification mechanism which slows down basic process, and most used methods were not defined as virtual, so can't be easily inherited
- stateless methods (like Add/Clear/Exists/Remove) are defined as virtual since can be overridden e.g. by TSynObjectListLocked to add a TSynLocker

**function** Add(item: pointer): integer; **virtual**;

*Add one item to the list*

**function** Exists(item: pointer): boolean; **virtual**;

*Fast check if one item exists in the list*

**function** IndexOf(item: pointer): integer; **virtual**;

*Fast retrieve one item in the list*

**function** Remove(item: pointer): integer; **virtual**;

*Fast delete one item in the list*

**procedure** Clear; **virtual**;

*Delete all items of the list*

**procedure** Delete(index: integer); **virtual**;

*Delete one item from the list*

**property** Count: integer **read** fCount;

*How many items are stored in this TList instance*

**property** Items[index: Integer]: pointer **read** Get;

*Low-level array-like access to the items stored in this TList instance*

- warning: if index is out of range, will return nil and won't raise any exception

**property** List: TPointerDynArray **read** fList;

*Low-level access to the items stored in this TList instance*

**TSynObjectList = class**(TSynList)

*Simple and efficient TObjectList, without any notification*

**constructor** Create(aOwnObjects: boolean=true); **reintroduce**;

*Initialize the object list*

**destructor** Destroy; **override**;

*Finalize the store items*

**procedure** Clear; **override**;

*Delete all objects of the list*

**procedure** ClearFromLast; **virtual**;

*Delete all objects of the list in reverse order*

- for some kind of processes, owned objects should be removed from the last added to the first

**procedure** Delete(index: integer); **override**;

*Delete one object from the list*

## **TSynLocker = object(TObject)**

*Allow to add cross-platform locking methods to any class instance*

- typical use is to define a Safe: TSynLocker property, call Safe.Init and Safe.Done in constructor/destructor methods, and use Safe.Lock/Unlock methods in a try ... finally section
- in respect to the TCriticalSection class, fix a potential CPU cache line conflict which may degrade the multi-threading performance, as reported by <http://www.delphitools.info/2011/11/30/fixing-tcriticalsection>
- internal padding is used to safely store up to 7 values protected from concurrent access with a mutex, so that `SizeOf(TSynLocker)>128`
- for object-level locking, see TSynPersistentLock which owns one such instance, or call low-level `fSafe := NewSynLocker` in your constructor, then `fSafe^.DoneAndFreeMem` in your destructor

### **Padding: array[0..6] of TVarData;**

*Internal padding data, also used to store up to 7 variant values*

- this memory buffer will ensure no CPU cache line mixup occurs
- you should not use this field directly, but rather the Locked[], LockedInt64[], LockedUTF8[] or LockedPointer[] methods
- if you want to access those array values, ensure you protect them using a Safe.Lock; try ... `Padding[n]` ... finally `Safe.Unlock` structure, and maintain the `PaddingUsedCount` field accurately

### **PaddingUsedCount: integer;**

*Number of values stored in the internal Padding[] array*

- equals 0 if no value is actually stored, or a 1..7 number otherwise
- you should not have to use this field, but for optimized low-level direct access to `Padding[]` values, within a Lock/Unlock safe block

### **function LockedExchange(Index: integer; const Value: variant): variant;**

*Safe locked in-place exchange of a Variant value*

- you may store up to 7 variables, using an 0..6 index, shared with Locked and LockedUTF8 array properties
- returns the previous stored value, or null if the Index is out of range

### **function LockedInt64Increment(Index: integer; const Increment: Int64): Int64;**

*Safe locked in-place increment to an Int64 value*

- you may store up to 7 variables, using an 0..6 index, shared with Locked and LockedUTF8 array properties
- Int64s will be stored internally as a varInt64 variant
- returns the newly stored value
- if the internal value is not defined yet, would use 0 as default value

### **function LockedPointerExchange(Index: integer; Value: pointer): pointer;**

*Safe locked in-place exchange of a pointer/TObject value*

- you may store up to 7 variables, using an 0..6 index, shared with Locked and LockedUTF8 array properties
- pointers will be stored internally as a varUnknown variant
- returns the previous stored value, nil if the Index is out of range, or does not store a pointer

#### **function** ProtectMethod: IUnknown;

*Will enter the mutex until the IUnknown reference is released*

- could be used as such under Delphi:

```
begin
 ... // unsafe code
 Safe.ProtectMethod;
 ... // thread-safe code
end; // local hidden IUnknown will release the lock for the method
```

- warning: under FPC, you should assign its result to a local variable - see bug  
<http://bugs.freepascal.org/view.php?id=26602>

```
var LockFPC: IUnknown;
begin
 ... // unsafe code
 LockFPC := Safe.ProtectMethod;
 ... // thread-safe code
end; // LockFPC will release the lock for the method
```

or

```
begin
 ... // unsafe code
 with Safe.ProtectMethod do begin
 ... // thread-safe code
 end; // local hidden IUnknown will release the lock for the method
end;
```

#### **function** TryLock: boolean;

*Will try to acquire the mutex*

- use as such to avoid race condition (from a Safe: TSynLocker property):

```
if Safe.TryLock then
 try
 ...
 finally
 Safe.Unlock;
 end;
```

#### **function** TryLockMS(retryms: integer): boolean;

*Will try to acquire the mutex for a given time*

- use as such to avoid race condition (from a Safe: TSynLocker property):

```
if Safe.TryLockMS(100) then
 try
 ...
 finally
 Safe.Unlock;
 end;
```

#### **procedure** Done;

*Finalize the mutex*

- calling this method is mandatory (e.g. in the class destructor owning the TSynLocker instance), otherwise you may encounter unexpected behavior, like access violations or memory leaks

#### **procedure** DoneAndFreeMem;

*Finalize the mutex, and call FreeMem() on the pointer of this instance*

- should have been initialized with a NewSynLocker call

**procedure** Init;

*Initialize the mutex*

- calling this method is mandatory (e.g. in the class constructor owning the TSynLocker instance), otherwise you may encounter unexpected behavior, like access violations or memory leaks

**procedure** Lock;

*Lock the instance for exclusive access*

- this method is re-entrant from the same thread (you can nest Lock/Unlock calls in the same thread), but would block any other Lock attempt in another thread
- use as such to avoid race condition (from a Safe: TSynLocker property):

```
Safe.Lock;
try
...
finally
 Safe.Unlock;
end;
```

**procedure** Unlock;

*Release the instance for exclusive access*

- each Lock/TryLock should have its exact Unlock opposite, so a try..finally block is mandatory for safe code

**property** IsInitialized: boolean **read** fInitialized;

*Returns true if the Init method has been called for this mutex*

- is only relevant if the whole object has been previously filled with 0, i.e. as part of a class or as global variable, but won't be accurate when allocated on stack

**property** IsLocked: boolean **read** GetIsLocked;

*Returns true if the mutex is currently locked by another thread*

**property** Locked[Index: integer]: Variant **read** GetVariant **write** SetVariant;

*Safe locked access to a Variant value*

- you may store up to 7 variables, using an 0..6 index, shared with LockedBool, LockedInt64, LockedPointer and LockedUTF8 array properties
- returns null if the Index is out of range

**property** LockedBool[Index: integer]: boolean **read** GetBool **write** SetBool;

*Safe locked access to a boolean value*

- you may store up to 7 variables, using an 0..6 index, shared with Locked, LockedInt64, LockedPointer and LockedUTF8 array properties
- value will be stored internally as a varBoolean variant
- returns nil if the Index is out of range, or does not store a boolean

**property** LockedInt64[Index: integer]: Int64 **read** GetInt64 **write** SetInt64;

*Safe locked access to a Int64 value*

- you may store up to 7 variables, using an 0..6 index, shared with Locked and LockedUTF8 array properties
- Int64s will be stored internally as a varInt64 variant
- returns nil if the Index is out of range, or does not store a Int64

**property** LockedPointer[Index: integer]: Pointer **read** GetPointer **write** SetPointer;

*Safe locked access to a pointer/TObject value*

- you may store up to 7 variables, using an 0..6 index, shared with Locked, LockedBool, LockedInt64 and LockedUTF8 array properties
- pointers will be stored internally as a varUnknown variant
- returns nil if the Index is out of range, or does not store a pointer

**property** LockedUTF8[Index: integer]: RawUTF8 **read** GetUTF8 **write** SetUTF8;

*Safe locked access to an UTF-8 string value*

- you may store up to 7 variables, using an 0..6 index, shared with Locked and LockedPointer array properties
- UTF-8 string will be stored internally as a varString variant
- returns '' if the Index is out of range, or does not store a string

**property** UnlockedInt64[Index: integer]: Int64 **read** GetUnlockedInt64 **write** SetUnlockedInt64;

*Unsafe access to a Int64 value*

- you may store up to 7 variables, using an 0..6 index, shared with Locked and LockedUTF8 array properties
- Int64s will be stored internally as a varInt64 variant
- returns nil if the Index is out of range, or does not store a Int64
- you should rather call LockedInt64[] property, or use this property with a Lock; try ... finally Unlock block

**TSynPersistentLock = class(TSynPersistent)**

*Adding locking methods to a TSynPersistent with virtual constructor*

- you may use this class instead of the RTL TCriticalSection, since it would use a TSynLocker which does not suffer from CPU cache line conflict

**constructor** Create; **override**;

*TSynLocker would increase inherited fields offset initialize the instance, and its associated lock*

**destructor** Destroy; **override**;

*Finalize the instance, and its associated lock*

**property** Safe: PSynLocker **read** fSafe;

*Access to the associated instance critical section*

- call Safe.Lock/Unlock to protect multi-thread access on this storage

**TSynPersistentLocked = class(TSynPersistentLock)**

*Used for backward compatibility only with existing code*

**TInterfacedObjectLocked = class(TInterfacedObjectWithCustomCreate)**

*Adding locking methods to a TInterfacedObject with virtual constructor*

**constructor** Create; **override**;

*TSynLocker would increase inherited fields offset initialize the object instance, and its associated lock*

**destructor** Destroy; **override**;

*Release the instance (including the locking resource)*

**property** Safe: PSynLocker **read** fSafe;

*Access to the locking methods of this instance*

- use Safe.Lock/TryLock with a try ... finally Safe.Unlock block

**TRawUTF8InterningSlot** = **object**(TObject)

*Used to store one list of hashed RawUTF8 in TRawUTF8Interning pool*

- Delphi "object" is buggy on stack -> also defined as record with methods

**Safe**: TSynLocker;

*Associated mutex for thread-safe process*

**Value**: TRawUTF8DynArray;

*Actual RawUTF8 storage*

**Values**: TDynArrayHashed;

*Hashed access to the Value[] list*

**function** Clean(aMaxRefCount: integer): integer;

*Reclaim any unique RawUTF8 values*

**function** Count: integer;

*How many items are currently stored in Value[]*

**procedure** Clear;

*Delete all stored RawUTF8 values*

**procedure** Done;

*Finalize the RawUTF8 slot - mainly its associated Safe mutex*

**procedure** Init;

*Initialize the RawUTF8 slot (and its Safe mutex)*

**procedure** Unique(var aResult: RawUTF8; const aText: RawUTF8; aTextHash: cardinal);

*Returns the interned RawUTF8 value*

**procedure** UniqueText(var aText: RawUTF8; aTextHash: cardinal);

*Ensure the supplied RawUTF8 value is interned*

**TRawUTF8Interning** = **class**(TSynPersistent)

*Allow to store only one copy of distinct RawUTF8 values*

- thanks to the Copy-On-Write feature of string variables, this may reduce a lot the memory overhead of duplicated text content

- this class is thread-safe and optimized for performance

**constructor** Create(aHashTables: integer=4); **reintroduce**;

*Initialize the storage and its internal hash pools*

- aHashTables is the pool size, and should be a power of two <= 512

**destructor** Destroy; **override**;

*Finalize the storage*

**function** Clean(aMaxRefCount: integer=1): integer;

*Reclaim any unique RawUTF8 values*

- i.e. run a garbage collection process of all values with RefCount=1 by default, i.e. all string which are not used any more; you may set aMaxRefCount to a higher value, depending on your expectations, i.e. 2 to delete all string which are referenced only once outside of the pool
- returns the number of unique RawUTF8 cleaned from the internal pool
- to be executed on a regular basis - but not too often, since the process can be time consuming, and void the benefit of interning

**function** Count: integer;

*How many items are currently stored in this instance*

**function** Unique(const aText: RawUTF8): RawUTF8; overload;

*Return a RawUTF8 variable stored within this class*

- if aText occurs for the first time, add it to the internal string pool
- if aText does exist in the internal string pool, return the shared instance (with its reference counter increased), to reduce memory usage

**function** Unique(aText: PUTF8Char; aTextLen: PtrInt): RawUTF8; overload;

*Return a RawUTF8 variable stored within this class from a text buffer*

- if aText occurs for the first time, add it to the internal string pool
- if aText does exist in the internal string pool, return the shared instance (with its reference counter increased), to reduce memory usage

**procedure** Clear;

*Delete any previous storage pool*

**procedure** Unique(var aResult: RawUTF8; const aText: RawUTF8); overload;

*Return a RawUTF8 variable stored within this class*

- if aText occurs for the first time, add it to the internal string pool
- if aText does exist in the internal string pool, return the shared instance (with its reference counter increased), to reduce memory usage

**procedure** Unique(var aResult: RawUTF8; aText: PUTF8Char; aTextLen: PtrInt); overload;

*Return a RawUTF8 variable stored within this class from a text buffer*

- if aText occurs for the first time, add it to the internal string pool
- if aText does exist in the internal string pool, return the shared instance (with its reference counter increased), to reduce memory usage

**procedure** UniqueText(var aText: RawUTF8);

*Ensure a RawUTF8 variable is stored within this class*

- if aText occurs for the first time, add it to the internal string pool
- if aText does exist in the internal string pool, set the shared instance (with its reference counter increased), to reduce memory usage

**procedure** UniqueVariant(var aResult: variant; const aText: RawUTF8); overload;

*Return a variant containing a RawUTF8 stored within this class*

- similar to RawUTF8ToVariant(), but with string interning

**procedure** UniqueVariant(**var** aResult: **variant**; aText: PUTF8Char; aTextLen: PtrInt; aAllowVarDouble: boolean=false); overload;

*Return a variant, may be containing a RawUTF8 stored within this class*

- similar to TextToVariant(), but with string interning
- first try with GetNumericVariantFromJSON(), then fallback to RawUTF8ToVariant() with string variable interning

**procedure** UniqueVariant(**var** aResult: **variant**); overload;

*Ensure a variant contains only RawUTF8 stored within this class*

- supplied variant should be a varString containing a RawUTF8 value

**procedure** UniqueVariantString(**var** aResult: **variant**; **const** aText: **string**);

*Return a variant containing a RawUTF8 stored within this class*

- similar to RawUTF8ToVariant(StringToUTF8()), but with string interning
- this method expects the text to be supplied as a VCL string, which will be converted into a variant containing a RawUTF8 varString instance

**TSynNameValueItem = record**

*Store one Name/Value pair, as used by TSynNameValue class*

**Name:** RawUTF8;

*The name of the Name/Value pair*

- this property is hashed by TSynNameValue for fast retrieval

**Tag:** PtrInt;

*Any associated Pointer or numerical value*

**Value:** RawUTF8;

*The value of the Name/Value pair*

**TSynNameValue = object(TObject)**

*Pseudo-class used to store Name/Value RawUTF8 pairs*

- use internally a TDynArrayHashed instance for fast retrieval
- is therefore faster than TRawUTF8List
- is defined as an object, not as a class: you can use this in any class, without the need to destroy the content
- Delphi "object" is buggy on stack -> also defined as record with methods

**Count:** integer;

*The number of Name/Value pairs*

**DynArray:** TDynArrayHashed;

*Low-level access to the internal storage hasher*

**List:** TSynNameValueItemDynArray;

*The internal Name/Value storage*

**function** AsCSV(**const** KeySeparator: RawUTF8='='; **const** ValueSeparator: RawUTF8='#13#10'; **const** IgnoreKey: RawUTF8=''): RawUTF8;

*Returns all values, as CSV or INI content*

```
function AsDocVariant(ExtendedJson: boolean=false; ValueAsString: boolean=true):
variant; overload;
```

*Compute a TDocVariant document from the stored values*

```
function AsJSON: RawUTF8;
```

*Returns all values as a JSON object of string fields*

```
function Delete(const aName: RawUTF8): boolean;
```

*Search for a Name, and delete its entry in the List if it exists*

```
function DeleteByValue(const aValue: RawUTF8; Limit: integer=1): integer;
```

*Search for a Value, and delete its entry in the List if it exists*

- returns the number of deleted entries
- you may search for more than one match, by setting a >1 Limit value

```
function Find(const aName: RawUTF8): integer;
```

*Search for a Name, return the index in List*

- using fast O(1) hash algorithm

```
function FindByValue(const aValue: RawUTF8): integer;
```

*Search for a Value, return the index in List*

- using O(n) brute force algorithm with case-sensitive aValue search

```
function FindStart(const aUpperName: RawUTF8): integer;
```

*Search for the first chars of a Name, return the index in List*

- using O(n) calls of IdempChar() function
- here aUpperName should be already uppercase, as expected by IdempChar()

```
function InitFromJSON(JSON: PUTF8Char; aCaseSensitive: boolean=false): boolean;
```

*Reset content, then add all fields from an JSON object*

- will first call Init() to initialize the internal array
- then parse the incoming JSON object, storing all its field values as RawUTF8, and returning TRUE if the supplied content is correct
- warning: the supplied JSON buffer will be decoded and modified in-place

```
function Initialized: boolean;
```

*Returns true if the Init() method has been called*

```
function MergeDocVariant(var DocVariant: variant; ValueAsString: boolean;
ChangedProps: PVariant=nil; ExtendedJson: boolean=false; AllowVarDouble:
boolean=false): integer;
```

*Merge the stored values into a TDocVariant document*

- existing properties would be updated, then new values will be added to the supplied TDocVariant instance, ready to be serialized as a JSON object
- if ValueAsString is TRUE, values would be stored as string
- if ValueAsString is FALSE, numerical values would be identified by IsString() and stored as such in the resulting TDocVariant
- if you let ChangedProps point to a TDocVariantData, it would contain an object with the stored values, just like AsDocVariant
- returns the number of updated values in the TDocVariant, 0 if no value was changed

```
function Value(const aName: RawUTF8; const aDefaultValue: RawUTF8=''): RawUTF8;
```

*Search for a Name, return the associated Value as a UTF-8 string*

**function** ValueBool(**const** aName: RawUTF8): Boolean;

*Search for a Name, return the associated Value as boolean*  
 - returns true only if the value is exactly '1'

**function** ValueEnum(**const** aName: RawUTF8; aEnumTypeInfo: pointer; **out** aEnum; aEnumDefault: byte=0): boolean; overload;

*Search for a Name, return the associated Value as an enumerate*  
 - returns true and set aEnum if aName was found, and associated value matched an aEnumTypeInfo item  
 - returns false if no match was found

**function** ValueInt(**const** aName: RawUTF8; **const** aDefaultValue: Int64=0): Int64;

*Search for a Name, return the associated Value as integer*

**function** ValueVariantOrNull(**const** aName: RawUTF8): variant;

*Search for a Name, return the associated Value as variant*  
 - returns null if the name was not found

**procedure** Add(**const** aName, aValue: RawUTF8; aTag: PtrInt=0);

*Add an element to the array*  
 - if aName already exists, its associated Value will be updated

**procedure** AsDocVariant(**out** DocVariant: variant; ExtendedJson: boolean=false; ValueAsString: boolean=true; AllowVarDouble: boolean=false); overload;

*Compute a TDocVariant document from the stored values*  
 - output variant will be reset and filled as a TDocVariant instance, ready to be serialized as a JSON object  
 - if there is no value stored (i.e. Count=0), set null

**procedure** AsNameValues(**out** Names, Values: TRawUTF8DynArray);

*Fill the supplied two arrays of RawUTF8 with the stored values*

**procedure** Init(aCaseSensitive: boolean);

*Initialize the storage*  
 - will also reset the internal List[] and the internal hash array

**procedure** InitFromCSV(CSV: PUTF8Char; NameValueSep: AnsiChar='='; ItemSep: AnsiChar=#10);

*Reset content, then add all name=value; CSV pairs*  
 - will first call Init(false) to initialize the internal array  
 - if ItemSep=#10, then any kind of line feed (CRLF or LF) will be handled

**procedure** InitFromIniSection(Section: PUTF8Char; OnTheFlyConvert: TOnSynNameValueConvertRawUTF8=nil; OnAdd: TOnSynNameValueNotify=nil);

*Reset content, then add all name=value pairs from a supplied .ini file section content*  
 - will first call Init(false) to initialize the internal array  
 - Section can be retrieved e.g. via FindSectionFirstLine()

**procedure** InitFromNamesValues(**const** Names, Values: array of RawUTF8);

*Reset content, then add all name, value pairs*  
 - will first call Init(false) to initialize the internal array

**procedure** SetBlobDataPtr(aValue: pointer);

*Can be used to set all data from one BLOB memory buffer*

**property** BlobData: RawByteString **read** GetBlobData **write** SetBlobData;

*Can be used to set or retrieve all stored data as one BLOB content*

**property** Bool[**const** aName: RawUTF8]: Boolean **read** GetBool;

*Search for a Name, return the associated Value as boolean*  
 - returns true if aName stores '1' as associated value

**property** Int[**const** aName: RawUTF8]: Int64 **read** GetInt;

*Search for a Name, return the associated Value as integer*  
 - returns 0 if aName is not found, or not a valid Int64 in the stored keys

**property** OnAfterAdd: TOnSynNameValueNotify **read** fOnAdd **write** fOnAdd;

*Event triggered after an item has just been added to the list*

**property** Str[**const** aName: RawUTF8]: RawUTF8 **read** GetStr;

*Search for a Name, return the associated Value as a UTF-8 string*  
 - returns '' if aName is not found in the stored keys

**TLecuyer** = **object**(TObject)

*Low-level object implementing a 32-bit Pierre L'Ecuyer software generator*

- as used by Random32gsl, and Random32 if no RDRAND hardware is available
- is not thread-safe by itself, but cross-compiler and cross-platform, still very fast with a much better distribution than Delphi system's Random() function
- Random32gsl/Random32 will use a threadvar to have thread safety

**function** Next(max: cardinal): cardinal; overload;

*Compute the next 32-bit generated value, in range [0..max-1]*  
 - will automatically reseed after around 65,000 generated values

**function** Next: cardinal; overload;

*Compute the next 32-bit generated value*  
 - will automatically reseed after around 65,000 generated values

**procedure** Seed(entropy: PByteArray; entropylen: PtrInt);

*Force an immediate seed of the generator from current system state*  
 - should be called before any call to the Next method

**TJSONCustomParserRTTI** = **class**(TObject)

*Used to store additional RTTI in TJSONCustomParser internal structures*

**constructor** Create(**const** aPropertyName: RawUTF8; aPropertyType: TJSONCustomParserRTTIType);

*Initialize the instance*

**class function** CreateFromRTTI(**const** PropertyName: RawUTF8; Info: pointer; ItemSize: integer): TJSONCustomParserRTTI;

*Initialize an instance from the RTTI type information*  
 - will return an instance of this class of any inherited class

```
class function CreateFromTypeName(const aPropertyName, aCustomRecordTypeName: RawUTF8): TJSONCustomParserRTTI;
```

*Create an instance from a specified type name*  
- will return an instance of this class of any inherited class

```
function ReadOneLevel(var P: PUTF8Char; var Data: PByte; Options: TJSONCustomParserSerializationOptions; CustomVariantOptions: PDocVariantOptions): boolean; virtual;
```

*Unserialize some JSON content into its binary internal representation*  
- on error, returns false and P should point to the faulty text input

```
class function TypeInfoToSimpleRTTIType(Info: pointer): TJSONCustomParserRTTIType;
```

*Recognize a simple type from a supplied type information*  
- to be called if TypeNameToSimpleRTTIType() did fail, i.e. return ptCustom  
- will return ptCustom for any complex type (e.g. a record)  
- see also TypeInfoToRttiType() function

```
class function TypeNameToSimpleBinary(const aTypeName: RawUTF8; out aDataSize, aFieldSize: integer): boolean;
```

*Recognize a ktBinary simple type from a supplied type name*  
- as registered by TTextWriter.RegisterCustomJSONSerializerFromTextBinaryType

```
class function TypeNameToSimpleRTTIType(const TypeName: RawUTF8): TJSONCustomParserRTTIType; overload;
```

*Recognize a simple type from a supplied type name*  
- will return ptCustom for any unknown type  
- see also TypeInfoToRttiType() function

```
class function TypeNameToSimpleRTTIType(TypeName: PShortString): TJSONCustomParserRTTIType; overload;
```

*Recognize a simple type from a supplied type name*  
- will return ptCustom for any unknown type  
- see also TypeInfoToRttiType() function

```
class function TypeNameToSimpleRTTIType(TypeName: PUTF8Char; TypeNameLen: PtrInt; ItemTypeName: PRawUTF8): TJSONCustomParserRTTIType; overload;
```

*Recognize a simple type from a supplied type name*  
- will return ptCustom for any unknown type  
- see also TypeInfoToRttiType() function

```
procedure WriteOneLevel(aWriter: TTextWriter; var P: PByte; Options: TJSONCustomParserSerializationOptions); virtual;
```

*Serialize a binary internal representation into JSON content*  
- this method won't append a trailing ',' character

```
property CustomTypeName: RawUTF8 read fCustomTypeName;
```

*The associated type name, e.g. for a record*

```
property FullPropertyName: RawUTF8 read fFullPropertyName;
```

*The property name, including all parent elements*  
- may be void for the Root element  
- e.g. 'MainProp.SubProp'

**property** NestedProperty: TJSONCustomParserRTTIIs read fNestedProperty;

*The nested array of properties (if any)*

- assigned only if PropertyType is [ptRecord,ptArray]
- is either the record type of each ptArray item:  
   SubProp: array of record ...
- or one NestedProperty[0] entry with PropertyName="" and PropertyType not in [ptRecord,ptArray]:  
   SubPropNumber: array of integer;  
   SubPropText: array of RawUTF8;

**property** PropertyName: RawUTF8 read fPropertyName;

*The property name*

- may be void for the Root element
- e.g. 'SubProp'

**property** PropertyType: TJSONCustomParserRTTIType read fPropertyType;

*The property type*

- support only a limited set of simple types, or ptRecord for a nested record, or ptArray for a nested array

**TJSONCustomParserCustom = class**(TJSONCustomParserRTTI)

*Used to store additional RTTI as a ptCustom kind of property*

**constructor** Create(const aPropertyName, aCustomTypeName: RawUTF8); **virtual**;

*Initialize the instance*

**function** CustomReader(P: PUTF8Char; var aValue; out EndOfObject: AnsiChar; CustomVariantOptions: PDocVariantOptions): PUTF8Char; **virtual**; **abstract**;

*Abstract method to read the instance from JSON*

- should return nil on parsing error

**procedure** CustomWriter(const aWriter: TTextWriter; const aValue); **virtual**; **abstract**;

*Abstract method to write the instance as JSON*

**procedure** FinalizeItem(Data: Pointer); **virtual**;

*Release any memory used by the instance*

**property** CustomTypeInfo: pointer read fCustomTypeInfo;

*The associated RTTI structure*

**TJSONCustomParserCustomSimple = class**(TJSONCustomParserCustom)

*Used to store additional RTTI for simple type as a ptCustom kind*

- this class handle currently enumerate, TGUID or static/dynamic arrays

**constructor** Create(const aPropertyName, aCustomTypeName: RawUTF8; aCustomType: pointer); **reintroduce**;

*Initialize the instance from the given RTTI structure*

**constructor** CreateBinary(const aPropertyName: RawUTF8; aDataSize, aFixedSize: cardinal);

*Initialize the instance for a binary blob*

**constructor** CreateFixedArray(const aPropertyName: RawUTF8; aFixedSize: cardinal);

*Initialize the instance for a static array*

**destructor** Destroy; **override**;

*Released used memory*

**function** CustomReader(P: PUTF8Char; var aValue; out EndOfObject: AnsiChar; CustomVariantOptions: PDocVariantOptions): PUTF8Char; **override**;

*Method to read the instance from JSON*

**procedure** CustomWriter(const aWriter: TTextWriter; const aValue); **override**;

*Method to write the instance as JSON*

**property** KnownType: TJSONCustomParserCustomSimpleKnownType **read** fKnownType;

*Which kind of simple property this instance does refer to*

**property** NestedArray: TJSONCustomParserRTTI **read** fNestedArray;

*The element type for ktStaticArray and ktDynamicArray*

TJSONCustomParserCustomRecord = **class**(TJSONCustomParserCustom)

*Implement a reference to a registered record type*

- i.e. ptCustom kind of property, handled by the TTextWriter.RegisterCustomJSONSerializer\*() internal list

**constructor** Create(const aPropertyName: RawUTF8; aCustomTypeIndex: integer); **reintroduce**; **overload**;

*Initialize the instance from the given record custom serialization index*

**function** CustomReader(P: PUTF8Char; var aValue; out EndOfObject: AnsiChar; CustomVariantOptions: PDocVariantOptions): PUTF8Char; **override**;

*Method to read the instance from JSON*

**procedure** CustomWriter(const aWriter: TTextWriter; const aValue); **override**;

*Method to write the instance as JSON*

**procedure** FinalizeItem(Data: Pointer); **override**;

*Release any memory used by the instance*

TJSONRecordAbstract = **class**(TObject)

*Used to handle additional RTTI for JSON record serialization*

- this class is used to define how a record is defined, and will work with any version of Delphi
- this Abstract class is not to be used as-is, but contains all needed information to provide CustomWriter/CustomReader methods
- you can use e.g. TJSONRecordTextDefinition for text-based RTTI manual definition, or (not yet provided) a version based on Delphi 2010+ new RTTI information

**constructor** Create;

*Initialize the class instance*

**destructor** Destroy; **override**;

*Release used memory*

- when created via Compute() call, instances of this class are managed via a GarbageCollector() global list, so you do not need to free them

**function** CustomReader(P: PUTF8Char; **var** aValue; **out** aValid: Boolean;  
CustomVariantOptions: PDocVariantOptions): PUTF8Char;

*Callback for custom JSON unserialization*

- will follow the RTTI textual information as supplied to the constructor

**procedure** CustomWriter(**const** aWriter: TTextWriter; **const** aValue);

*Callback for custom JSON serialization*

- will follow the RTTI textual information as supplied to the constructor

**property** Options: TJSONCustomParserSerializationOptions **read** fOptions **write** fOptions;

*How this class would serialize/unserialize JSON content*

- by default, no option is defined
- you can customize the expected options with the instance returned by TTextWriter.RegisterCustomJSONSerializerFromText() method, or via the TTextWriter.RegisterCustomJSONSerializerSetOptions() overloaded methods

**property** Root: TJSONCustomParserRTTI **read** fRoot;

*Store the RTTI information of properties at root level*

- is one instance with PropertyType=ptRecord and PropertyName=""

**TJSONRecordRTTI = class**(TJSONRecordAbstract)

*Used to handle JSON record serialization using RTTI*

- is able to handle any kind of record since Delphi 2010, thanks to enhanced RTTI

**constructor** Create(aRecordTypeInfo: pointer; aRoot: TJSONCustomParserRTTI);  
**reintroduce**;

*Initialize the instance*

- you should NOT use this constructor directly, but let e.g. TJSONCustomParsers.TryToGetFromRTTI() create it for you

**property** RecordTypeInfo: pointer **read** fRecordTypeInfo;

*The low-level address of the enhanced RTTI*

**TJSONRecordTextDefinition = class**(TJSONRecordAbstract)

*Used to handle text-defined additional RTTI for JSON record serialization*

- is used by TTextWriter.RegisterCustomJSONSerializerFromText() method

**constructor** Create(aRecordTypeInfo: pointer; **const** aDefinition: RawUTF8);  
**reintroduce**;

*Initialize a custom JSON serializer/unserializer from pseudo RTTI*

- you should NOT use this constructor directly, but call the FromCache() class function, which will use an internal definition cache

```
class function FromCache(aTypeInfo: pointer; const aDefinition: RawUTF8):
TJSONRecordTextDefinition;
```

*Retrieve a custom cached JSON serializer/unserializer from pseudo RTTI*

- returned class instance will be cached for any further use
- the record where the data will be stored should be defined as PACKED:

```
type TMyRecord = packed record
 A,B,C: integer;
 D: RawUTF8;
 E: record; // or array of record/integer/string/...
 E1,E2: double;
 end;
end;
```

- only known sub types are integer, cardinal, Int64, single, double, currency, TDateTime, TTimeLog, RawUTF8, String, WideString, SynUnicode, or a nested record or dynamic array
- RTTI textual information shall be supplied as text, with the same format as with a pascal record, or with some shorter variations:

```
FromCache('A,B,C: integer; D: RawUTF8; E: record E1,E2: double; end;');
FromCache('A,B,C: integer; D: RawUTF8; E: array of record E1,E2: double; end;');
'A,B,C: integer; D: RawUTF8; E: array of SynUnicode; F: array of integer'
```

or a shorter alternative syntax for records and arrays:

```
FromCache('A,B,C: integer; D: RawUTF8; E: {E1,E2: double}');
FromCache('A,B,C: integer; D: RawUTF8; E: [E1,E2: double]');
```

in fact ; could be ignored:

```
FromCache('A,B,C:integer D:RawUTF8 E:{E1,E2:double}');
FromCache('A,B,C:integer D:RawUTF8 E:[E1,E2:double]');
```

or even : could be ignored:

```
FromCache('A,B,C integer D RawUTF8 E{E1,E2 double}');
FromCache('A,B,C integer D RawUTF8 E[E1,E2 double]');
```

```
property Definition: RawUTF8 read fDefinition;
```

*The textual definition of this RTTI information*

```
TTextWriter = class(TObject)
```

*Simple writer to a Stream, specialized for the TEXT format*

- use an internal buffer, faster than string+string
- some dedicated methods is able to encode any data with JSON/XML escape
- see TTextWriterWithEcho below for optional output redirection (for TSynLog)
- see SynTable.pas for SQL resultset export via TJSONWriter
- see mORMot.pas for proper class serialization via TJSONSerializer.WriteObject

*Used for DI-2.1.2 (page 2555).*

```
constructor Create(aStream: TStream; aBuf: pointer; aBufSize: integer); overload;
```

*The data will be written to the specified Stream*

- aStream may be nil: in this case, it MUST be set before using any Add\*() method
- will use an external buffer (which may be allocated on stack)

*Used for DI-2.1.2 (page 2555).*

**constructor** `Create(aStream: TStream; aBufSize: integer=8192); overload;`

*The data will be written to the specified Stream*

- aStream may be nil: in this case, it MUST be set before using any Add\*() method
- default internal buffer size if 8192

*Used for DI-2.1.2 (page 2555).*

**constructor** `CreateOwnedFileStream(const aFileName: TFileName; aBufSize: integer=8192);`

*The data will be written to an external file*

- you should call explicitly FlushFinal or FlushToStream to write any pending data to the file

**constructor** `CreateOwnedStream(aBufSize: integer=4096); overload;`

*The data will be written to an internal TRawByteStringStream*

- TRawByteStringStream.DataString method will be used by TTextWriter.Text to retrieve directly the content without any data move nor allocation
- default internal buffer size if 4096 (enough for most JSON objects)
- consider using a stack-allocated buffer and the overloaded method

**constructor** `CreateOwnedStream(var aStackBuf: TTextWriterStackBuffer; aBufSize: integer=SizeOf(TTextWriterStackBuffer)); overload;`

*The data will be written to an internal TRawByteStringStream*

- will use the stack-allocated TTextWriterStackBuffer if possible
- TRawByteStringStream.DataString method will be used by TTextWriter.Text to retrieve directly the content without any data move nor allocation

**constructor** `CreateOwnedStream(aBuf: pointer; aBufSize: integer); overload;`

*The data will be written to an internal TRawByteStringStream*

- will use an external buffer (which may be allocated on stack)
- TRawByteStringStream.DataString method will be used by TTextWriter.Text to retrieve directly the content without any data move nor allocation

**destructor** `Destroy; override;`

*Release all internal structures*

- e.g. free fStream if the instance was owned by this class

**function** `AddJSONReformat(JSON: PUTF8Char; Format: TTextWriterJSONFormat; EndOfObject: PUTF8Char): PUTF8Char;`

*Append a JSON value, array or document, in a specified format*

- will parse the JSON buffer and write its content with proper line feeds and indentation, according to the supplied TTextWriterJSONFormat
- see also JSONReformat() and JSONBufferReformat() wrappers
- this method is called recursively to handle all kind of JSON values
- WARNING: the JSON buffer is decoded in-place, so will be changed
- returns the end of the current JSON converted level, or nil if the supplied content was not valid JSON

**function** AddJSONToXML(JSON: PUTF8Char; ArrayName: PUTF8Char=nil; EndOfObject: PUTF8Char=nil): PUTF8Char;

*Append a JSON value, array or document as simple XML content*

- you can use JSONBufferToXML() and JSONToXML() functions as wrappers
- this method is called recursively to handle all kind of JSON values
- WARNING: the JSON buffer is decoded in-place, so will be changed
- returns the end of the current JSON converted level, or nil if the supplied content was not correct JSON

**class function** GetCustomJSONParser(var DynArray: TDynArray; out CustomReader: TDynArrayJSONCustomReader; out CustomWriter: TDynArrayJSONCustomWriter): boolean;

*Retrieve low-level custom serialization callbacks for a dynamic array*

- returns TRUE if this array has a custom JSON parser, and set the corresponding serialization/unserialization callbacks

**function** InternalJSONWriter: TTextWriter;

*Gives access to an internal temporary TTextWriter*

- may be used to escape some JSON escaped value (i.e. escape it twice), in conjunction with AddJSONEscape(Source: TTextWriter)

**function** LastChar: AnsiChar;

*Return the last char appended*

- returns #0 if no char has been written yet

**function** PendingBytes: PtrUInt;

*How many bytes are currently in the internal buffer and not on disk*

- see TextLength for the total number of bytes, on both disk and memory

**class function** RegisterCustomJSONSerializerFindParser( aTypeInfo: pointer; aAddIfNotExisting: boolean=false): TJSONRecordAbstract;

*Retrieve a previously registered custom parser instance from its type*

- will return nil if the type info was not available, or defined just with some callbacks
- if AddIfNotExisting is TRUE, and enhanced RTTI is available (since Delphi 2010), you would be able to retrieve this type's parser even if the record type has not been previously used

```
class function RegisterCustomJSONSerializerFromText(aTypeInfo: pointer; const
aRTTIDefinition: RawUTF8): TJSONRecordAbstract; overload;
```

*Define a custom serialization for a given dynamic array or record*

- the RTTI information will here be defined as plain text
- since Delphi 2010, you can call directly RegisterCustomJSONSerializerFromTextSimpleType()
- aTypeInfo may be valid TypeInfo(), or any fixed pointer value if the record does not have any RTTI (e.g. a record without any nested reference- counted types)
- the record where the data will be stored should be defined as PACKED:

```
type TMyRecord = packed record
 A,B,C: integer;
 D: RawUTF8;
 E: record; // or array of record/integer/string/...
 E1,E2: double;
end;
end;
```

- call this method with aRTTIDefinition="" to return back to the default binary + Base64 encoding serialization (i.e. undefine custom serializer)

- only known sub types are byte, word, integer, cardinal, Int64, single, double, currency, TDateTime, TTimeLog, RawUTF8, String, WideString, SynUnicode, TGUID (encoded via GUIDToText) or a nested record or dynamic array of the same simple types or record
- RTTI textual information shall be supplied as text, with the same format as with a pascal record:

```
'A,B,C: integer; D: RawUTF8; E: record E1,E2: double;'
'A,B,C: integer; D: RawUTF8; E: array of record E1,E2: double;'
'A,B,C: integer; D: RawUTF8; E: array of SynUnicode; F: array of TGUID'
```

or a shorter alternative syntax for records and arrays:

```
'A,B,C: integer; D: RawUTF8; E: {E1,E2: double}'
'A,B,C: integer; D: RawUTF8; E: [E1,E2: double]'
```

in fact ; could be ignored:

```
'A,B,C:integer D:RawUTF8 E:{E1,E2:double}'
'A,B,C:integer D:RawUTF8 E:[E1,E2:double]'
```

or even : could be ignored:

```
'A,B,C integer D RawUTF8 E{E1,E2 double}'
'A,B,C integer D RawUTF8 E[E1,E2 double]'
```

- it will return the cached TJSONRecordTextDefinition instance corresponding to the supplied RTTI text definition

```
class function RegisterCustomJSONSerializerSetOptions(const aTypeInfo: array of
pointer; aOptions: TJSONCustomParserSerializationOptions; aAddIfNotExisting:
boolean=false): boolean; overload;
```

*Change options for custom serialization of dynamic arrays or records*

- will return TRUE if the options have been changed, FALSE if the supplied type info was not previously registered for at least one type
- if AddIfNotExisting is TRUE, and enhanced RTTI is available (since Delphi 2010), you would be able to customize the options of this type

```
class function RegisterCustomJSONSerializerSetOptions(aTypeInfo: pointer;
aOptions: TJSONCustomParserSerializationOptions; aAddIfNotExisting:
boolean=false): boolean; overload;
```

*Change options for custom serialization of dynamic array or record*

- will return TRUE if the options have been changed, FALSE if the supplied type info was not previously registered
- if AddIfNotExisting is TRUE, and enhanced RTTI is available (since Delphi 2010), you would be able to customize the options of this type

```
function Text: RawUTF8;
```

*Retrieve the data as a string*

```
procedure Add(const Format: RawUTF8; const Values: array of const; Escape:
TTextWriterKind=twNone; WriteObjectOptions:
TTextWriterWriteObjectOptions=[woFullExpand]); overload;
```

*Append strings or integers with a specified format*

- % = #37 marks a string, integer, floating-point, or class parameter to be appended as text (e.g. class name)
- if StringEscape is false (by default), the text won't be escaped before adding; but if set to true text will be JSON escaped at writing
- note that due to a limitation of the "array of const" format, cardinal values should be type-casted to Int64() - otherwise the integer mapped value will be transmitted, therefore wrongly

```
procedure Add(Value: Extended; precision: integer; noexp: boolean=false); overload;
```

*Append a floating-point Value as a String*

- write "Infinity", "-Infinity", and "NaN" for corresponding IEEE values
- noexp=true will call ExtendedToShortNoExp() to avoid any scientific notation in the resulting text

```
procedure Add(const guid: TGUID); overload;
```

*Append a GUID value, encoded as text without any {}*

- will store e.g. '3F2504E0-4F89-11D3-9A0C-0305E82C3301'

```
procedure Add(const Values: array of const); overload;
```

*Append some values at once*

- text values (e.g. RawUTF8) will be escaped as JSON

```
procedure Add(const V: TVarRec; Escape: TTextWriterKind=twNone; WriteObjectOptions:
TTextWriterWriteObjectOptions=[woFullExpand]); overload;
```

*Append an open array constant value to the buffer*

- "" won't be added for string values
- string values may be escaped, depending on the supplied parameter
- very fast (avoid most temporary storage)

```
procedure Add(P: PUTF8Char; Len: PtrInt; Escape: TTextWriterKind); overload;
```

*Write some #0 ended UTF-8 text, according to the specified format*

- if Escape is a constant, consider calling directly AddNoJSONEscape, AddJSONEscape or AddOnSameLine methods

**procedure** Add(P: PUTF8Char; Escape: TTextWriterKind); overload;

*Write some #0 ended UTF-8 text, according to the specified format*

- if Escape is a constant, consider calling directly AddNoJSONEscape, AddJSONEscape or AddOnSameLine methods

**procedure** Add(c1,c2: AnsiChar); overload;

*Append two chars to the buffer*

**procedure** Add(Value: Int64); overload;

*Already implemented by Add(Value: PtrInt) method append a 64-bit signed Integer Value as text*

**procedure** Add(Value: PtrInt); overload;

*Append a 32-bit signed Integer Value as text*

**procedure** Add(c: AnsiChar); overload;

*Append one ASCII char to the buffer*

**procedure** Add(Value: boolean); overload;

*Append a boolean Value as text*

- write either 'true' or 'false'

**procedure** Add2(Value: PtrUInt);

*Append an Integer Value as a 2 digits String with comma*

**procedure** Add3(Value: PtrUInt);

*Append an Integer Value as a 3 digits String without any added comma*

**procedure** Add4(Value: PtrUInt);

*Append an Integer Value as a 4 digits String with comma*

**procedure** AddAnsiString(const s: AnsiString; Escape: TTextWriterKind); overload;

*Append some UTF-8 encoded chars to the buffer, from the main AnsiString type*

- use the current system code page for AnsiString parameter

**procedure** AddAnyAnsiBuffer(P: PAnsiChar; Len: PtrInt; Escape: TTextWriterKind; CodePage: Integer);

*Append some UTF-8 encoded chars to the buffer, from any Ansi buffer*

- the codepage should be specified, e.g. CP\_UTF8, CP\_RAWBYTESTRING, CODEPAGE\_US, or any version supported by the Operating System

- if codepage is 0, the current CurrentAnsiConvert.CodePage would be used

- will use TSynAnsiConvert to perform the conversion to UTF-8

**procedure** AddAnyAnsiString(const s: RawByteString; Escape: TTextWriterKind; CodePage: Integer=-1);

*Append some UTF-8 encoded chars to the buffer, from any AnsiString value*

- if CodePage is left to its default value of -1, it will assume CurrentAnsiConvert.CodePage prior to Delphi 2009, but newer UNICODE versions of Delphi will retrieve the code page from string

- if CodePage is defined to a >= 0 value, the encoding will take place

**procedure** AddBinToHex(Bin: Pointer; BinBytes: integer);

*Append some binary data as hexadecimal text conversion*

**procedure** AddBinToHexDisplay(Bin: pointer; BinBytes: integer);

*Fast conversion from binary data into hexa chars, ready to be displayed*

- using this function with Bin^ as an integer value will serialize it in big-endian order (most-significant byte first), as used by humans
- up to the internal buffer bytes may be converted

**procedure** AddBinToHexDisplayLower(Bin: pointer; BinBytes: integer);

*Fast conversion from binary data into MSB hexa chars*

- up to the internal buffer bytes may be converted

**procedure** AddBinToHexDisplayMinChars(Bin: pointer; BinBytes: PtrInt);

*Append a Value as significant hexadecimal text*

- append its minimal size, i.e. excluding highest bytes containing 0
- use GetNextItemHexa() to decode such a text value

**procedure** AddBinToHexDisplayQuoted(Bin: pointer; BinBytes: integer);

*Fast conversion from binary data into quoted MSB lowercase hexa chars*

- up to the internal buffer bytes may be converted

**procedure** AddByteToHex(Value: byte);

*Write a byte as hexa chars*

**procedure** AddChars(aChar: AnsiChar; aCount: integer);

*Write the same character multiple times*

**procedure** AddClassName(aClass: TClass);

*Append the class name of an Object instance as text*

- aClass must be not nil

**procedure** AddCR;

*Append CR+LF (#13#10) chars*

- this method won't call EchoAdd() registered events - use AddEndOfLine() method instead
- AddEndOfLine() will append either CR+LF (#13#10) or LF (#10) depending on a flag

**procedure** AddCRAndIndent;

*Append CR+LF (#13#10) chars and #9 indentation*

- indentation depth is defined by fHumanReadableLevel protected field

**procedure** AddCSVConst(const Values: array of const);

*Append an array of const as CSV of JSON values*

**procedure** AddCSVDouble(const Doubles: array of double); overload;

*Append an array of doubles as CSV*

**procedure** AddCSVInteger(const Integers: array of Integer); overload;

*Append an array of integers as CSV*

**procedure** AddCSVUTF8(const Values: array of RawUTF8); overload;

*Append an array of RawUTF8 as CSV of JSON strings*

**procedure** AddCurr64(const Value: currency); overload;

*Append a Currency from its Int64 in-memory representation*

**procedure** AddCurr64(const Value: Int64); overload;

*Append a Currency from its Int64 in-memory representation*

**procedure** AddCurrentLogTime(LocalTime: boolean);

*Append the current UTC date and time, in our log-friendly format*

- e.g. append '20110325 19241502' - with no trailing space nor tab
- you may set LocalTime=TRUE to write the local date and time instead
- this method is very fast, and avoid most calculation or API calls

**procedure** AddCurrentNCSALogTime(LocalTime: boolean);

*Append the current UTC date and time, in our log-friendly format*

- e.g. append '19/Feb/2019:06:18:55 ' - including a trailing space
- you may set LocalTime=TRUE to write the local date and time instead
- this method is very fast, and avoid most calculation or API calls

**procedure** AddDateTime(Value: TDateTime; FirstChar: AnsiChar='T'; QuoteChar: AnsiChar=#0; WithMS: boolean=false); overload;

*Append a TDateTime value, expanded as Iso-8601 encoded text*

- use 'YYYY-MM-DDThh:mm:ss' format (with FirstChar='T')
- if twoDateTimeWithZ CustomOption is set, will append an ending 'Z'
- if WithMS is TRUE, will append '.sss' for milliseconds resolution
- if QuoteChar is not #0, it will be written before and after the date

**procedure** AddDateTime(const Value: TDateTime; WithMS: boolean=false); overload;

*Append a TDateTime value, expanded as Iso-8601 encoded text*

- use 'YYYY-MM-DDThh:mm:ss' format
- if twoDateTimeWithZ CustomOption is set, will append an ending 'Z'
- append nothing if Value=0
- if WithMS is TRUE, will append '.sss' for milliseconds resolution

**procedure** AddDateTimeMS(const Value: TDateTime; Expanded: boolean=true; FirstTimeChar: AnsiChar = 'T'; const TZD: RawUTF8='Z');

*Append a TDateTime value, expanded as Iso-8601 text with milliseconds and Time Zone designator*

- twoDateTimeWithZ CustomOption is ignored in favor of the TZD parameter
- i.e. 'YYYY-MM-DDThh:mm:ss.sssZ' format
- TZD is the ending time zone designator ('', 'Z' or '+hh:mm' or '-hh:mm')

**procedure** AddDouble(Value: double; noexp: boolean=false);

*Append a floating-point Value as a String*

- write "Infinity", "-Infinity", and "NaN" for corresponding IEEE values
- noexp=true will call ExtendedToShortNoExp() to avoid any scientific notation in the resulting text

**procedure** AddDynArrayJSON(**var** aDynArray: TDynArray); overload;

*Append a dynamic array content as UTF-8 encoded JSON array*

- expect a dynamic array TDynArray wrapper as incoming parameter
- TIntegerDynArray, TInt64DynArray, TCardinalDynArray, TDoubleDynArray, TCurrencyDynArray, TWordDynArray and TByteDynArray will be written as numerical JSON values
- TRawUTF8DynArray, TWinAnsiDynArray, TRawByteStringDynArray, TStringDynArray, TWideStringDynArray, TSynUnicodeDynArray, TTimeLogDynArray, and TDateTimeDynArray will be written as escaped UTF-8 JSON strings (and Iso-8601 textual encoding if necessary)
- you can add some custom serializers via RegisterCustomJSONSerializer() class method, to serialize any dynamic array as valid JSON
- any other non-standard or non-registered kind of dynamic array (including array of records) will be written as Base64 encoded binary stream, with a JSON\_BASE64\_MAGIC prefix (UTF-8 encoded \uFFFF0 special code) - this will include TBytes (i.e. array of bytes) content, which is a good candidate for BLOB stream
- typical content could be  
`'[1,2,3,4]'` or `'["\uFFFF0base64encodedbinary"]'`
- by default, custom serializers defined via RegisterCustomJSONSerializer() would write enumerates and sets as integer numbers, unless twoEnumSetsAsTextInRecord is set in the instance Options

**procedure** AddDynArrayJSON(**var** aDynArray: TDynArrayHashed); overload;

*Append a dynamic array content as UTF-8 encoded JSON array*

- expect a dynamic array TDynArrayHashed wrapper as incoming parameter

**procedure** AddDynArrayJSON(aTypeInfo: pointer; **const** aValue); overload;

*Append a dynamic array content as UTF-8 encoded JSON array*

- just a wrapper around the other overloaded method, creating a temporary TDynArray wrapper on the stack
- to be used e.g. for custom record JSON serialization, within a TDynArrayJSONCustomWriter callback

**procedure** AddDynArrayJSONAsString(aTypeInfo: pointer; **var** aValue);

*Same as AddDynArrayJSON(), but will double all internal " and bound with "*

- this implementation will avoid most memory allocations

**procedure** AddFieldName(**const** FieldName: RawUTF8);

*Append a RawUTF8 property name, as "FieldName":'*

- FieldName content should not need to be JSON escaped (e.g. no " within)
- if twoForceJSONExtended is defined in CustomOptions, it would append 'PropName:' without the double quotes
- is a wrapper around AddProp()

**procedure** AddFloatStr(P: PUTF8Char);

*Append a floating-point text buffer*

- will correct on the fly '.5' -> '0.5' and '-.5' -> '-0.5'
- will end not only on #0 but on any char not matching 1[.2[e[-]3]] pattern
- is used when the input comes from a third-party source with no regular output, e.g. a database driver

**procedure** AddHTMLEscape(Text: PUTF8Char; TextLen: PtrInt; Fmt: TTextWriterHTMLFormat=hfAnyWhere); overload;

*Append some chars, escaping all HTML special chars as expected*

```
procedure AddHtmlEscape(Text: PUTF8Char; Fmt: TTextWriterHTMLFormat=hfAnywhere);
overload;
```

*Append some chars, escaping all HTML special chars as expected*

```
procedure AddHtmlEscapeString(const Text: string; Fmt:
TTextWriterHTMLFormat=hfAnywhere);
```

*Append some chars, escaping all HTML special chars as expected*

```
procedure AddHtmlEscapeUTF8(const Text: RawUTF8; Fmt:
TTextWriterHTMLFormat=hfAnywhere);
```

*Append some chars, escaping all HTML special chars as expected*

```
procedure AddInstanceName(Instance: TObject; SepChar: AnsiChar);
```

*Append an Instance name and pointer, as "'ObjectList(00425E68)'+SepChar*  
- Instance must be not nil

```
procedure AddInstancePointer(Instance: TObject; SepChar: AnsiChar;
IncludeUnitName, IncludePointer: boolean); virtual;
```

*Append an Instance name and pointer, as 'ObjectList(00425E68)'+SepChar*  
- Instance must be not nil  
- overridden version in TJSONSerializer would implement IncludeUnitName

```
procedure AddInt18ToChars3(Value: cardinal);
```

*Write a Int18 value (0..262143) as 3 chars*  
- this encoding is faster than Base64, and has spaces on the left side  
- use function Chars3ToInt18() to decode the textual content

```
procedure AddJSON(const Format: RawUTF8; const Args,Params: array of const);
```

*Encode the supplied (extended) JSON content, with parameters, as an UTF-8 valid JSON object content*

- in addition to the JSON RFC specification strict mode, this method will handle some BSON-like extensions, e.g. unquoted field names:

```
aWriter.AddJSON(' {id:?,%:{name:?,birthyear:??}}', ['doc'], [10, 'John', 1982]);
```

- you can use nested \_Obj() / \_Arr() instances

```
aWriter.AddJSON(' %:{$in:[?,?]}', ['type'], ['food', 'snack']);
aWriter.AddJSON(' {type:{$in:??}}', [], [_Arr(['food', 'snack'])]);
// which are the same as:
aWriter.AddShort(' {"type":{"$in":["food","snack"]}}');
```

- if the SynMongoDB unit is used in the application, the MongoDB Shell syntax will also be recognized to create TBSONVariant, like

```
new Date() ObjectId() MinKey MaxKey /<jRegex>/<jOptions>
```

see @<http://docs.mongodb.org/manual/reference/mongodb-extended-json>

```
aWriter.AddJSON(' {name:?,field:/%/i}', ['acme.*corp'], ['John'])
// will write
' {"name":"John", "field":{"$regex":"acme.*corp", "$options":"i"}}'
```

- will call internally \_JSONFastFmt() to create a temporary TDocVariant with all its features - so is slightly slower than other AddJSON\* methods

**procedure** AddJSONArraysAsJSONObject(keys, values: PUTF8Char);

*Append two JSON arrays of keys and values as one JSON object*

- i.e. makes the following transformation:

[key1, key2...] + [value1, value2...] -> {key1:value1, key2:value2...}

- this method won't allocate any memory during its process, nor modify the keys and values input buffers

- is the reverse of the JSONObjectAsJSONArrays() function

**procedure** AddJSONEscape(const V: TVarRec); overload;

*Append an open array constant value to the buffer*

- "" will be added if necessary

- escapes chars according to the JSON RFC

- very fast (avoid most temporary storage)

*Used for DI-2.1.2 (page 2555).*

**procedure** AddJSONEscape(P: Pointer; Len: PtrInt=0); overload;

*Append some UTF-8 encoded chars to the buffer*

- escapes chars according to the JSON RFC

- if Len is 0, writing will stop at #0 (default Len=0 is slightly faster than specifying Len>0 if you are sure P is zero-ended - e.g. from RawUTF8)

*Used for DI-2.1.2 (page 2555).*

**procedure** AddJSONEscape(const NameValuePairs: array of const); overload;

*Encode the supplied data as an UTF-8 valid JSON object content*

- data must be supplied two by two, as Name, Value pairs, e.g.

aWriter.AddJSONEscape(['name', 'John', 'year', 1972]);

will append to the buffer:

'{"name": "John", "year": 1972}'

- or you can specify nested arrays or objects with '['..'']' or '{'..'}':

aWriter.AddJSONEscape(['doc', '{', 'name', 'John', 'ab', '[', 'a', 'b', ']', '}', 'id', 123]);

will append to the buffer:

'{"doc": {"name": "John", "abc": ["a", "b"]}, "id": 123}'

- note that, due to a Delphi compiler limitation, cardinal values should be type-casted to Int64() (otherwise the integer mapped value will be converted)

- you can pass nil as parameter for a null JSON value

*Used for DI-2.1.2 (page 2555).*

**procedure** AddJSONEscape(Source: TTextWriter); overload;

*Flush a supplied TTextWriter, and write pending data as JSON escaped text*

- may be used with InternalJSONWriter, as a faster alternative to

AddJSONEscape(Pointer(fInternalJSONWriter.Text), 0);

*Used for DI-2.1.2 (page 2555).*

**procedure** AddJSONEscapeAnsiString(const s: AnsiString);

*Append some UTF-8 encoded chars to the buffer, from the main AnsiString type*

- escapes chars according to the JSON RFC

**procedure** AddJSONEscapeString(**const** s: **string**);

*Append some UTF-8 encoded chars to the buffer, from a generic string type*

- faster than AddJSONEscape(pointer(StringToUTF8(string)))
- escapes chars according to the JSON RFC

**procedure** AddJSONEscapeW(P: PWord; Len: PtrInt=0);

*Append some Unicode encoded chars to the buffer*

- if Len is 0, Len is calculated from zero-ended widechar
- escapes chars according to the JSON RFC

**procedure** AddJSONString(**const** Text: RawUTF8);

*Append a UTF-8 JSON String, between double quotes and with JSON escaping*

**procedure** AddLine(**const** Text: shortstring);

*Append a line of text with CR+LF at the end*

**procedure** AddMicroSec(MS: cardinal);

*Append a time period, specified in micro seconds, in 00.000.000 TSynLog format*

**procedure** AddNoJSONEscape(P: Pointer; Len: PtrInt); overload;

*Append some UTF-8 chars to the buffer*

- don't escapes chars according to the JSON RFC

**procedure** AddNoJSONEscape(Source: TTextWriter); overload;

*Flush a supplied TTextWriter, and write pending data as JSON escaped text*

- may be used with InternalJSONWriter, as a faster alternative to AddNoJSONEscapeUTF8(Source.Text);

**procedure** AddNoJSONEscape(P: Pointer); overload;

*Append some UTF-8 chars to the buffer*

- input length is calculated from zero-ended char
- don't escapes chars according to the JSON RFC

**procedure** AddNoJSONEscapeString(**const** s: **string**);

*Append some UTF-8 encoded chars to the buffer, from a generic string type*

- faster than AddNoJSONEscape(pointer(StringToUTF8(string)))
- don't escapes chars according to the JSON RFC
- will convert the Unicode chars into UTF-8

**procedure** AddNoJSONEscapeUTF8(**const** text: RawByteString);

*Append some UTF-8 chars to the buffer*

- don't escapes chars according to the JSON RFC

**procedure** AddNoJSONEscapeW(WideChar: PWord; WideCharCount: integer);

*Append some unicode chars to the buffer*

- WideCharCount is the unicode chars count, not the byte size
- don't escapes chars according to the JSON RFC
- will convert the Unicode chars into UTF-8

**procedure** AddObjArrayJSON(**const** aObjArray; aOptions: TTextWriterWriteObjectOptions=[woDontStoreDefault]);

*Append a T\*ObjArray dynamic array as a JSON array*

- as expected by TJSONSerializer.RegisterObjArrayForJSON()

**procedure** AddOnce(c: AnsiChar); overload;

*Append one ASCII char to the buffer, if not already there as LastChar*

**procedure** AddOnSameLine(P: PUTF8Char; Len: PtrInt); overload;

*Append some chars to the buffer in one line*

- will write #0..#31 chars as spaces (so content will stay on the same line)

**procedure** AddOnSameLine(P: PUTF8Char); overload;

*Append some chars to the buffer in one line*

- P should be ended with a #0

- will write #1..#31 chars as spaces (so content will stay on the same line)

**procedure** AddOnSameLineW(P: PWord; Len: PtrInt);

*Append some wide chars to the buffer in one line*

- will write #0..#31 chars as spaces (so content will stay on the same line)

**procedure** AddPointer(P: PtrUInt);

*Add the pointer into significant hexa chars, ready to be displayed*

**procedure** AddProp(PropName: PUTF8Char; PropNameLen: PtrInt);

*Append a property name, as "PropName":'*

- PropName content should not need to be JSON escaped (e.g. no " within, and only ASCII 7-bit characters)

- if twoForceJSONExtended is defined in CustomOptions, it would append 'PropName:' without the double quotes

**procedure** AddPropJSONInt64(const PropName: shortstring; Value: Int64);

*Append a JSON field name, followed by a number value and a comma (',')*

**procedure** AddPropJSONString(const PropName: shortstring; const Text: RawUTF8);

*Append a JSON field name, followed by an escaped UTF-8 JSON String and a comma (',')*

**procedure** AddPropName(const PropName: ShortString);

*Append a ShortString property name, as "PropName":'*

- PropName content should not need to be JSON escaped (e.g. no " within, and only ASCII 7-bit characters)

- if twoForceJSONExtended is defined in CustomOptions, it would append 'PropName:' without the double quotes

- is a wrapper around AddProp()

**procedure** AddQ(Value: QWord);

*Append an Unsigned 64-bit Integer Value as a String*

**procedure** AddQHex(Value: Qword);

*Append an Unsigned 64-bit Integer Value as a quoted hexadecimal String*

**procedure** AddQuotedStr(Text: PUTF8Char; Quote: AnsiChar; TextMaxLen: PtrInt=0);

*Append some UTF-8 text, quoting all " chars*

- same algorithm than AddString(QuotedStr()) - without memory allocation, and with an optional maximum text length (truncated with ending '...')

- this function implements what is specified in the official SQLite3 documentation: "A string constant is formed by enclosing the string in single quotes ('). A single quote within the string can be encoded by putting two single quotes in a row - as in Pascal."

**procedure** AddQuotedStringAsJSON(**const** QuotedString: RawUTF8);

*Append a quoted string as JSON, with in-place decoding*

- if QuotedString does not start with ' or ", it will be written directly (i.e. expects to be a number, or null/true/false constants)
- as used e.g. by TJSONObjectDecoder.EncodeAsJSON method and JSONEncodeNameSQLValue() function

**procedure** AddRawJSON(**const** json: RawJSON);

*Append some UTF-8 chars to the buffer*

- if supplied json is "", will write 'null'

**procedure** AddRecordJSON(**const** Rec; TypeInfo: pointer);

*Append a record content as UTF-8 encoded JSON or custom serialization*

- default serialization will use Base64 encoded binary stream, or a custom serialization, in case of a previous registration via RegisterCustomJSONSerializer() class method - from a dynamic array handling this kind of records, or directly from TypeInfo() of the record
- by default, custom serializers defined via RegisterCustomJSONSerializer() would write enumerates and sets as integer numbers, unless twoEnumSetsAsTextInRecord or twoEnumSetsAsBooleanInRecord is set in the instance CustomOptions

**procedure** AddReplace(Text: PUTF8Char; Orig, Replaced: AnsiChar);

*Append some chars, replacing a given character with another*

**procedure** AddShort(**const** Text: ShortString);

*Append a ShortString*

**procedure** AddSingle(Value: single; noexp: boolean=false);

*Append a floating-point Value as a String*

- write "Infinity", "-Infinity", and "NaN" for corresponding IEEE values
- noexp=true will call ExtendedToShortNoExp() to avoid any scientific notation in the resulting text

**procedure** AddString(**const** Text: RawUTF8);

*Append an UTF-8 String, with no JSON escaping*

**procedure** AddStringCopy(**const** Text: RawUTF8; start, len: PtrInt);

*Append a sub-part of an UTF-8 String*

- emulates AddString(copy(Text, start, len))

**procedure** AddStrings(**const** Text: array of RawUTF8); overload;

*Append several UTF-8 strings*

**procedure** AddStrings(**const** Text: RawUTF8; count: integer); overload;

*Append an UTF-8 string several times*

**procedure** AddTimeLog(Value: PInt64);

*Append a TTimeLog value, expanded as Iso-8601 encoded text*

**procedure** AddTrimLeftLowerCase(Text: PShortString);

*Append after trim first lowercase chars ('otDone' will add 'Done' e.g.)*

**procedure** AddTrimSpaces(P: PUTF8Char); overload;

*Append a UTF-8 String excluding any space or control char*

- this won't escape the text as expected by JSON

**procedure** AddTrimSpaces(const Text: RawUTF8); overload;

*Append a UTF-8 String excluding any space or control char*  
- this won't escape the text as expected by JSON

**procedure** AddTypedJSON(aTypeInfo: pointer; const aValue);

*Append a JSON value from its RTTI type*  
- handle tkClass, tkEnumeration, tkSet, tkRecord, tkDynArray, tkVariant types  
- write null for other types

**procedure** AddU(Value: cardinal);

*Append an Unsigned 32-bit Integer Value as a String*

**procedure** AddUnixMSTime(Value: PInt64; WithMS: boolean=false);

*Append a TUnixMSTime value, expanded as Iso-8601 encoded text*

**procedure** AddUnixTime(Value: PInt64);

*Append a TUnixTime value, expanded as Iso-8601 encoded text*

**procedure** AddVariant(const Value: variant; Escape: TTextWriterKind=twJSONEscape);

*Append a variant content as number or string*  
- default Escape=twJSONEscape will create valid JSON content, which can be converted back to a variant value using VariantLoadJSON()  
- default JSON serialization options would apply, unless twoForceJSONExtended or twoForceJSONStandard is defined  
- note that before Delphi 2009, any varString value is expected to be a RawUTF8 instance - which does make sense in the mORMot context

**procedure** AddVoidRecordJSON(TypeInfo: pointer);

*Append a void record content as UTF-8 encoded JSON or custom serialization*  
- this method will first create a void record (i.e. filled with #0 bytes) then save its content with default or custom serialization

**procedure** AddW(P: PWord; Len: PtrInt; Escape: TTextWriterKind);

*Write some #0 ended Unicode text as UTF-8, according to the specified format*  
- if Escape is a constant, consider calling directly AddNoJSONEscapeW, AddJSONEscapeW or AddOnSameLineW methods

**procedure** AddXmlEscape(Text: PUTF8Char);

*Append some chars, escaping all XML special chars as expected*  
- i.e. < > & " ' as &lt; &gt; &amp; &quote; &apos;  
- and all control chars (i.e. #1..#31) as &#..;  
- see @<http://www.w3.org/TR/xml/#syntax>

**procedure** CancelAll;

*Rewind the Stream to the position when Create() was called*  
- note that this does not clear the Stream content itself, just move back its writing position to its initial place

**procedure** CancelLastChar(aCharToCancel: AnsiChar); overload;

*The last char appended is canceled, if match the supplied one*  
- only one char cancelation is allowed at the same position: don't call CancelLastChar/CancelLastComma more than once without appending text inbetween

**procedure** CancelLastChar; overload;

*The last char appended is canceled*

- only one char cancelation is allowed at the same position: don't call CancelLastChar/CancelLastComma more than once without appending text inbetween

**procedure** CancelLastComma;

*The last char appended is canceled if it was a ','*

- only one char cancelation is allowed at the same position: don't call CancelLastChar/CancelLastComma more than once without appending text inbetween

**procedure** FlushFinal;

*Write pending data to the Stream, without automatic buffer resizal*

- will append the internal memory buffer to the Stream
- in short, FlushToStream may be called during the adding process, and FlushFinal at the end of the process, just before using the resulting Stream
- if you don't call FlushToStream or FlushFinal, some pending characters may not be copied to the Stream: you should call it before using the Stream

**procedure** FlushToStream; virtual;

*Write pending data to the Stream, with automatic buffer resizal*

- you should not have to call FlushToStream in most cases, but FlushFinal at the end of the process, just before using the resulting Stream
- FlushToStream may be used to force immediate writing of the internal memory buffer to the destination Stream
- you can set FlushToStreamNoAutoResize=true or call FlushFinal if you do not want the automatic memory buffer resizal to take place

**procedure** ForceContent(const text: RawUTF8);

*Set the internal stream content with the supplied UTF-8 text*

**class procedure** RegisterCustomJSONSerializer(aTypeInfo: pointer; aReader: TDynArrayJSONCustomReader; aWriter: TDynArrayJSONCustomWriter);

*Define a custom serialization for a given dynamic array or record*

- expects TypeInfo() from a dynamic array or a record (will raise an exception otherwise)
- for a dynamic array, the associated item record RTTI will be registered
- for a record, any matching dynamic array will also be registered
- by default, TIntegerDynArray and such known classes are processed as true JSON arrays: but you can specify here some callbacks to perform the serialization process for any kind of dynamic array
- any previous registration is overridden
- setting both aReader=aWriter=nil will return back to the default binary + Base64 encoding serialization (i.e. undefine custom serializer)

**class procedure** RegisterCustomJSONSerializerForVariant(aClass: TCustomVariantType; aReader: TDynArrayJSONCustomReader; aWriter: TDynArrayJSONCustomWriter);

*Define a custom serialization for a given variant custom type*

- used e.g. to serialize TBCD values

**class procedure** RegisterCustomJSONSerializerForVariantByType(aVarType: TVarType; aReader: TDynArrayJSONCustomReader; aWriter: TDynArrayJSONCustomWriter);

*Define a custom serialization for a given variant custom type*

- used e.g. to serialize TBCD values

```
class procedure RegisterCustomJSONSerializerFromText(const
aTypeInfoTextDefinitionPairs: array of const); overload;
```

*Define a custom serialization for several dynamic arrays or records*

- the TypeInfo() and textual RTTI information will here be defined as ([TypeInfo(TType1),\_TType1,TypeInfo(TType2),\_TType2]) pairs
- a wrapper around the overloaded RegisterCustomJSONSerializerFromText()

```
class procedure RegisterCustomJSONSerializerFromTextBinaryType(aTypeInfo:
pointer; aDataSize: integer; aFieldSize: integer=0); overload;
```

*Define a custom binary serialization for a given simple type*

- you should be able to use this type in the RTTI text definition of any further RegisterCustomJSONSerializerFromText() call
- data will be serialized as BinToHexDisplayLower() JSON hexadecimal string
- you can truncate the original data size (e.g. if all bits of an integer are not used) by specifying the aFieldSize optional parameter

```
class procedure RegisterCustomJSONSerializerFromTextBinaryType(const
aTypeInfoDataFieldSize: array of const); overload;
```

*Define custom binary serialization for several simple types*

- data will be serialized as BinToHexDisplayLower() JSON hexadecimal string
- the TypeInfo() and associated size information will here be defined as triplets: ([TypeInfo(TType1),SizeOf(TType1),TYPE1\_BYTES,TypeInfo(TType2),SizeOf(TType2),TYPE2\_BYTES])
- a wrapper around the overloaded RegisterCustomJSONSerializerFromTextBinaryType()

```
class procedure RegisterCustomJSONSerializerFromTextSimpleType(aTypeInfo:
pointer; const aTypeName: RawUTF8=''); overload;
```

*Define a custom serialization for a given simple type*

- you should be able to use this type in the RTTI text definition of any further RegisterCustomJSONSerializerFromText() call
- the RTTI information should be enough to serialize the type from its name (e.g. an enumeration for older Delphi revision, but all records since Delphi 2010)
- you can supply a custom type name, which will be registered in addition to the "official" name defined at RTTI level
- on older Delphi versions (up to Delphi 2009), it will handle only enumerations, which will be transmitted as JSON string instead of numbers
- since Delphi 2010, any record type can be supplied - which is more convenient than calling RegisterCustomJSONSerializerFromText()

```
class procedure RegisterCustomJSONSerializerFromTextSimpleType(const aTypeInfos:
array of pointer); overload;
```

*Define a custom serialization for several simple types*

- will call the overloaded RegisterCustomJSONSerializerFromTextSimpleType method for each supplied type information

**class procedure** SetDefaultEnumTrim(aShouldTrimEnumsAsText: boolean);

*Allow to override the default JSON serialization of enumerations and sets as text, which would write the whole identifier (e.g. 'sllError')*

- calling SetDefaultEnumTrim(true) would force the enumerations to be trimmed for any lower case char, e.g. sllError -> 'Error'
- this is global to the current process, and should be use mainly for compatibility purposes for the whole process
- you may change the default behavior by setting twoTrimLeftEnumSets in the TTextWriter.CustomOptions property of a given serializer
- note that unserialization process would recognize both formats

**procedure** SetText(var result: RawUTF8; reformat: TTextWriterJSONFormat=jsonCompact);

*Retrieve the data as a string*

- will avoid creation of a temporary RawUTF8 variable as for Text function

**class procedure** UnRegisterCustomJSONSerializer(aTypeInfo: pointer);

*Undefine a custom serialization for a given dynamic array or record*

- it will un-register any callback or text-based custom serialization i.e. any previous RegisterCustomJSONSerializer() or RegisterCustomJSONSerializerFromText() call
- expects TypeInfo() from a dynamic array or a record (will raise an exception otherwise)
- it will set back to the default binary + Base64 encoding serialization

**procedure** WrBase64(P: PAnsiChar; Len: PtrUInt; withMagic: boolean);

*Write some data Base64 encoded*

- if withMagic is TRUE, will write as ""\uFFF0base64encodedbinary""

**procedure** WriteObject(Value: TObject; Options: TTextWriterWriteObjectOptions=[woDontStoreDefault]); **virtual**;

*Serialize as JSON the given object*

- this default implementation will write null, or only write the class name and pointer if FullExpand is true - use TJSONSerializer.WriteObject method for full RTTI handling
- default implementation will write TList/TCollection/TStrings/TRawUTF8List as appropriate array of class name/pointer (if woFullExpand is set)

**procedure** WriteObjectAsString(Value: TObject; Options: TTextWriterWriteObjectOptions=[woDontStoreDefault]);

*Same as WriteObject(), but will double all internal " and bound with "*

- this implementation will avoid most memory allocations

**procedure** WrRecord(const Rec; TypeInfo: pointer);

*Write some record content as binary, Base64 encoded with our magic prefix*

**property** CustomOptions: TTextWriterOptions **read** fCustomOptions **write** fCustomOptions;

*Global options to customize this TTextWriter instance process*

- allows to override e.g. AddRecordJSON() and AddDynArrayJSON() behavior

**property** HumanReadableLevel: integer **read** fHumanReadableLevel **write** fHumanReadableLevel;

*Low-level access to the current indentation level*

**property** OnFlushToStream: TOnTextWriterFlush read fOnFlushToStream write fOnFlushToStream;

*Optional event called before FlushToStream method process*

**property** OnWriteObject: TOnTextWriterObjectProp read fOnWriteObject write fOnWriteObject;

*Allows to override default WriteObject property JSON serialization*

**property** Stream: TStream read fStream write SetStream;

*The internal TStream used for storage*

- you should call the FlushFinal (or FlushToStream) methods before using this TStream content, to flush all pending characters
- if the TStream instance has not been specified when calling the TTextWriter constructor, it can be forced via this property, before any writing

**property** TextLength: PtrUInt read GetTextLength;

*Count of added bytes to the stream*

- see PendingBytes for the number of bytes currently in the memory buffer or WrittenBytes for the number of bytes already written to disk

**property** WrittenBytes: PtrUInt read fTotalFileSize;

*How many bytes were currently written on disk*

- excluding the bytes in the internal buffer
- see TextLength for the total number of bytes, on both disk and memory

**TTextWriterWithEcho = class(TTextWriter)**

*Stream TEXT writer, with optional echoing of the lines*

- as used e.g. by TSynLog writer for log optional redirection
- is defined as a sub-class to reduce plain TTextWriter scope
- see SynTable.pas for SQL resultset export via TJSONWriter
- see mORMot.pas for proper class serialization via TJSONSerializer.WriteObject

**procedure** AddEndOfLine(aLevel: TSynLogInfo=sllNone);

*Mark an end of line, ready to be "echoed" to registered listeners*

- append a LF (#10) char or CR+LF (#13#10) chars to the buffer, depending on the EndOfLineCRLF property value (default is LF, to minimize storage)
- any callback registered via EchoAdd() will monitor this line
- used e.g. by TSynLog for console output, as stated by Level parameter

**procedure** EchoAdd(const aEcho: TOnTextWriterEcho);

*Add a callback to echo each line written by this class*

- this class expects AddEndOfLine to mark the end of each line

**procedure** EchoRemove(const aEcho: TOnTextWriterEcho);

*Remove a callback to echo each line written by this class*

- event should have been previously registered by a EchoAdd() call

**procedure** EchoReset;

*Reset the internal buffer used for echoing content*

**procedure** FlushToStream; **override**;

*Write pending data to the Stream, with automatic buffer resizal and echoing*  
- this overridden method will handle proper echoing

**property** EndOfLineCRLF: boolean **read** GetEndOfLineCRLF **write** SetEndOfLineCRLF;

*Define how AddEndOfLine method stores its line feed characters*  
- by default (FALSE), it will append a LF (#10) char to the buffer  
- you can set this property to TRUE, so that CR+LF (#13#10) chars will be appended instead  
- is just a wrapper around twoEndOfLineCRLF item in CustomOptions

**TObjectListHashedAbstract** = **class**(TObject)

*Abstract ancestor to manage a dynamic array of TObject*  
- do not use this abstract class directly, but rather the inherited TObjectListHashed and TObjectListPropertyHashed

**constructor** Create(aFreeItems: boolean=true); **reintroduce**;

*Initialize the class instance*  
- if aFreeItems is TRUE (default), will behave like a TObjectList  
- if aFreeItems is FALSE, will behave like a TList

**destructor** Destroy; **override**;

*Release used memory*

**function** Add(aObject: TObject; **out** wasAdded: boolean): integer; **virtual**; **abstract**;

*Search and add an object reference to the list*  
- returns the found/added index

**function** IndexOf(aObject: TObject): integer; **virtual**; **abstract**;

*Retrieve an object index within the list, using a fast hash table*  
- returns -1 if not found

**procedure** Delete(aObject: TObject); **overload**; **virtual**;

*Delete an object from the list*  
- will invalide the whole hash table

**procedure** Delete(aIndex: integer); **overload**;

*Delete an object from the list*  
- the internal hash table is not recreated, just invalidated (i.e. this method calls HashInvalidate not FindHashedAndDelete)  
- will invalide the whole hash table

**property** Count: integer **read** fCount;

*Returns the count of stored objects*

**property** Hash: TDynArrayHashed **read** fHash;

*Direct access to the underlying hashing engine*

**property** List: TObjectDynArray **read** fList;

*Direct access to the items list array*

**TObjectListHashed = class(TObjectListHashedAbstract)**

*This class behaves like TList/TObjectList, but will use hashing for (much) faster IndexOf() method*

**function** Add(aObject: TObject; **out** wasAdded: boolean): integer; **override;**

*Search and add an object reference to the list*

- returns the found/added index
- if added, hash is stored and Items[] := aObject

**function** IndexOf(aObject: TObject): integer; **override;**

*Retrieve an object index within the list, using a fast hash table*

- returns -1 if not found

**procedure** Delete(aObject: TObject); **override;**

*Delete an object from the list*

- overridden method won't invalidate the whole hash table, but refresh it

**TObjectListPropertyHashed = class(TObjectListHashedAbstract)**

*This class will hash and search for a sub property of the stored objects*

**constructor** Create(aSubPropAccess: TObjectListPropertyHashedAccessProp;  
 aHashElement: TDynArrayHashOne=nil; aCompare: TDynArraySortCompare=nil;  
 aFreeItems: boolean=true); **reintroduce;**

*Initialize the class instance with the corresponding callback in order to handle sub-property hashing and search*

- see TSetWeakZeroClass in mORMot.pas unit as example:

```
function WeakZeroClassSubProp(aObject: TObject): TObject;
begin
 result := TSetWeakZeroInstance(aObject).fInstance;
end;
```

- by default, aHashElement/aCompare will hash/search for pointers: you can specify the hash/search methods according to your sub property (e.g.

HashAnsiStringI/SortDynArrayAnsiStringI for a RawUTF8)

- if aFreeItems is TRUE (default), will behave like a TObjectList; if aFreeItems is FALSE, will behave like a TList

**function** Add(aObject: TObject; **out** wasAdded: boolean): integer; **override;**

*Search and add an object reference to the list*

- returns the found/added index
- if added, only the hash is stored: caller has to set List[i]

**function** IndexOf(aObject: TObject): integer; **override;**

*Retrieve an object index within the list, using a fast hash table*

- returns -1 if not found

**TPointerClassHashed = class(TObject)**

*Abstract class stored by a TPointerClassHash list*

**constructor** Create(aInfo: pointer);

*Initialize the instance*

**property** Info: pointer read fInfo write fInfo;

*The associated information of this instance*

- may be e.g. a PTypeInfo value, when caching RTTI information

**TPointerClassHash = class(TObjectListPropertyHashed)**

*Handle a O(1) hashed-based storage of TPointerClassHashed, from a pointer*

- used e.g. to store RTTI information from its PTypeInfo value

- if not thread safe, but could be used to store RTTI, since all type information should have been initialized before actual process

**constructor** Create;

*Initialize the storage list*

**function** Find(aInfo: pointer): TPointerClassHashed;

*Search for a stored instance, from its supplied pointer reference*

- returns nil if aInfo was not previously added by FindOrAdd()

- this method is not thread-safe

**function** TryAdd(aInfo: pointer): PPointerClassHashed;

*Try to add an entry to the storage*

- returns nil if the supplied information is already in the list

- returns a pointer to where a newly created TPointerClassHashed instance should be stored

- this method is not thread-safe

**TPointerClassHashLocked = class(TPointerClassHash)**

*Handle a O(1) hashed-based storage of TPointerClassHashed, from a pointer*

- this inherited class add a mutex to be thread-safe

**constructor** Create;

*Initialize the storage list*

**destructor** Destroy; **override;**

*Finalize the storage list*

**function** FindLocked(aInfo: pointer): TPointerClassHashed;

*Search for a stored instance, from its supplied pointer reference*

- returns nil if aInfo was not previously added by FindOrAdd()

- this overridden method is thread-safe, unless returned TPointerClassHashed instance is deleted in-between

**function** TryAddLocked(aInfo: pointer; **out** aNewEntry: PPointerClassHashed): boolean;

*Try to add an entry to the storage*

- returns false if the supplied information is already in the list
- returns true, and a pointer to where a newly created TPointerClassHashed instance should be stored: in this case, you should call Unlock once set
- could be used as such:

```
var entry: PPointerClassHashed;
...
if HashList.TryAddLocked(aTypeInfo,entry) then
 try
 entry^ := TMyCustomPointerClassHashed.Create(aTypeInfo,...);
 finally
 HashList.Unlock;
 end;
...
```

**procedure** Unlock;

*Release the lock after a previous TryAddLocked(=true call*

**TSynObjectListLocked = class**(TSynObjectList)

*Add locking methods to a TSynObjectList*

- this class overrides the regular TSynObjectList, and do not share any code with the TObjectListHashedAbstract/TObjectListHashed classes
- you need to call the Safe.Lock/Unlock methods by hand to protect the execution of index-oriented methods (like Delete/Items/Count...): the list content may change in the background, so using indexes is thread-safe
- on the other hand, Add/Clear/ClearFromLast/Remove stateless methods have been overridden in this class to call Safe.Lock/Unlock, and therefore are thread-safe and protected to any background change

**constructor** Create(aOwnsObjects: boolean=true); **reintroduce**;

*Initialize the list instance*

- the stored TObject instances will be owned by this TSynObjectListLocked, unless AOwnsObjects is set to false

**destructor** Destroy; **override**;

*Release the list instance (including the locking resource)*

**function** Add(item: pointer): integer; **override**;

*Add one item to the list using the global critical section*

**function** Exists(item: pointer): boolean; **override**;

*Check an item using the global critical section*

**function** Remove(item: pointer): integer; **override**;

*Fast delete one item in the list*

**procedure** Clear; **override**;

*Delete all items of the list using the global critical section*

**procedure** ClearFromLast; **override**;

*Delete all items of the list in reverse order, using the global critical section*

**property** Safe: TSynLocker read fSafe;

*The critical section associated to this list instance*

- could be used to protect shared resources within the internal process, for index-oriented methods like Delete/Items/Count...
- use Safe.Lock/TryLock with a try ... finally Safe.Unlock block

**TRawUTF8List = class**(TObject)

*TStringList-class optimized to work with our native UTF-8 string type*

- can optionally store associated some TObject instances
- high-level methods of this class are thread-safe
- if fNoDuplicate flag is defined, an internal hash table will be maintained to perform IndexOf() lookups in O(1) linear way

**constructor** Create(aOwnObjects: boolean; aNoDuplicate: boolean=false; aCaseSensitive: boolean=true); overload;

*Backward compatibility overloaded constructor*

- please rather use the overloaded Create(TRawUTF8ListFlags)

**constructor** Create(aFlags: TRawUTF8ListFlags=[fCaseSensitive]); overload;

*Initialize the RawUTF8/Objects storage*

- by default, any associated Objects[] are just weak references; you may supply fOwnObjects flag to force object instance management
- if you want the stored text items to be unique, set fNoDuplicate and then an internal hash table will be maintained for fast IndexOf()
- you can unset fCaseSensitive to let the UTF-8 lookup be case-insensitive

**destructor** Destroy; **override**;

*Finalize the internal objects stored*

- if instance was created with fOwnObjects flag

**function** Add(const aText: RawUTF8; aRaiseExceptionIfExists: boolean=false): PtrInt;

*Store a new RawUTF8 item*

- without the fNoDuplicate flag, it will always add the supplied value
- if fNoDuplicate was set and aText already exists (using the internal hash table), it will return -1 unless aRaiseExceptionIfExists is forced
- thread-safe method

**function** AddObject(const aText: RawUTF8; aObject: TObject; aRaiseExceptionIfExists: boolean=false; aFreeAndReturnExistingObject: PPointer=nil): PtrInt;

*Store a new RawUTF8 item, and its associated TObject*

- without the fNoDuplicate flag, it will always add the supplied value
- if fNoDuplicate was set and aText already exists (using the internal hash table), it will return -1 unless aRaiseExceptionIfExists is forced; optionally freeing the supplied aObject if aFreeAndReturnExistingObject is true, in which pointer the existing Objects[] is copied (see AddObjectUnique as a convenient wrapper around this behavior)
- thread-safe method

**function** Contains(**const** aText: RawUTF8; aFirstIndex: integer=0): PtrInt;

*Search for any RawUTF8 item containing some text*

- uses PosEx() on the stored lines
- this method is not thread-safe since the internal list may change and the returned index may not be accurate any more
- by design, aText lookup can't use the internal Hash Table

**function** Delete(**const** aText: RawUTF8): PtrInt; overload;

*Delete a stored RawUTF8 item, and its associated TObjet*

- will search for the value using IndexOf(aText), and returns its index
- returns -1 if no entry was found and deleted
- thread-safe method, using the internal Hash Table if fNoDuplicate is set

**function** DeleteFromName(**const** Name: RawUTF8): PtrInt; **virtual**;

*Delete a stored RawUTF8 item, and its associated TObjet, from a given Name when stored as 'Name=Value' pairs*

- raise no exception in case of out of range supplied index
- thread-safe method, but not using the internal Hash Table
- consider using TSynNameValue if you expect efficient name/value process

**function** GetObjectFrom(**const** aText: RawUTF8): pointer;

*Get a stored Object item by its associated UTF-8 text*

- returns nil and raise no exception if aText doesn't exist
- thread-safe method, unless returned TObjet is deleted in the background

**function** GetText(**const** Delimiter: RawUTF8=#13#10): RawUTF8;

*Retrieve the all lines, separated by the supplied delimiter*

- this method is thread-safe

**function** GetValueAt(Index: PtrInt): RawUTF8;

*Access to the Value of a given 'Name=Value' pair at a given position*

- this method is not thread-safe
- consider using TSynNameValue if you expect efficient name/value process

**function** IndexOf(**const** aText: RawUTF8): PtrInt;

*Find a RawUTF8 item in the stored Strings[] list*

- this search is case sensitive if fCaseSensitive flag was set (which is the default)
- this method is not thread-safe since the internal list may change and the returned index may not be accurate any more
- see also GetObjectFrom()
- uses the internal Hash Table if fNoDuplicate was set

**function** IndexOfName(**const** Name: RawUTF8): PtrInt;

*Find the index of a given Name when stored as 'Name=Value' pairs*

- search on Name is case-insensitive with 'Name=Value' pairs
- this method is not thread-safe, and won't use the internal Hash Table
- consider using TSynNameValue if you expect efficient name/value process

**function** IndexOfObject(aObject: TObject): PtrInt;

*Find a TObject item index in the stored Objects[] list*

- this method is not thread-safe since the internal list may change and the returned index may not be accurate any more
- aObject lookup won't use the internal Hash Table

**function** PopFirst(out aText: RawUTF8; aObject: PObject=nil): boolean;

*Retrieve and delete the first RawUTF8 item in the list*

- could be used as a FIFO, calling Add() as a "push" method
- thread-safe method

**function** PopLast(out aText: RawUTF8; aObject: PObject=nil): boolean;

*Retrieve and delete the last RawUTF8 item in the list*

- could be used as a FILO, calling Add() as a "push" method
- thread-safe method

**function** UpdateValue(const Name: RawUTF8; var Value: RawUTF8; ThenDelete: boolean): boolean;

*Retrieve Value from an existing Name=Value, then optionally delete the entry*

- if Name is found, will fill Value with the stored content and return true
- if Name is not found, Value is not modified, and false is returned
- thread-safe method, but not using the internal Hash Table
- consider using TSynNameValue if you expect efficient name/value process

**procedure** AddObjectUnique(const aText: RawUTF8; aObjectToAddOrFree: PPointer);

*Try to store a new RawUTF8 item and its associated TObject*

- fNoDuplicate should have been specified in the list flags
- if aText doesn't exist, will add the values
- if aText exist, will call aObjectToAddOrFree.Free and set the value already stored in Objects[] into aObjectToAddOrFree - allowing dual commit thread-safe update of the list, e.g. after a previous unsuccessful call to GetObjectFrom(aText)
- thread-safe method, using an internal Hash Table to speedup IndexOf()
- in fact, this method is just a wrapper around  
AddObject(aText, aObjectToAddOrFree^, false, @aObjectToAddOrFree);

**procedure** AddRawUTF8List(List: TRawUTF8List);

*Append a specified list to the current content*

- thread-safe method

**procedure** BeginUpdate;

*The OnChange event will be raised only when EndUpdate will be called*

- this method will also call Safe.Lock for thread-safety

**procedure** Clear; virtual;

*Erase all stored RawUTF8 items*

- and corresponding objects (if aOwnObjects was true at constructor)
- thread-safe method, also clearing the internal Hash Table

**procedure** Delete(Index: PtrInt); overload;

*Delete a stored RawUTF8 item, and its associated TObject*

- raise no exception in case of out of range supplied index
- this method is not thread-safe: use Safe.Lock/UnLock if needed

**procedure** EndUpdate;

*Call the OnChange event if changes occurred*  
- this method will also call Safe.Unlock for thread-safety

**procedure** LoadFromFile(const FileName: TFileName);

*Set all lines from an UTF-8 text file*  
- expect the file is explicitly an UTF-8 file  
- will ignore any trailing UTF-8 BOM in the file content, but will not expect one either  
- this method is thread-safe

**procedure** SaveToFile(const FileName: TFileName; const Delimiter: RawUTF8=#13#10);

*Write all lines into a new file*  
- this method is thread-safe

**procedure** SaveToStream(Dest: TStream; const Delimiter: RawUTF8=#13#10);

*Write all lines into the supplied stream*  
- this method is thread-safe

**procedure** SetFrom(const aText: TRawUTF8DynArray; const aObject: TObjectDynArray);

*Set low-level text and objects from existing arrays*

**procedure** SetText(const aText: RawUTF8; const Delimiter: RawUTF8=#13#10);

*Set all lines, separated by the supplied delimiter*  
- this method is thread-safe

**property** Capacity: PtrInt **read** GetCapacity **write** SetCapacity;

*Set or retrieve the current memory capacity of the RawUTF8 list*  
- reading this property is not thread-safe, since size may change

**property** CaseSensitive: boolean **read** GetCaseSensitive **write** SetCaseSensitive;

*Set if IndexOf() shall be case sensitive or not*  
- default is TRUE  
- matches fCaseSensitive in Flags

**property** Count: PtrInt **read** GetCount;

*Return the count of stored RawUTF8*  
- reading this property is not thread-safe, since size may change

**property** Flags: TRawUTF8ListFlags **read** fFlags **write** fFlags;

*Access to the low-level flags of this list*

**property** Names[Index: PtrInt]: RawUTF8 **read** GetName;

*Retrieve the corresponding Name when stored as 'Name=Value' pairs*  
- reading this property is not thread-safe, since content may change  
- consider TSynNameValue if you expect more efficient name/value process

**property** NameValueSep: AnsiChar **read** fNameValueSep **write** fNameValueSep;

*The char separator between 'Name=Value' pairs*  
- equals '=' by default  
- consider TSynNameValue if you expect more efficient name/value process

**property** NoDuplicate: boolean **read** GetNoDuplicate;

*Set if the list doesn't allow duplicated UTF-8 text*

- if true, an internal hash table is maintained for faster IndexOf()
- matches fNoDuplicate in Flags

**property** ObjectPtr: PPointerArray **read** GetObjectPtr;

*Direct access to the memory of the TObjectDynArray items*

- reading this property is not thread-safe, since content may change

**property** Objects[Index: PtrInt]: pointer **read** GetObject **write** PutObject;

*Get or set a Object item*

- returns nil and raise no exception in case of out of range supplied index
- reading this property is not thread-safe, since content may change

**property** OnChange: TNotifyEvent **read** fOnChange **write** fOnChange;

*Event triggered when an entry is modified*

**property** Safe: TSynLocker **read** fSafe;

*Access to the locking methods of this instance*

- use Safe.Lock/TryLock with a try ... finally Safe.Unlock block

**property** Strings[Index: PtrInt]: RawUTF8 **read** Get **write** Put;

*Get or set a RawUTF8 item*

- returns "" and raise no exception in case of out of range supplied index
- if you want to use it with the VCL, use UTF8ToString() function
- reading this property is not thread-safe, since content may change

**property** Text: RawUTF8 **read** GetTextCRLF **write** SetTextCRLF;

*Set or retrieve all items as text lines*

- lines are separated by #13#10 (CRLF) by default; use GetText and SetText methods if you want to use another line delimiter (even a comma)
- this property is thread-safe

**property** TextPtr: PUtf8CharArray **read** GetTextPtr;

*Direct access to the memory of the TRawUTF8DynArray items*

- reading this property is not thread-safe, since content may change

**property** Values[const Name: RawUTF8]: RawUTF8 **read** GetValue **write** SetValue;

*Access to the corresponding 'Name=Value' pairs*

- search on Name is case-insensitive with 'Name=Value' pairs
- reading this property is thread-safe, but won't use the hash table
- consider TSynNameValue if you expect more efficient name/value process

**property** ValuesArray: TDynArrayHashed **read** fValues;

*Direct access to the TRawUTF8DynArray items dynamic array wrapper*

- using this property is not thread-safe, since content may change

**TAlgoCompress = class(TSynPersistent)**

*Abstract low-level parent class for generic compression/decompression algorithms*

- will encapsulate the compression algorithm with crc32c hashing
- all Algo\* abstract methods should be overridden by inherited classes

**constructor** Create; **override**;

*Will register AlgoID in the global list, for Algo() class methods*

- no need to free this instance, since it will be owned by the global list
- raise a ESynException if the class or its AlgoID are already registered
- you should never have to call this constructor, but define a global variable holding a reference to a shared instance

**class function** Algo(Comp: PAnsiChar; CompLen: integer; **out** IsStored: boolean): TAlgoCompress; **overload**;

*Get the TAlgoCompress instance corresponding to the AlgoID stored in the supplied compressed buffer*

- returns nil if no algorithm was identified
- also identifies "stored" content in IsStored variable

**class function** Algo(**const** Comp: RawByteString): TAlgoCompress; **overload**;

*Get the TAlgoCompress instance corresponding to the AlgoID stored in the supplied compressed buffer*

- returns nil if no algorithm was identified

**class function** Algo(Comp: PAnsiChar; CompLen: integer): TAlgoCompress; **overload**;

*Get the TAlgoCompress instance corresponding to the AlgoID stored in the supplied compressed buffer*

- returns nil if no algorithm was identified

**class function** Algo(**const** Comp: TByteDynArray): TAlgoCompress; **overload**;

*Get the TAlgoCompress instance corresponding to the AlgoID stored in the supplied compressed buffer*

- returns nil if no algorithm was identified

**class function** Algo(AlgoID: byte): TAlgoCompress; **overload**;

*Get the TAlgoCompress instance corresponding to the supplied AlgoID*

- returns nil if no algorithm was identified
- stored content is identified as TAlgoSynLZ

**function** AlgoCompress(Plain: pointer; PlainLen: integer; Comp: pointer): integer; **virtual**; **abstract**;

*This method will compress the supplied data*

**function** AlgoCompressDestLen(PlainLen: integer): integer; **virtual**; **abstract**;

*Get maximum possible (worse) compressed size for the supplied length*

**function** AlgoDecompress(Comp: pointer; CompLen: integer; Plain: pointer): integer; **virtual**; **abstract**;

*This method will decompress the supplied data*

**function** AlgoDecompressDestLen(Comp: pointer): integer; **virtual**; **abstract**;

*This method will return the size of the decompressed data*

**function** AlgoDecompressPartial(Comp: pointer; CompLen: integer; Partial: pointer; PartialLen, PartialLenMax: integer): integer; **virtual**; **abstract**;

*This method will partially and safely decompress the supplied data*

- expects PartialLen <= result < PartialLenMax, depending on the algorithm

```
function AlgoHash(Previous: cardinal; Data: pointer; DataLen: integer): cardinal;
virtual;
```

*Computes by default the crc32c() digital signature of the buffer*

```
function AlgoID: byte; virtual; abstract;
```

*Should return a genuine byte identifier*

- 0 is reserved for stored, 1 for TAlgoSynLz, 2/3 for TAlgoDeflate/Fast (in mORMot.pas), 4/5/6 for TAlgoLizard/Fast/Huffman (in SynLizard.pas)

```
function AlgoName: TShort16;
```

*Returns the algorithm name, from its classname*

- e.g. TAlgoSynLz->'synlz' TAlgoLizard->'lizard' nil->'none'

```
function Compress(Plain: PAnsiChar; PlainLen: integer; CompressionSizeTrigger:
integer=100; CheckMagicForCompressed: boolean=false; BufferOffset: integer=0):
RawByteString; overload;
```

*Compress a memory buffer with crc32c hashing to a RawByteString*

```
function Compress(const Plain: RawByteString; CompressionSizeTrigger: integer=100;
CheckMagicForCompressed: boolean=false; BufferOffset: integer=0): RawByteString;
overload;
```

*Compress a memory buffer with crc32c hashing to a RawByteString*

```
function Compress(Plain, Comp: PAnsiChar; PlainLen, CompLen: integer;
CompressionSizeTrigger: integer=100; CheckMagicForCompressed: boolean=false):
integer; overload;
```

*Compress a memory buffer with crc32c hashing*

- supplied Comp buffer should contain at least CompressDestLen(PlainLen) bytes

```
function CompressDestLen(PlainLen: integer): integer;
```

*Get maximum possible (worse) compressed size for the supplied length*

- including the crc32c + algo 9 bytes header

```
function CompressToBytes(Plain: PAnsiChar; PlainLen: integer;
CompressionSizeTrigger: integer=100; CheckMagicForCompressed: boolean=false):
TByteDynArray; overload;
```

*Compress a memory buffer with crc32c hashing to a TByteDynArray*

```
function CompressToBytes(const Plain: RawByteString; CompressionSizeTrigger:
integer=100; CheckMagicForCompressed: boolean=false): TByteDynArray; overload;
```

*Compress a memory buffer with crc32c hashing to a TByteDynArray*

```
function Decompress(const Comp: RawByteString; out PlainLen: integer; var tmp:
RawByteString; Load: TAlgoCompressLoad=aclNormal): pointer; overload;
```

*Uncompress a RawByteString memory buffer with crc32c hashing*

- returns nil if crc32 hash failed, i.e. if the supplied Comp is not correct

- returns a pointer to the uncompressed data and fill PlainLen variable, after crc32c hash

- avoid any memory allocation in case of a stored content - otherwise, would uncompress to the tmp variable, and return pointer(tmp) and length(tmp)

```
function Decompress(const Comp: TByteDynArray): RawByteString; overload;
```

*Uncompress a RawByteString memory buffer with crc32c hashing*

**function** Decompress(const Comp: RawByteString; Load: TAlgoCompressLoad=aclNormal; BufferOffset: integer=0): RawByteString; overload;

*Uncompress a RawByteString memory buffer with crc32c hashing*

**function** Decompress(Comp: PAnsiChar; CompLen: integer; out PlainLen: integer; var tmp: RawByteString; Load: TAlgoCompressLoad=aclNormal): pointer; overload;

*Uncompress a RawByteString memory buffer with crc32c hashing*

- returns nil if crc32 hash failed, i.e. if the supplied Data is not correct
- returns a pointer to an uncompressed data buffer of PlainLen bytes
- avoid any memory allocation in case of a stored content - otherwise, would uncompress to the tmp variable, and return pointer(tmp) and length(tmp)

**function** DecompressBody(Comp, Plain: PAnsiChar; CompLen, PlainLen: integer; Load: TAlgoCompressLoad=aclNormal): boolean;

*Decode the content of a memory buffer compressed via the Compress() method*

- PlainLen has been returned by a previous call to DecompressHeader()

**function** DecompressHeader(Comp: PAnsiChar; CompLen: integer; Load: TAlgoCompressLoad=aclNormal): integer;

*Decode the header of a memory buffer compressed via the Compress() method*

- validates the crc32c of the compressed data (unless Load=aclNoCrcFast), then return the uncompressed size in bytes, or 0 if the crc32c does not match
- should call DecompressBody() later on to actually retrieve the content

**function** DecompressPartial(Comp, Partial: PAnsiChar; CompLen, PartialLen, PartialLenMax: integer): integer;

*Partial decoding of a memory buffer compressed via the Compress() method*

- returns 0 on error, or how many bytes have been written to Partial
- will call virtual AlgoDecompressPartial() which is slower, but expected to avoid any buffer overflow on the Partial destination buffer
- some algorithms (e.g. Lizard) may need some additional bytes in the decode buffer, so PartialLenMax bytes should be allocated in Partial^, with PartialLenMax > expected PartialLen, and returned bytes may be > PartialLen, but always <= PartialLenMax

**function** TryDecompress(const Comp: RawByteString; out Dest: RawByteString; Load: TAlgoCompressLoad=aclNormal): boolean;

*Uncompress a RawByteString memory buffer with crc32c hashing*

- returns TRUE on success

**class function** UncompressedSize(const Comp: RawByteString): integer;

*Quickly validate a compressed buffer content, without uncompression*

- extract the TAlgoCompress, and call DecompressHeader() to check the hash of the compressed data, and return then uncompressed size
- returns 0 on error (e.g. unknown algorithm or incorrect hash)

**procedure** Decompress(Comp: PAnsiChar; CompLen: integer; out Result: RawByteString; Load: TAlgoCompressLoad=aclNormal; BufferOffset: integer=0); overload;

*Uncompress a memory buffer with crc32c hashing*

```
TAlgoSynLZ = class(TAlgoCompress)
```

*Implement our fast SynLZ compression as a TAlgoCompress class*

- please use the AlgoSynLZ global variable methods instead of the deprecated SynLZCompress/SynLZDecompress wrapper functions

```
function AlgoCompress(Plain: pointer; PlainLen: integer; Comp: pointer): integer;
override;
```

*Compress the supplied data using SynLZ*

```
function AlgoCompressDestLen(PlainLen: integer): integer; override;
```

*Get maximum possible (worse) SynLZ compressed size for the supplied length*

```
function AlgoDecompress(Comp: pointer; CompLen: integer; Plain: pointer): integer;
override;
```

*Decompress the supplied data using SynLZ*

```
function AlgoDecompressDestLen(Comp: pointer): integer; override;
```

*Return the size of the SynLZ decompressed data*

```
function AlgoDecompressPartial(Comp: pointer; CompLen: integer; Partial: pointer;
PartialLen, PartialLenMax: integer): integer; override;
```

*Partial (and safe) decompression of the supplied data using SynLZ*

```
function AlgoID: byte; override;
```

*Returns 1 as genuine byte identifier for SynLZ*

```
TAlgoCompressWithNoDestLen = class(TAlgoCompress)
```

*Abstract class storing the plain length before calling compression API*

- some libraries (e.g. Deflate or Lizard) don't provide the uncompressed length from its output buffer - inherit from this class to store this value as ToVarUInt32, and override the RawProcess abstract protected method

```
function AlgoCompress(Plain: pointer; PlainLen: integer; Comp: pointer): integer;
override;
```

*Performs the compression, storing PlainLen and calling protected RawProcess*

```
function AlgoDecompress(Comp: pointer; CompLen: integer; Plain: pointer): integer;
override;
```

*Performs the decompression, retrieving PlainLen and calling protected RawProcess*

```
function AlgoDecompressDestLen(Comp: pointer): integer; override;
```

*Return the size of the decompressed data (using FromVarUInt32)*

```
function AlgoDecompressPartial(Comp: pointer; CompLen: integer; Partial: pointer;
PartialLen, PartialLenMax: integer): integer; override;
```

*Performs the decompression, retrieving PlainLen and calling protected RawProcess*

**TSynDictionary = class(TSynPersistentLock)**

*Thread-safe dictionary to store some values from associated keys*

- will maintain a dynamic array of values, associated with a hash table for the keys, so that setting or retrieving values would be O(1)
- all process is protected by a TSynLocker, so will be thread-safe
- TDynArray is a wrapper which do not store anything, whereas this class is able to store both keys and values, and provide convenient methods to access the stored data, including JSON serialization and binary storage

**constructor** Create(aKeyTypeInfo,aValueTypeInfo: pointer; aKeyCaseInsensitive: boolean=false; aTimeoutSeconds: cardinal=0; aCompressAlgo: TAlgoCompress=nil);  
**reintroduce; virtual;**

*Initialize the dictionary storage, specifying dynamic array keys/values*

- aKeyTypeInfo should be a dynamic array TypeInfo() RTTI pointer, which would store the keys within this TSynDictionary instance
- aValueTypeInfo should be a dynamic array TypeInfo() RTTI pointer, which would store the values within this TSynDictionary instance
- by default, string keys would be searched following exact case, unless aKeyCaseInsensitive is TRUE
- you can set an optional timeout period, in seconds - you should call DeleteDeprecated periodically to search for deprecated items

**destructor** Destroy; **override;**

*Finalize the storage*

- would release all internal stored values

**function** Add(const aKey, aValue): integer;

*Try to add a value associated with a primary key*

- returns the index of the inserted item, -1 if aKey is already existing
- this method is thread-safe, since it will lock the instance

**function** AddInArray(const aKey, aArrayValue): boolean;

*Add aArrayValue item within a dynamic-array value associated via aKey*

- expect the stored value to be a dynamic array itself
- would search for aKey as primary key, then use TDynArray.Add to add aArrayValue to the associated dynamic array
- returns FALSE if Values is not a tkDynArray, or if aKey was not found
- this method is thread-safe, since it will lock the instance

**function** AddOnceInArray(const aKey, aArrayValue): boolean;

*Add once aArrayValue within a dynamic-array value associated via aKey*

- expect the stored value to be a dynamic array itself
- would search for aKey as primary key, then use TDynArray.FindAndAddIfNotExisting to add once aArrayValue to the associated dynamic array
- returns FALSE if Values is not a tkDynArray, or if aKey was not found
- this method is thread-safe, since it will lock the instance

**function** AddOrUpdate(**const** aKey, aValue): integer;

*Store a value associated with a primary key*

- returns the index of the matching item
- if aKey does not exist, a new entry is added
- if aKey does exist, the existing entry is overridden with aValue
- this method is thread-safe, since it will lock the instance

**function** Clear(**const** aKey): integer;

*Clear the value associated via aKey*

- does not delete the entry, but reset its value
- returns the index of the matching item, -1 if aKey was not found
- this method is thread-safe, since it will lock the instance

**function** Count: integer;

*Returns how many items are currently stored in this dictionary*

- this method is thread-safe

**function** Delete(**const** aKey): integer;

*Delete a key/value association from its supplied aKey*

- this would delete the entry, i.e. matching key and value pair
- returns the index of the deleted item, -1 if aKey was not found
- this method is thread-safe, since it will lock the instance

**function** DeleteAt(aIndex: integer): boolean;

*Delete a key/value association from its internal index*

- this method is not thread-safe: you should use fSafe.Lock/Unlock e.g. then Find/FindValue to retrieve the index value

**function** DeleteDeprecated: integer;

*Search and delete all deprecated items according to TimeoutSeconds*

- returns how many items have been deleted
- you can call this method very often: it will ensure that the search process will take place at most once every second
- this method is thread-safe, but blocking during the process

**function** DeleteInArray(**const** aKey, aArrayValue): boolean;

*Clear aArrayValue item of a dynamic-array value associated via aKey*

- expect the stored value to be a dynamic array itself
- would search for aKey as primary key, then use TDynArray.FindAndDelete to delete any aArrayValue match in the associated dynamic array
- returns FALSE if Values is not a tkDynArray, or if aKey or aArrayValue were not found
- this method is thread-safe, since it will lock the instance

**function** Exists(**const** aKey): boolean;

*Search for a primary key presence*

- returns TRUE if aKey was found, FALSE if no match exists
- this method is thread-safe

**function** Find(const aKey; aUpdateTimeOut: boolean=false): integer;

*Search of a primary key within the internal hashed dictionary*

- returns the index of the matching item, -1 if aKey was not found
- if you want to access the value, you should use fSafe.Lock/Unlock: consider using Exists or FindAndCopy thread-safe methods instead
- aUpdateTimeOut will update the associated timeout value of the entry

**function** FindAndCopy(const aKey; out aValue; aUpdateTimeOut: boolean=true): boolean;

*Search of a stored value by its primary key, and return a local copy*

- so this method is thread-safe
- returns TRUE if aKey was found, FALSE if no match exists
- will update the associated timeout value of the entry, unless aUpdateTimeOut is set to false

**function** FindAndExtract(const aKey; out aValue): boolean;

*Search of a stored value by its primary key, then delete and return it*

- returns TRUE if aKey was found, fill aValue with its content, and delete the entry in the internal storage
- so this method is thread-safe
- returns FALSE if no match exists

**function** FindInArray(const aKey, aArrayValue): boolean;

*Search aArrayValue item in a dynamic-array value associated via aKey*

- expect the stored value to be a dynamic array itself
- would search for aKey as primary key, then use TDynArray.Find to delete any aArrayValue match in the associated dynamic array
- returns FALSE if Values is not a tkDynArray, or if aKey or aArrayValue were not found
- this method is thread-safe, since it will lock the instance

**function** FindKeyFromValue(const aValue; out aKey; aUpdateTimeOut: boolean=true): boolean;

*Search of a stored key by its associated key, and return a key local copy*

- won't use any hashed index but TDynArray.IndexOf over fValues, so is much slower than FindAndCopy()
- will update the associated timeout value of the entry, unless aUpdateTimeOut is set to false
- so this method is thread-safe
- returns TRUE if aValue was found, FALSE if no match exists

**function** FindValue(const aKey; aUpdateTimeOut: boolean=false; aIndex: PInteger=nil): pointer;

*Search of a primary key within the internal hashed dictionary*

- returns a pointer to the matching item, nil if aKey was not found
- if you want to access the value, you should use fSafe.Lock/Unlock: consider using Exists or FindAndCopy thread-safe methods instead
- aUpdateTimeOut will update the associated timeout value of the entry

**function** FindValueOrAdd(**const** aKey; **var** added: boolean; aIndex: PInteger=**nil**): pointer;

*Search of a primary key within the internal hashed dictionary*

- returns a pointer to the matching or already existing item
- if you want to access the value, you should use fSafe.Lock/Unlock: consider using Exists or FindAndCopy thread-safe methods instead
- will update the associated timeout value of the entry, if applying

**function** ForEach(**const** OnMatch: TSynDictionaryEvent; KeyCompare, ValueCompare: TDynArraySortCompare; **const** aKey, aValue; Opaque: pointer=**nil**): integer; overload;

*Apply a specified event over matching items stored in this dictionary*

- would browse the list in the adding order, comparing each key and/or value item with the supplied comparison functions and aKey/aValue content
- returns the number of times OnMatch has been called, i.e. how many times KeyCompare(aKey, Keys[#])=0 or ValueCompare(aValue, Values[#])=0
- this method is thread-safe, since it will lock the instance

**function** ForEach(**const** OnEach: TSynDictionaryEvent; Opaque: pointer=**nil**): integer; overload;

*Apply a specified event over all items stored in this dictionary*

- would browse the list in the adding order
- returns the number of times OnEach has been called
- this method is thread-safe, since it will lock the instance

**function** LoadFromBinary(**const** binary: RawByteString): boolean;

- Load the content from SynLZ-compressed raw binary data*
- as previously saved by SaveToBinary method

**function** LoadFromJSON(JSON: PUTF8Char ; CustomVariantOptions: PDocVariantOptions=**nil**): boolean; overload;

*Unserialize the content from "key":value JSON object*

- note that input JSON buffer is not modified in place: no need to create a temporary copy if the buffer is about to be re-used

**function** LoadFromJSON(**const** JSON: RawUTF8 ; CustomVariantOptions: PDocVariantOptions=**nil**): boolean; overload;

*Unserialize the content from "key":value JSON object*

- if the JSON input may not be correct (i.e. if not coming from SaveToJSON), you may set EnsureNoKeyCollision=TRUE for a slow but safe keys validation

**class function** OnCanDeleteSynPersistentLock(**const** aKey, aValue; aIndex: integer): boolean;

*Can be assigned to OnCanDeleteDeprecated to check TSynPersistentLock(aValue).Safe.IsLocked*

**class function** OnCanDeleteSynPersistentLocked(**const** aKey, aValue; aIndex: integer): boolean;

*Can be assigned to OnCanDeleteDeprecated to check TSynPersistentLock(aValue).Safe.IsLocked*

**function** RawCount: integer;

*Fast returns how many items are currently stored in this dictionary*

- this method is NOT thread-safe so should be protected by fSafe.Lock/UnLock

**function** SaveToBinary(NoCompression: boolean=false): RawByteString;

*Save the content as SynLZ-compressed raw binary data*

- warning: this format is tied to the values low-level RTTI, so if you change the value/key type definitions, LoadFromBinary() would fail

**function** SaveToJSON(EnumSetsAsText: boolean=false): RawUTF8; overload;

*Serialize the content as a "key":value JSON object*

**function** SaveValuesToJSON(EnumSetsAsText: boolean=false): RawUTF8;

*Serialize the Values[] as a JSON array*

**function** UpdateInArray(const aKey, aArrayValue): boolean;

*Replace aArrayValue item of a dynamic-array value associated via aKey*

- expect the stored value to be a dynamic array itself  
- would search for aKey as primary key, then use TDynArray.FindAndUpdate to delete any aArrayValue match in the associated dynamic array  
- returns FALSE if Values is not a tkDynArray, or if aKey or aArrayValue were not found  
- this method is thread-safe, since it will lock the instance

**procedure** CopyValues(out Dest; ObjArrayByRef: boolean=false);

*Make a copy of the stored values*

- this method is thread-safe, since it will lock the instance during copy  
- resulting length(Dest) will match the exact values count  
- T\*ObjArray will be reallocated and copied by content (using a temporary JSON serialization), unless ObjArrayByRef is true and pointers are copied

**procedure** DeleteAll;

*Delete all key/value stored in the current instance*

**procedure** SaveToJSON(W: TTextWriter; EnumSetsAsText: boolean=false); overload;

*Serialize the content as a "key":value JSON object*

**procedure** SetTimeoutAtIndex(aIndex: integer);

*Touch the entry timeout field so that it won't be deprecated sooner*

- this method is not thread-safe, and is expected to be execute e.g. from a ForEach()  
TSynDictionaryEvent callback

**property** Capacity: integer read GetCapacity write SetCapacity;

*Defines how many items are currently stored in Keys/Values internal arrays*

**property** CompressAlgo: TAlgoCompress read fCompressAlgo write fCompressAlgo;

*The compression algorithm used for binary serialization*

**property** Keys: TDynArrayHashed read fKeys;

*Direct access to the primary key identifiers*

- if you want to access the keys, you should use fSafe.Lock/Unlock

**property** OnCanDeleteDeprecated: TSynDictionaryCanDeleteEvent read fOnCanDelete  
write fOnCanDelete;

*Callback to by-pass DeleteDeprecated deletion by returning false*

- can be assigned e.g. to OnCanDeleteSynPersistentLock if Value is a TSynPersistentLock instance, to avoid any potential access violation

**property** Timeout: TCardinalDynArray **read** fTimeout;

*Direct low-level access to the internal access tick (GetTickCount64 shr 10)*  
- may be nil if TimeoutSeconds=0

**property** TimeoutSeconds: cardinal **read** GetTimeoutSeconds;

*Returns the aTimeoutSeconds parameter value, as specified to Create()*

**property** Values: TDynArray **read** fValues;

*Direct access to the associated stored values*  
- if you want to access the values, you should use fSafe.Lock/Unlock

**TMemoryMap = object(TObject)**

*Handle memory mapping of a file content*

**function** Map(const aFileName: TFileName): boolean; overload;

*Map the file specified by its name*  
- file will be closed when UnMap will be called

**function** Map(aFile: THandle; aCustomSize: PtrUInt=0; aCustomOffset: Int64=0): boolean; overload;

*Map the corresponding file handle*  
- if aCustomSize and aCustomOffset are specified, the corresponding map view is created (by default, will map whole file)

**procedure** Map(aBuffer: pointer; aBufferSize: PtrUInt); overload;

*Set a fixed buffer for the content*  
- emulated a memory-mapping from an existing buffer

**procedure** UnMap;

*Unmap the file*

**property** Buffer: PAnsiChar **read** fBuf;

*Retrieve the memory buffer mapped to the file content*

**property** FileHandle: THandle **read** fFile;

*Access to the low-level associated File handle (if any)*

**property** FileSize: Int64 **read** fFileSize;

*Retrieve the mapped file size*

**property** Size: PtrUInt **read** fBufSize;

*Retrieve the buffer size*

**TMemoryMapText = class(TObject)**

*Able to read a UTF-8 text file using memory map*  
- much faster than TStringList.LoadFromFile()  
- will ignore any trailing UTF-8 BOM in the file content, but will not expect one either

**constructor** Create(aFileContent: PUTF8Char; aFileSize: integer); overload;

*Read an UTF-8 encoded text file content*

- every line beginning is stored into LinePointers[]
- this overloaded constructor accept an existing memory buffer (some uncompressed data e.g.)

**constructor** Create(const aFileName: TFileName); overload;

*Read an UTF-8 encoded text file*

- every line beginning is stored into LinePointers[]

**constructor** Create; overload; **virtual**;

*Initialize the memory mapped text file*

- this default implementation just do nothing but is called by overloaded constructors so may be overridden to initialize an inherited class

**destructor** Destroy; **override**;

*Release the memory map and internal LinePointers[]*

**function** LineContains(const aUpperSearch: RawUTF8; aIndex: Integer): Boolean;  
**virtual**;

*Returns TRUE if the supplied text is contained in the corresponding line*

**function** LineSize(aIndex: integer): integer;

*Retrieve the number of UTF-8 chars of the given line*

- warning: no range check is performed about supplied index

**function** LineSizeSmallerThan(aIndex, aMinimalCount: integer): boolean;

*Check if there is at least a given number of UTF-8 chars in the given line*

- this is faster than LineSize(aIndex)<aMinimalCount for big lines

**procedure** AddInMemoryLine(const aNewLine: RawUTF8); **virtual**;

*Add a new line to the already parsed content*

- this line won't be stored in the memory mapped file, but stay in memory and appended to the existing lines, until this instance is released

**procedure** AddInMemoryLinesClear; **virtual**;

*Clear all in-memory appended rows*

**procedure** SaveToFile(FileName: TFileName; const Header: RawUTF8='');

*Save the whole content into a specified file*

- including any runtime appended values via AddInMemoryLine()
- an optional header text can be added to the beginning of the file

**procedure** SaveToStream(Dest: TStream; const Header: RawUTF8);

*Save the whole content into a specified stream*

- including any runtime appended values via AddInMemoryLine()

**property** Count: integer **read** fCount;

*The number of text lines*

**property** FileName: TFileName **read** fFileName **write** fFileName;

*The file name which was opened by this instance*

**property** LinePointers: PPointerArray read fLines;

*Direct access to each text line*

- use LineSize() method to retrieve line length, since end of line will NOT end with #0, but with #13 or #10
- warning: no range check is performed about supplied index

**property** Lines[aIndex: integer]: RawUTF8 read GetLine;

*Retrieve a line content as UTF-8*

- a temporary UTF-8 string is created
- will return "" if aIndex is out of range

**property** Map: TMemoryMap read fMap;

*The memory map used to access the raw file content*

**property** Strings[aIndex: integer]: string read GetString;

*Retrieve a line content as generic VCL string type*

- a temporary VCL string is created (after conversion for UNICODE Delphi)
- will return "" if aIndex is out of range

TFakeWriterStream = **class**(TStream)

*A fake TStream, which will just count the number of bytes written*

TRawByteStringStream = **class**(TStream)

*A TStream using a RawByteString as internal storage*

- default TStringStream uses WideChars since Delphi 2009, so it is not compatible with previous versions, and it does make sense to work with RawByteString in our UTF-8 oriented framework
- just like TStringStream, is designed for appending data, not modifying in-place, as requested e.g. by TTextWriter or TFileBufferWriter classes

**constructor** Create(const aString: RawByteString=''); overload;

*Initialize the storage, optionally with some RawByteString content*

**function** Read(var Buffer; Count: Longint): Longint; **override**;

*Read some bytes from the internal storage*

- returns the number of bytes filled into Buffer (<=Count)

**function** Seek(Offset: Longint; Origin: Word): Longint; **override**;

*Change the current Read/Write position, within current stored range*

**function** Write(const Buffer; Count: Longint): Longint; **override**;

*Append some data to the buffer*

- will resize the buffer, i.e. will replace the end of the string from the current position with the supplied data

**property** DataString: RawByteString read fDataString write fDataString;

*Direct low-level access to the internal RawByteString storage*

**TSynMemoryStream = class(TCustomMemoryStream)**

*A TStream pointing to some in-memory data, for instance UTF-8 text*

- warning: there is no local copy of the supplied content: the source data must be available during all the TSynMemoryStream usage

**constructor** Create(Data: pointer; DataLen: PtrInt); overload;

*Create a TStream with the supplied data buffer*

- warning: there is no local copy of the supplied content: the Data/DataLen buffer must be available during all the TSynMemoryStream usage: don't release the source Data before calling TSynMemoryStream.Free

**constructor** Create(const aText: RawByteString); overload;

*Create a TStream with the supplied text data*

- warning: there is no local copy of the supplied content: the aText variable must be available during all the TSynMemoryStream usage: don't release aText before calling TSynMemoryStream.Free

- aText can be on any AnsiString format, e.g. RawUTF8 or RawByteString

**function** Write(const Buffer; Count: Longint): Longint; **override;**

*This TStream is read-only: calling this method will raise an exception*

**TSynMemoryStreamMapped = class(TSynMemoryStream)**

*A TStream created from a file content, using fast memory mapping*

**constructor** Create(aFile: THandle; aCustomSize: PtrUInt=0; aCustomOffset: Int64=0); overload;

*Create a TStream from a file content using fast memory mapping*

- if aCustomSize and aCustomOffset are specified, the corresponding map view is created (by default, will map whole file)

**constructor** Create(const aFileName: TFileName; aCustomSize: PtrUInt=0; aCustomOffset: Int64=0); overload;

*Create a TStream from a file content using fast memory mapping*

- if aCustomSize and aCustomOffset are specified, the corresponding map view is created (by default, will map whole file)

**destructor** Destroy; **override;**

*Release any internal mapped file instance*

**property** FileName: TFileName **read** fFileName;

*The file name, if created from such Create(aFileName) constructor*

**TValuePUTF8Char = object(TObject)**

*Points to one value of raw UTF-8 content, decoded from a JSON buffer*

- used e.g. by JSONDecode() overloaded function to return names/values

**Value:** PUTF8Char;

*A pointer to the actual UTF-8 text*

**ValueLen: PtrInt;**

*How many UTF-8 bytes are stored in Value*

**function** Idem(**const** Text: RawUTF8): boolean;

*Will call IdemPropNameU() over the stored text Value*

**function** ToCardinal: PtrUInt;

*Convert the value into an unsigned integer*

**function** ToInteger: PtrInt;

*Convert the value into a signed integer*

**function** ToString: string;

*Convert the value into a VCL/generic string*

**function** ToUTF8: RawUTF8; overload;

*Convert the value into a UTF-8 string*

**procedure** ToUTF8(**var** Text: RawUTF8); overload;

*Convert the value into a UTF-8 string*

**TNameValuePUTF8Char = record**

*Store one name/value pair of raw UTF-8 content, from a JSON buffer*

*- used e.g. by JSONDecode() overloaded function or UrlEncodeJsonObject() to returns names/values*

**Name: PUTF8Char;**

*A pointer to the actual UTF-8 name text*

**NameLen: integer;**

*How many UTF-8 bytes are stored in Name (should be integer, not PtrInt)*

**Value: PUTF8Char;**

*A pointer to the actual UTF-8 value text*

**ValueLen: integer;**

*How many UTF-8 bytes are stored in Value*

**TSynLogExceptionContext = record**

*Calling context of TSynLogExceptionToStr callbacks*

**EAddr: PtrUInt;**

*The address where the exception occurred*

**EClass: ExceptClass;**

*The raised exception class*

**ECode: DWord;**

*The OS-level exception code*

*- could be \$0EEDFAE0 of \$0EEDFADE for Delphi-generated exceptions*

**EInstance:** Exception;

*The Delphi Exception instance*

- may be nil for external/OS exceptions

**ELevel:** TSynLogInfo;

*The logging level corresponding to this exception*

- may be either sllException or sllExceptionOS

**EStack:** PPtrUInt;

*The optional stack trace*

**EStackCount:** integer;

= FPC's RaiseProc() FrameCount if EStack is Frame: PCodePointer

**ETimestamp:** TUnixTime;

*The timestamp of this exception, as number of seconds since UNIX Epoch*

- UnixTimeUTC is faster than NowUTC or GetSystemTime

- use UnixTimeToDateTime() to convert it into a regular TDateTime

**ESynException = class(Exception)**

*Generic parent class of all custom Exception types of this unit*

- all our classes inheriting from ESynException are serializable, so you could use

ObjectToJSONDebug(anyESynException) to retrieve some extended information

**constructor** CreateLastOSError(const Format: RawUTF8; const Args: array of const; const Trailer: RawUtf8 = 'OSError');

*Constructor appending some FormatUTF8() content to the GetLastError*

- message will contain GetLastError value followed by the formatted text

- expect % as delimiter, so is less error prone than %s %d %g

- will handle vtPointer/vtClass/vtObject/vtVariant kind of arguments, appending class name for any class or object, the hexa value for a pointer, or the JSON representation of any supplied TDocVariant

**constructor** CreateUTF8(const Format: RawUTF8; const Args: array of const);

*Constructor which will use FormatUTF8() instead of Format()*

- expect % as delimiter, so is less error prone than %s %d %g

- will handle vtPointer/vtClass/vtObject/vtVariant kind of arguments, appending class name for any class or object, the hexa value for a pointer, or the JSON representation of any supplied TDocVariant

**function** CustomLog(WR: TTextWriter; const Context: TSynLogExceptionContext): boolean; **virtual**;

*Can be used to customize how the exception is logged*

- this default implementation will call the DefaultSynLogExceptionToStr() function or the TSynLogExceptionToStrCustom global callback, if defined

- override this method to provide a custom logging content

- should return TRUE if Context.EAddr and Stack trace is not to be written (i.e. as for any TSynLogExceptionToStr callback)

**property** RaisedAt: pointer read fRaisedAt write fRaisedAt;

*The code location when this exception was triggered*

- populated by SynLog unit, during interception - so may be nil
- you can use TSynMapFile.FindLocation(ESynException) class function to guess the corresponding source code line
- will be serialized as "Address": hexadecimal and source code location (using TSynMapFile.map/.mab information) in TJSONSerializer.WriteObject when woStorePointer option is defined - e.g. with ObjectToJSONDebug()

**EDocVariant** = **class**(ESynException)

*Exception class associated to TDocVariant JSON/BSON document*

**EFastReader** = **class**(ESynException)

*Exception raised during TFastReader decoding*

**TDWordRec** = **record**

*Binary access to an unsigned 32-bit value (4 bytes in memory)*

**TQWordRec** = **record**

*Binary access to an unsigned 64-bit value (8 bytes in memory)*

**THash128Rec** = **packed record**

*Map a 128-bit hash as an array of lower bit size values*

- consumes 16 bytes of memory

**THash256Rec** = **packed record**

*Map a 256-bit hash as an array of lower bit size values*

- consumes 32 bytes of memory

**THash512Rec** = **packed record**

*Map a 512-bit hash as an array of lower bit size values*

- consumes 64 bytes of memory

**TSynDate** = **object**(TObject)

*A simple way to store a date as Year/Month/Day*

- with no needed computation as with TDate/TUnixTime values
- consider using TSynSystemTime if you need to handle both Date and Time
- match the first 4 fields of TSynSystemTime - so PSynDate(@aSynSystemTime)^ is safe to be used
- DayOfWeek field is not handled by its methods by default, but could be filled on demand via ComputeDayOfWeek - making this record 64-bit long
- some Delphi revisions have trouble with "object" as own method parameters (e.g. IsEqual) so we force to use "record" type if possible

**function** Compare(const another: TSynDate): integer;

*Compare the stored value to a supplied value*

- returns <0 if the stored value is smaller than the supplied value, 0 if both are equals, and >0 if the stored value is bigger
- DayOfWeek field value is not compared

**function** IsEqual(const another: TSynDate): boolean;

*Returns true if all fields do match - ignoring DayOfWeek field value*

**function** IsZero: boolean;

*Returns true if all fields are zero*

**function** ParseFromText(**var** P: PUTF8Char): boolean;

*Try to parse a YYYY-MM-DD or YYYYMMDD ISO-8601 date from the supplied buffer*  
 - on success, move P^ just after the date, and return TRUE

**function** ToDate: TDate;

*Convert the stored date into a Delphi TDate floating-point value*

**function** ToText(Expanded: boolean=true): RawUTF8;

*Encode the stored date as ISO-8601 text*  
 - returns "" if the stored date is 0 (i.e. after Clear)

**procedure** Clear;

*Set all fields to 0*

**procedure** ComputeDayOfWeek;

*Fill the DayOfWeek field from the stored Year/Month/Day*  
 - by default, most methods will just store 0 in the DayOfWeek field  
 - sunday is DayOfWeek 1, saturday is 7

**procedure** FromDate(date: TDate);

*Fill fields with the supplied date*

**procedure** FromNow(localtime: boolean=false);

*Fill fields with the current UTC/local date, using a 8-16ms thread-safe cache*

**procedure** SetMax;

*Set internal date to 9999-12-31*

**TSynSystemTime = object(TObject)**

*A cross-platform and cross-compiler TSystemTime 128-bit structure*

- FPC's TSystemTime in datih.inc does NOT match Windows TSystemTime fields!  
 - also used to store a Date/Time in TSynTimeZone internal structures, or for fast conversion from TDateTime to its ready-to-display members  
 - DayOfWeek field is not handled by most methods by default (left as 0), but could be filled on demand via ComputeDayOfWeek into its 1..7 value  
 - some Delphi revisions have trouble with "object" as own method parameters (e.g. IsEqual) so we force to use "record" type if possible

**function** EncodeForTimeChange(**const** aYear: word): TDateTime;

*Used by TSynTimeZone*

**function** FromText(**const** iso: RawUTF8): boolean;

*Fill Year/Month/Day and Hour/Minute/Second fields from the given ISO-8601 text*  
 - returns true on success

**function** IsDateEqual(**const** date: TSynDate): boolean;

*Returns true if date fields do match (ignoring DayOfWeek)*

**function** IsEqual(**const** another: TSynSystemTime): boolean;

*Returns true if all fields do match*

**function** IsZero: boolean;

*Returns true if all fields are zero*

**function** ToDateTime: TDateTime;

*Convert the stored time into a TDateTime*

**function** ToNCSAText(P: PUTF8Char): PtrInt;

*Append the stored date and time, in apache-like format, to a memory buffer*

- e.g. append '19/Feb/2019:06:18:55 ' - including a trailing space
- returns the number of chars added to P, i.e. always 21

**function** ToText(Expanded: boolean=true; FirstTimeChar: AnsiChar='T'; **const** TZD: RawUTF8=''): RawUTF8;

*Encode the stored date/time as ISO-8601 text with Milliseconds*

**procedure** AddLogTime(WR: TTextWriter);

*Append the stored date and time, in a log-friendly format*

- e.g. append '20110325 19241502' - with no trailing space nor tab
- as called by TTextWriter.AddCurrentLogTime()

**procedure** AddNCSAText(WR: TTextWriter);

*Append the stored date and time, in apache-like format, to a TTextWriter*

- e.g. append '19/Feb/2019:06:18:55 ' - including a trailing space

**procedure** Clear;

*Set all fields to 0*

**procedure** ComputeDayOfWeek;

*Fill the DayOfWeek field from the stored Year/Month/Day*

- by default, most methods will just store 0 in the DayOfWeek field
- sunday is DayOfWeek 1, saturday is 7

**procedure** FromDate(**const** dt: TDateTime);

*Fill Year/Month/Day fields from the given value - but not DayOfWeek*

- faster than the RTL DecodeDate() function

**procedure** FromDateTime(**const** dt: TDateTime);

*Fill fields from the given value - but not DayOfWeek*

**procedure** FromMS(ms: PtrUInt);

*Fill Hour/Minute/Second/Millisecond fields from the given number of milliseconds*

- faster than the RTL DecodeTime() function

**procedure** FromNowLocal;

*Fill fields with the current Local time, using a 8-16ms thread-safe cache*

**procedure** FromNowUTC;

*Fill fields with the current UTC time, using a 8-16ms thread-safe cache*

**procedure** FromSec(s: PtrUInt);

*Fill Hour/Minute/Second/Millisecond fields from the given number of seconds*

- faster than the RTL DecodeTime() function

**procedure** FromTime(**const** dt: TDateTime);

*Fill Hour/Minute/Second/Millisecond fields from the given TDateTime value*  
- faster than the RTL DecodeTime() function

**procedure** IncrementMS(ms: integer);

*Add some 1..999 milliseconds to the stored time*  
- not to be used for computation, but e.g. for fast AddLogTime generation

**procedure** ToHTTPDate(**out** text: RawUTF8; **const** tz: RawUTF8='GMT');

*Convert the stored date and time to its text in HTTP-like format*  
- i.e. "Tue, 15 Nov 1994 12:45:26 GMT" to be used as a value of "Date", "Expires" or "Last-Modified" HTTP header  
- handle UTC/GMT time zone by default

**procedure** ToIsoDate(**out** text: RawUTF8);

*Convert the stored date into its Iso-8601 text with no time part*

**procedure** ToIsoDateTime(**out** text: RawUTF8; **const** FirstTimeChar: AnsiChar='T');

*Convert the stored date and time into its Iso-8601 text, with no Milliseconds*

**procedure** ToIsoTime(**out** text: RawUTF8; **const** FirstTimeChar: RawUTF8='T');

*Convert the stored time into its Iso-8601 text with no date part nor Milliseconds*

**procedure** ToSynDate(**out** date: TSynDate);

*Copy Year/Month/DayOfWeek/Day fields to a TSynDate*

**TTimeLogBits = object(TObject)**

*Internal memory structure for direct access to a TTimeLog type value*  
- most of the time, you should not use this object, but higher level  
TimeLogFromDate/TimeLogToDate/TimeLogNow/Iso8601ToTimeLog functions  
- since TTimeLogBits.Value is bit-oriented, you can't just add or subtract two TTimeLog values  
when doing date/time computation: use a TDateTime temporary conversion in such case  
- TTimeLogBits.Value needs up to 40-bit precision, so features exact representation as JavaScript  
numbers (stored in a 52-bit mantissa)

**Value: Int64;**

*The bit-encoded value itself, which follows an abstract "year" of 16 months of 32 days of 32  
hours of 64 minutes of 64 seconds*  
- bits 0..5 = Seconds (0..59)  
- bits 6..11 = Minutes (0..59)  
- bits 12..16 = Hours (0..23)  
- bits 17..21 = Day-1 (0..31)  
- bits 22..25 = Month-1 (0..11)  
- bits 26..40 = Year (0..9999)

**function** Day: Integer;

*Get the day (1..31) of the TTimeLog value*

**function** FullText(Expanded: boolean; FirstTimeChar: AnsiChar = 'T'; QuotedChar: AnsiChar = #0): RawUTF8; overload;

*Convert to Iso-8601 encoded text with date and time part*  
- never truncate to date/time nor return "" as Text() does

**function** FullText(Dest: PUTF8Char; Expanded: boolean; FirstTimeChar: AnsiChar = 'T'; QuotedChar: AnsiChar = #0): PUTF8Char; overload;

*URW1111 on Delphi 2010 and URW1136 on XE convert to Iso-8601 encoded text with date and time part*

- never truncate to date/time or return '' as Text() does

**function** Hour: integer;

*Get the hour (0..23) of the TTimeLog value*

**function** i18nText: string;

*Convert to ready-to-be displayed text*

- using i18nDateText global event, if set (e.g. by mORMoti18n.pas)

**function** Minute: integer;

*Get the minute (0..59) of the TTimeLog value*

**function** Month: Integer;

*Get the month (1..12) of the TTimeLog value*

**function** Second: integer;

*Get the second (0..59) of the TTimeLog value*

**function** Text(Dest: PUTF8Char; Expanded: boolean; FirstTimeChar: AnsiChar = 'T'): integer; overload;

*Convert to Iso-8601 encoded text, truncated to date/time only if needed*

**function** Text(Expanded: boolean; FirstTimeChar: AnsiChar = 'T'): RawUTF8; overload;

*Convert to Iso-8601 encoded text, truncated to date/time only if needed*

**function** ToDate: TDateTime;

*Convert to a Delphi Date*

- will return 0 if the stored value is not a valid date

**function** ToDateTime: TDateTime;

*Convert to a Delphi Date and Time*

- will return 0 if the stored value is not a valid date

**function** ToTime: TDateTime;

*Convert to a Delphi Time*

**function** ToUnixMSTime: TUnixMSTime;

*Convert to a millisecond-based c-encoded time (from Unix epoch 1/1/1970)*

- of course, milliseconds will be 0 due to TTimeLog second resolution

**function** ToUnixTime: TUnixTime;

*Convert to a second-based c-encoded time (from Unix epoch 1/1/1970)*

**function** Year: Integer;

*Get the year (e.g. 2015) of the TTimeLog value*

**procedure** Expand(out Date: TSynSystemTime);

*Extract the date and time content in Value into individual values*

**procedure** From(P: PUTF8Char; L: integer); overload;

*Fill Value from Iso-8601 encoded text*

**procedure** From(const S: RawUTF8); overload;

*Fill Value from Iso-8601 encoded text*

**procedure** From(FileDate: integer); overload;

*Fill Value from specified File Date*

**procedure** From(Y,M,D, HH,MM,SS: cardinal); overload;

*Fill Value from specified Date and Time*

**procedure** From(DateTime: TDateTime; DateOnly: Boolean=false); overload;

*Fill Value from specified TDateTime*

**procedure** From(Time: PSynSystemTime); overload;

*Fill Value from specified Date/Time individual fields*

**procedure** FromNow;

*Fill Value from current local system Date and Time*

**procedure** FromUnixMSTime(const UnixMSTime: TUnixMSTime);

*Fill Value from millisecond-based c-encoded time (from Unix epoch 1/1/1970)*

- of course, millisecond resolution will be lost during conversion

**procedure** FromUnixTime(const UnixTime: TUnixTime);

*Fill Value from second-based c-encoded time (from Unix epoch 1/1/1970)*

**procedure** FromUTCTime;

*Fill Value from current UTC system Date and Time*

- FromNow uses local time: this function retrieves the system time expressed in Coordinated Universal Time (UTC)

**TFileVersion = class(TObject)**

*To have existing RTTI for published properties used to retrieve version information from any EXE*

- under Linux, all version numbers are set to 0 by default

- you should not have to use this class directly, but via the ExeVersion global variable

**Build: Integer;**

*Executable release build number*

**BuildYear: word;**

*Build year of this exe file*

**Comments: RawUTF8;**

*Associated Comments string version resource*

- only available on Windows - contains " under Linux/POSIX

**CompanyName: RawUTF8;**

*Associated CompanyName string version resource*

- only available on Windows - contains " under Linux/POSIX

**FileDescription: RawUTF8;**

*Associated FileDescription string version resource*

- only available on Windows - contains " under Linux/POSIX

**FileVersion:** RawUTF8;

*Associated FileVersion string version resource*

- only available on Windows - contains "" under Linux/POSIX

**InternalName:** RawUTF8;

*Associated InternalName string version resource*

- only available on Windows - contains "" under Linux/POSIX

**LegalCopyright:** RawUTF8;

*Associated LegalCopyright string version resource*

- only available on Windows - contains "" under Linux/POSIX

**Main:** string;

*Version info of the exe file as '3.1'*

- return "string" type, i.e. UnicodeString for Delphi 2009+

**Major:** Integer;

*Executable major version number*

**Minor:** Integer;

*Executable minor version number*

**OriginalFilename:** RawUTF8;

*Associated OriginalFileName string version resource*

- only available on Windows - contains "" under Linux/POSIX

**ProductName:** RawUTF8;

*Associated ProductName string version resource*

- only available on Windows - contains "" under Linux/POSIX

**ProductVersion:** RawUTF8;

*Associated ProductVersion string version resource*

- only available on Windows - contains "" under Linux/POSIX

**Release:** Integer;

*Executable release version number*

**constructor** Create(const aFileName: TFileName; aMajor: integer=0; aMinor: integer=0; aRelease: integer=0; aBuild: integer=0);

*Retrieve application version from exe file name*

- DefaultVersion32 is used if no information Version was included into the executable resources (on compilation time)

- you should not have to use this constructor, but rather access the ExeVersion global variable

**function** BuildDateTimeString: string;

*Build date and time of this exe file, as plain text*

**function** DetailedOrVoid: string;

*Version info of the exe file as '3.1.0.123' or ""*

- this method returns "" if Detailed is '0.0.0.0'

**class function** GetVersionInfo(**const** aFileName: TFileName): RawUTF8;

*Returns the version information of a specified exe file as text*  
 - includes FileName (without path), Detailed and BuildDateTime properties  
 - e.g. 'myprogram.exe 3.1.0.123 2016-06-14 19:07:55'

**function** UserAgent: RawUTF8;

*Returns a ready-to-use User-Agent header with exe name, version and OS*  
 - e.g. 'myprogram/3.1.0.123W32' for myprogram running on Win32  
 - here OS\_INITIAL[] character is used to identify the OS, with '32' appended on Win32 only (e.g. 'myprogram/3.1.0.2W', is for Win64)

**function** Version32: integer;

*Retrieve the version as a 32-bit integer with Major.Minor.Release*  
 - following Major shl 16+Minor shl 8+Release bit pattern

**function** VersionInfo: RawUTF8;

*Returns the version information of this exe file as text*  
 - includes FileName (without path), Detailed and BuildDateTime properties  
 - e.g. 'myprogram.exe 3.1.0.123 (2016-06-14 19:07:55)'

**property** BuildDateTime: TDateTime **read** fBuildDateTime **write** fBuildDateTime;

*Build date and time of this exe file*

**property** Detailed: string **read** fDetailed **write** fDetailed;

*Version info of the exe file as '3.1.0.123'*  
 - return "string" type, i.e. UnicodeString for Delphi 2009+  
 - under Linux, always return '0.0.0.0' if no custom version number has been defined  
 - consider using DetailedOrVoid method if '0.0.0.0' is not expected

**TOperatingSystemVersion = packed record**

*The running Operating System, encoded as a 32-bit integer*

**TOSVersionInfoEx = record**

*Low-level API structure, not defined in older Delphi versions*

**TwinRegistry = object(TObject)**

*Direct access to the Windows Registry*  
 - could be used as alternative to TRegistry, which doesn't behave the same on all Delphi versions, and is enhanced on FPC (e.g. which supports REG\_MULTI\_SZ)  
 - is also Unicode ready for text, using UTF-8 conversion on all compilers

**key: HKEY;**

*The opened HKEY handle*

**function** ReadData(**const** entry: SynUnicode): RawByteString;

*Low-level read a Windows Registry content after ReadOpen()*  
 - works with any kind of key, but was designed for REG\_BINARY

**function** ReadDword(**const** entry: SynUnicode): cardinal;

*Low-level read a Windows Registry 32-bit REG\_DWORD value after ReadOpen()*

**function** ReadEnumEntries: TRawUTF8DynArray;

*Low-level enumeration of all sub-entries names of a Windows Registry key*

**function** ReadOpen(root: HKEY; **const** keyname: RawUTF8; closefirst: boolean=false): boolean;

*Start low-level read access to a Windows Registry node*  
 - on success (returned true), ReadClose() should be called

**function** ReadQword(**const** entry: SynUnicode): QWord;

*Low-level read a Windows Registry 64-bit REG\_QWORD value after ReadOpen()*

**function** ReadString(**const** entry: SynUnicode; andtrim: boolean=true): RawUTF8;

*Low-level read a string from the Windows Registry after ReadOpen()*  
 - in respect to Delphi's TRegistry, will properly handle REG\_MULTI\_SZ (return the first value of the multi-list)

**procedure** Close;

*Finalize low-level read access to the Windows Registry after ReadOpen()*

**TExeVersion = record**

*Stores some global information about the current executable and computer*

Hash: THash128Rec;

*Some hash representation of this information*  
 - the very same executable on the very same computer run by the very same user will always have the same Hash value  
 - is computed from the crc32c of this TExeVersion fields: c0 from Version32, CpuFeatures and Host, c1 from User, c2 from ProgramFullSpec and c3 from InstanceFileName  
 - may be used as an entropy seed, or to identify a process execution

Host: RawUTF8;

*The current computer host name*

InstanceFileName: TFileName;

*The full path of the running executable or library*  
 - for an executable, same as paramstr(0)  
 - for a library, will contain the whole .dll file name

ProgramFileName: TFileName;

*The main executable file name (including full path)*  
 - same as paramstr(0)

ProgramFilePath: TFileName;

*The main executable full path (excluding .exe file name)*  
 - same as ExtractFilePath(paramstr(0))

ProgramFullSpec: RawUTF8;

*The main executable details, as used e.g. by TSynLog*  
 - e.g. 'C:\Dev\lib\SQLite3\exe\TestSQL3.exe 1.2.3.123 (2011-03-29 11:09:06)'

ProgramName: RawUTF8;

*The main executable name, without any path nor extension*  
 - e.g. 'Test' for 'c:\pathto\Test.exe'

**User: RawUTF8;**

*The current computer user name*

**Version: TFileVersion;**

*The current executable version*

**THeapMemoryStream = class(TMemoryStream)**

*To be used instead of TMemoryStream, for speed*

- allocates memory from Delphi heap (i.e. FastMM4/SynScaleMM) and not GlobalAlloc(), as was the case for oldest versions of Delphi
- uses bigger growing size of the capacity
- consider using TRawByteStringStream, as we do in our units old Delphi used GlobalAlloc()

**TSynInvokeableVariantType = class(TInvokeableVariantType)**

*Custom variant handler with easier/faster access of variant properties, and JSON serialization support*

- default GetProperty/SetProperty methods are called via some protected virtual IntGet/IntSet methods, with less overhead (to be overridden)
- these kind of custom variants will be faster than the default TInvokeableVariantType for properties getter/setter, but you should manually register each type by calling SynRegisterCustomVariantType()
- also feature custom JSON parsing, via TryJSONToVariant() protected method

**function FindSynVariantType(aVarType: Word; out CustomType: TSynInvokeableVariantType): boolean;**

*Search of a registered custom variant type from its low-level VarType*  
- will first compare with its own VarType for efficiency

**function GetProperty(var Dest: TVarData; const V: TVarData; const Name: String): Boolean; override;**

*Retrieve the field/column value*  
- this method will call protected IntGet abstract method

**function IsOfType(const V: variant): boolean;**

*Returns TRUE if the supplied variant is of the exact custom type*

**function IterateCount(const V: TVarData): integer; virtual;**

*Will check if the value is an array, and return the number of items*  
- if the document is an array, will return the items count (0 meaning void array) - used e.g. by TSynMustacheContextVariant  
- this default implementation will return -1 (meaning this is not an array)  
- overridden method could implement it, e.g. for TDocVariant of kind dvArray

**function SetProperty(const V: TVarData; const Name: string; const Value: TVarData): Boolean; override;**

*Set the field/column value*  
- this method will call protected IntSet abstract method

```
function TryJSONToVariant(var JSON: PUTF8Char; var Value: variant; EndOfObject:
PUTF8Char): boolean; virtual;
```

*Customization of JSON parsing into variants*

- will be called by e.g. by VariantLoadJSON() or GetVariantFromJSON() with Options: PDocVariantOptions parameter not nil
- this default implementation will always returns FALSE, meaning that the supplied JSON is not to be handled by this custom (abstract) variant type
- this method could be overridden to identify any custom JSON content and convert it into a dedicated variant instance, then return TRUE
- warning: should NOT modify JSON buffer in-place, unless it returns true

```
procedure Clear(var V: TVarData); override;
```

*Clear the content*

- this default implementation will set VType := varEmpty
- override it if your custom type needs to manage its internal memory

```
procedure Copy(var Dest: TVarData; const Source: TVarData; const Indirect: Boolean);
override;
```

*Copy two variant content*

- this default implementation will copy the TVarData memory
- override it if your custom type needs to manage its internal structure

```
procedure CopyByValue(var Dest: TVarData; const Source: TVarData); virtual;
```

*Copy two variant content by value*

- this default implementation will call the Copy() method
- override it if your custom types may use a by reference copy pattern

```
procedure Iterate(var Dest: TVarData; const V: TVarData; Index: integer); virtual;
```

*Allow to loop over an array document*

- Index should be in 0..IterateCount-1 range
- this default implementation will do nothing

```
procedure Lookup(var Dest: TVarData; const Instance: TVarData; FullName: PUTF8Char);
```

*This method will allow to look for dotted name spaces, e.g. 'parent.child'*

- should return Unassigned if the FullName does not match any value
- will identify TDocVariant storage, or resolve and call the generic TSynInvokeableVariantType.IntGet() method until nested value match

```
procedure ToJSON(W: TTextWriter; const Value: variant; Escape: TTextWriterKind);
overload; virtual;
```

*Customization of variant into JSON serialization*

**TDocVariant = class(TSynInvokeableVariantType)**

*A custom variant type used to store any JSON/BSON document-based content*

- i.e. name/value pairs for objects, or an array of values (including nested documents), stored in a TDocVariantData memory structure
- you can use `_Obj()/_ObjFast()` `_Arr()/_ArrFast()` `_Json()/_JsonFast()` or `_JsonFmt()/_JsonFastFmt()` functions to create instances of such variants
- property access may be done via late-binding - with some restrictions for older versions of FPC, e.g. allowing to write:

```
TDocVariant.NewFast(aVariant);
aVariant.Name := 'John';
aVariant.Age := 35;
writeln(aVariant.Name, ' is ', aVariant.Age, ' years old');
```

- it also supports a small set of pseudo-properties or pseudo-methods:

```
aVariant._Count = DocVariantData(aVariant).Count
aVariant._Kind = ord(DocVariantData(aVariant).Kind)
aVariant._JSON = DocVariantData(aVariant).JSON
aVariant._(i) = DocVariantData(aVariant).Value[i]
aVariant.Value(i) = DocVariantData(aVariant).Value[i]
aVariant.Value(aName) = DocVariantData(aVariant).Value[aName]
aVariant.Name(i) = DocVariantData(aVariant).Name[i]
aVariant.Add(aItem) = DocVariantData(aVariant).AddItem(aItem)
aVariant._ := aItem = DocVariantData(aVariant).AddItem(aItem)
aVariant.Add(aName, aValue) = DocVariantData(aVariant).AddValue(aName, aValue)
aVariant.Exists(aName) = DocVariantData(aVariant).GetValueIndex(aName) >= 0
aVariant.Delete(i) = DocVariantData(aVariant).Delete(i)
aVariant.Delete(aName) = DocVariantData(aVariant).Delete(aName)
aVariant.NameIndex(aName) = DocVariantData(aVariant).GetValueIndex(aName)
```

- it features direct JSON serialization/unserialization, e.g.:

```
assert(_Json('["one", 2, 3]')._JSON = '["one", 2, 3]');
```

- it features direct trans-typing into a string encoded as JSON, e.g.:

```
assert(_Json('["one", 2, 3]') = '["one", 2, 3]');
```

**destructor Destroy; override;**

*Finalize the stored information*

**function DoFunction(var Dest: TVarData; const V: TVarData; const Name: string; const Arguments: TVarDataArray): Boolean; override;**

*Low-level callback to access internal pseudo-methods*

- mainly the `_(Index: integer)`: variant method to retrieve an item if the document is an array

**function InternNames: TRawUTF8Interning;**

*Used by `dvoInternNames` for string interning of all `Names[]` values*

**function InternValues: TRawUTF8Interning;**

*Used by `dvoInternValues` for string interning of all `RawUTF8 Values[]`*

**function IterateCount(const V: TVarData): integer; override;**

*Will check if the value is an array, and return the number of items*

- if the document is an array, will return the items count (0 meaning void array) - used e.g. by `TSynMustacheContextVariant`
- this overridden method will implement it for `dvArray` instance kind

```
class function New(Options: TDocVariantOptions=[]): variant; overload;
```

*Initialize a variant instance to store some document-based content*

- you can use this function to create a variant, which can be nested into another document, e.g.:

```
aVariant := TDocVariant.New;
aVariant.id := 10;
```

- by default, every internal value will be copied, so access of nested properties can be slow - if you expect the data to be read-only or not propagated into another place, set Options=[dvoValueCopiedByReference] will increase the process speed a lot  
- in practice, you should better use \_Obj()/\_ObjFast() \_Arr()/\_ArrFast() functions or TDocVariant.NewFast()

```
class function NewArray(const Items: TVariantDynArray; Options:
TDocVariantOptions=[]): variant; overload;
```

*Initialize a variant instance to store some document-based array content*

- array will be initialized with data supplied dynamic array of variants

```
class function NewArray(const Items: array of const; Options:
TDocVariantOptions=[]): variant; overload;
```

*Initialize a variant instance to store some document-based array content*

- array will be initialized with data supplied as parameters, e.g.

```
aVariant := TDocVariant.NewArray(['one', 2, 3.0]);
```

which is the same as:

```
TDocVariant.New(aVariant);
TDocVariantData(aVariant).AddItem('one');
TDocVariantData(aVariant).AddItem(2);
TDocVariantData(aVariant).AddItem(3.0);
```

- by default, every internal value will be copied, so access of nested properties can be slow - if you expect the data to be read-only or not propagated into another place, set aOptions=[dvoValueCopiedByReference] will increase the process speed a lot  
- in practice, you should better use the function \_Arr() which is a wrapper around this class method

```
class function NewJSON(const JSON: RawUTF8; Options:
TDocVariantOptions=[dvoReturnNullForUnknownProperty]): variant;
```

*Initialize a variant instance to store some document-based object content from a supplied (extended) JSON content*

- in addition to the JSON RFC specification strict mode, this method will handle some BSON-like extensions, e.g. unquoted field names
- a private copy of the incoming JSON buffer will be used, then it will call the TDocVariantData.InitJSONInPlace() method

- to be used e.g. as:

```
var V: variant;
begin
 V := TDocVariant.NewJSON('{"id":10,"doc":{"name":"John","birthyear":1972}}');
 assert(V.id=10);
 assert(V.doc.name='John');
 assert(V.doc.birthYear=1972);
 // and also some pseudo-properties:
 assert(V._count=2);
 assert(V.doc._kind=ord(dvObject));
```

- or with a JSON array:

```
V := TDocVariant.NewJSON('["one",2,3]');
assert(V._kind=ord(dvArray));
for i := 0 to V._count-1 do
 writeln(V._(i));
```

- by default, every internal value will be copied, so access of nested properties can be slow - if you expect the data to be read-only or not propagated into another place, add dvoValueCopiedByReference in Options will increase the process speed a lot
- warning: exclude dvoAllowDoubleValue so won't parse any float, just currency
- in practice, you should better use the function \_Json()/\_JsonFast() which are handy wrappers around this class method

```
class function NewObject(const NameValuePairs: array of const; Options:
TDocVariantOptions=[]): variant;
```

*Initialize a variant instance to store some document-based object content*

- object will be initialized with data supplied two by two, as Name,Value pairs, e.g.  
 aVariant := TDocVariant.NewObject(['name','John','year',1972]);

which is the same as:

```
TDocVariant.New(aVariant);
TDocVariantData(aVariant).AddValue('name','John');
TDocVariantData(aVariant).AddValue('year',1972);
```

- by default, every internal value will be copied, so access of nested properties can be slow - if you expect the data to be read-only or not propagated into another place, set Options=[dvoValueCopiedByReference] will increase the process speed a lot
- in practice, you should better use the function \_Obj() which is a wrapper around this class method

```
class function NewUnique(const SourceDocVariant: variant; Options:
TDocVariantOptions=[dvoReturnNullForUnknownProperty]): variant;
```

*Initialize a variant instance to store some document-based object content from a supplied existing TDocVariant instance*

- use it on a value returned as varByRef (e.g. by \_()) pseudo-method), to ensure the returned variant will behave as a stand-alone value

- for instance, the following:

```
oSeasons := TDocVariant.NewUnique(o.Seasons);
```

is the same as:

```
oSeasons := o.Seasons;
_Unique(oSeasons);
```

or even:

```
oSeasons := _Copy(o.Seasons);
```

```
procedure Cast(var Dest: TVarData; const Source: TVarData); override;
```

*Handle type conversion*

- only types processed by now are string/OleStr/UnicodeString/date

```
procedure CastTo(var Dest: TVarData; const Source: TVarData; const AVarType:
TVarType); override;
```

*Handle type conversion*

- only types processed by now are string/OleStr/UnicodeString/date

```
procedure Clear(var V: TVarData); override;
```

*Low-level callback to clear the content*

```
procedure Compare(const Left, Right: TVarData; var Relationship:
TVarCompareResult); override;
```

*Compare two variant values*

- it uses case-sensitive text comparison of the JSON representation of each variant (including TDocVariant instances)

```
procedure Copy(var Dest: TVarData; const Source: TVarData; const Indirect: Boolean);
override;
```

*Low-level callback to copy two variant content*

- such copy will by default be done by-value, for safety
- if you are sure you will use the variants as read-only, you can set the dvoValueCopiedByReference Option to use faster by-reference copy

```
procedure CopyByValue(var Dest: TVarData; const Source: TVarData); override;
```

*Copy two variant content by value*

- overridden method since instance may use a by-reference copy pattern

```
class procedure GetSingleOrDefault(const docVariantArray, default: variant; var
result: variant);
```

*Will return the unique element of a TDocVariant array or a default*

- if the value is a dvArray with one single item, it will this value
- if the value is not a TDocVariant nor a dvArray with one single item, it will return the default value

```
class procedure IsOfTypeOrNewFast(var aValue: variant);
```

*Ensure a variant is a TDocVariant instance*

- if aValue is not a TDocVariant, will create a new JSON\_OPTIONS[true]

```
procedure Iterate(var Dest: TVarData; const V: TVarData; Index: integer); override;
```

*Allow to loop over an array document*

- Index should be in 0..IterateCount-1 range

- this default implementation will do handle dvArray instance kind

```
class procedure New(out aValue: variant; aOptions: TDocVariantOptions=[]);
overload;
```

*Initialize a variant instance to store some document-based content*

- by default, every internal value will be copied, so access of nested properties can be slow - if you expect the data to be read-only or not propagated into another place, set aOptions=[dvoValueCopiedByReference] will increase the process speed a lot

```
class procedure NewFast(const aValues: array of PDocVariantData); overload;
```

*Initialize several variant instances to store document-based content*

- replace several calls to TDocVariantData.InitFast

- to be used e.g. as

```
var v1,v2,v3: TDocVariantData;
begin
 TDocVariant.NewFast([@v1,@v2,@v3]);
 ...
```

```
class procedure NewFast(out aValue: variant); overload;
```

*Initialize a variant instance to store per-reference document-based content*

- same as New(aValue,JSON\_OPTIONS[true]);

- to be used e.g. as

```
var v: variant;
begin
 TDocVariant.NewFast(v);
 ...
```

```
procedure ToJSON(W: TTextWriter; const Value: variant; Escape: TTextWriterKind);
override;
```

*This implementation will write the content as JSON object or array*

**TDocVariantData = object(TObject)**

*Memory structure used for TDocVariant storage of any JSON/BSON document-based content as variant*

- i.e. name/value pairs for objects, or an array of values (including nested documents)
- you can use `_Obj()`/`_ObjFast()` `_Arr()`/`_ArrFast()` `_Json()`/`_JsonFast()` or `_JsonFmt()`/`_JsonFastFmt()` functions to create instances of such variants
- you can transtype such an allocated variant into TDocVariantData to access directly its internals (like `Count` or `Values[]/Names[]`):

```
aVariantObject := TDocVariant.NewObject(['name','John','year',1972]);
aVariantObject := _ObjFast(['name','John','year',1972]);
with _Safe(aVariantObject)^ do
 for i := 0 to Count-1 do
 writeln(Names[i], '=', Values[i]); // for an object
aVariantArray := TDocVariant.NewArray(['one',2,3.0]);
aVariantArray := _JsonFast('["one",2,3.0]');
with _Safe(aVariantArray)^ do
 for i := 0 to Count-1 do
 writeln(Values[i]); // for an array
```

- use "with \_Safe(...) ^ do" and not "with TDocVariantData(...) do" as the former will handle internal variant redirection (`varByRef`), e.g. from late binding or assigned another TDocVariant
- Delphi "object" is buggy on stack -> also defined as record with methods

**function AddItem(const aValue: variant): integer;**

*Add a value to this document, handled as array*

- if instance's Kind is `dvObject`, it will raise an EDocVariant exception
- you can therefore write e.g.:  

```
TDocVariant.New(aVariant);
Assert(TDocVariantData(aVariant).Kind=dvUndefined);
TDocVariantData(aVariant).AddItem('one');
Assert(TDocVariantData(aVariant).Kind=dvArray);
```
- returns the index of the corresponding newly added item

**function AddItemFromText(const aValue: RawUTF8; AllowVarDouble: boolean=false): integer;**

*Add a value to this document, handled as array, from its text representation*

- this function expects a UTF-8 text for the value, which would be converted to a variant number, if possible (as `varInt`/`varInt64`/`varCurrency` unless `AllowVarDouble` is set)
- if instance's Kind is `dvObject`, it will raise an EDocVariant exception
- returns the index of the corresponding newly added item

**function AddItemText(const aValue: RawUTF8): integer;**

*Add a RawUTF8 value to this document, handled as array*

- if instance's Kind is `dvObject`, it will raise an EDocVariant exception
- returns the index of the corresponding newly added item

**function AddOrUpdateValue(const aName: RawUTF8; const aValue: variant; wasAdded: PBoolean=nil; OnlyAddMissing: boolean=false): integer;**

*Add a value in this document, or update an existing entry*

- if instance's Kind is `dvArray`, it will raise an EDocVariant exception
- any existing Name would be updated with the new Value, unless `OnlyAddMissing` is set to `TRUE`, in which case existing values would remain
- returns the index of the corresponding value, which may be just added

```
function AddValue(aName: PUTF8Char; aNameLen: integer; const aValue: variant;
aValueOwned: boolean=false): integer; overload;
```

*Add a value in this document*

- overloaded function accepting a UTF-8 encoded buffer for the name

```
function AddValue(const aName: RawUTF8; const aValue: variant; aValueOwned:
boolean=false): integer; overload;
```

*Add a value in this document*

- if aName is set, if dvoCheckForDuplicatedNames option is set, any existing duplicated aName will raise an EDocVariant; if instance's kind is dvArray and aName is defined, it will raise an EDocVariant

- aName may be " e.g. if you want to store an array: in this case, dvoCheckForDuplicatedNames option should not be set; if instance's Kind is dvObject, it will raise an EDocVariant exception

- if aValueOwned is true, then the supplied aValue will be assigned to the internal values - by default, it will use SetVariantByValue()

- you can therefore write e.g.:

```
TDocVariant.New(aVariant);
Assert(TDocVariantData(aVariant).Kind=dvUndefined);
TDocVariantData(aVariant).AddValue('name', 'John');
Assert(TDocVariantData(aVariant).Kind=dvObject);
```

- returns the index of the corresponding newly added value

```
function AddValueFromText(const aName, aValue: RawUTF8; Update: boolean=false;
AllowVarDouble: boolean=false): integer;
```

*Add a value in this document, from its text representation*

- this function expects a UTF-8 text for the value, which would be converted to a variant number, if possible (as varInt/varInt64/varCurrency and/or as varDouble is AllowVarDouble is set)

- if Update=TRUE, will set the property, even if it is existing

```
function Delete(Index: integer): boolean; overload;
```

*Delete a value/item in this document, from its index*

- return TRUE on success, FALSE if the supplied index is not correct

```
function Delete(const aName: RawUTF8): boolean; overload;
```

*Delete a value/item in this document, from its name*

- return TRUE on success, FALSE if the supplied name does not exist

```
function DeleteByProp(const aPropName, aPropValue: RawUTF8;
aPropValueCaseSensitive: boolean): boolean;
```

*Delete a value in this document, by property name match*

- {aPropName:aPropValue} will be searched within the stored array or object, and the corresponding item will be deleted, on match

- returns FALSE if no match is found, TRUE if found and deleted

- will call VariantEquals() for value comparison

```
function DeleteByStartName(aStartName: PUTF8Char; aStartNameLen: integer):
integer;
```

*Delete all values matching the first characters of a property name*

- returns the number of deleted items

- returns 0 if the document is not a dvObject, or if no match was found

- will use IdempChar(), so search would be case-insensitive

```
function DeleteByValue(const aValue: Variant; CaseInsensitive: boolean=false):
integer;
```

*Delete one or several value/item in this document, from its value*

- returns the number of deleted items
- returns 0 if the document is not a dvObject, or if no match was found
- if the value exists several times, all occurrences would be removed
- is optimized for DeleteByValue(null) call

```
function FlattenAsNestedObject(const aObjectPropName: RawUTF8): boolean;
```

*Map {"obj.prop1"...,"obj.prop2"...} into {"obj":{"prop1"...,"prop2"...}}*

- the supplied aObjectPropName should match the incoming dotted value of all properties (e.g. 'obj' for "obj.prop1")
- if any of the incoming property is not of "obj.prop#" form, the whole process would be ignored
- return FALSE if the TDocVariant did not change
- return TRUE if the TDocVariant has been flattened

```
function GetAsBoolean(const aName: RawUTF8; out aValue: boolean; aSortedCompare:
TUTF8Compare=nil): Boolean;
```

*Find an item in this document, and returns its value as boolean*

- return false if aName is not found, or if the instance is not a TDocVariant
- return true if the name has been found, and aValue stores the value
- after a SortByName(aSortedCompare), could use faster binary search
- consider using B[] property if you want simple read/write typed access

```
function GetAsDocVariant(const aName: RawUTF8; out aValue: PDocVariantData;
aSortedCompare: TUTF8Compare=nil): boolean; overload;
```

*Find an item in this document, and returns its value as a TDocVariantData*

- return false if aName is not found, or if the instance is not a TDocVariant
- return true if the name has been found and points to a TDocVariant: then aValue stores a pointer to the value
- after a SortByName(aSortedCompare), could use faster binary search

```
function GetAsDocVariantSafe(const aName: RawUTF8; aSortedCompare:
TUTF8Compare=nil): PDocVariantData;
```

*Find an item in this document, and returns its value as a TDocVariantData*

- returns a void TDocVariant if aName is not a document
- after a SortByName(aSortedCompare), could use faster binary search
- consider using O[] or A[] properties if you want simple read-only access, or O\_[] or A\_[] properties if you want the ability to add a missing object or array in the document

```
function GetAsDouble(const aName: RawUTF8; out aValue: double; aSortedCompare:
TUTF8Compare=nil): Boolean;
```

*Find an item in this document, and returns its value as floating point*

- return false if aName is not found, or if the instance is not a TDocVariant
- return true if the name has been found, and aValue stores the value
- after a SortByName(aSortedCompare), could use faster binary search
- consider using D[] property if you want simple read/write typed access

```
function GetAsInt64(const aName: RawUTF8; out aValue: Int64; aSortedCompare:
TUTF8Compare=nil): Boolean;
```

*Find an item in this document, and returns its value as integer*

- return false if aName is not found, or if the instance is not a TDocVariant
- return true if the name has been found, and aValue stores the value
- after a SortByName(aSortedCompare), could use faster binary search
- consider using I[] property if you want simple read/write typed access

```
function GetAsInteger(const aName: RawUTF8; out aValue: integer; aSortedCompare:
TUTF8Compare=nil): Boolean;
```

*Find an item in this document, and returns its value as integer*

- return false if aName is not found, or if the instance is not a TDocVariant
- return true if the name has been found, and aValue stores the value
- after a SortByName(aSortedCompare), could use faster binary search
- consider using I[] property if you want simple read/write typed access

```
function GetAsPVariant(aName: PUTF8Char; aNameLen: PtrInt): PVariant; overload;
```

*Find an item in this document, and returns pointer to its value*

- lookup the value by aName/aNameLen for an object document, or accept an integer text as index for an array document
- return nil if aName is not found, or if the instance is not a TDocVariant
- return a pointer to the stored variant, if the name has been found

```
function GetAsPVariant(const aName: RawUTF8; out aValue: PVariant; aSortedCompare:
TUTF8Compare=nil): boolean; overload;
```

*Find an item in this document, and returns pointer to its value*

- return false if aName is not found
- return true if the name has been found: then aValue stores a pointer to the value
- after a SortByName(aSortedCompare), could use faster binary search

```
function GetAsRawUTF8(const aName: RawUTF8; out aValue: RawUTF8; aSortedCompare:
TUTF8Compare=nil): Boolean;
```

*Find an item in this document, and returns its value as RawUTF8*

- return false if aName is not found, or if the instance is not a TDocVariant
- return true if the name has been found, and aValue stores the value
- after a SortByName(aSortedCompare), could use faster binary search
- consider using U[] property if you want simple read/write typed access

```
function GetDocVariantByPath(const aPath: RawUTF8; out aValue: PDocVariantData):
boolean;
```

*Retrieve a reference to a TDocVariant, given its path*

- path is defined as a dotted name-space, e.g. 'doc.glossary.title'
- if the supplied aPath does not match any object, it will return false
- if aPath stores a valid TDocVariant, returns true and a pointer to it

```
function GetDocVariantByProp(const aPropName, aPropValue: RawUTF8;
aPropValueCaseSensitive: boolean; out Dest: PDocVariantData): boolean;
```

*Retrieve a reference to a dvObject in the dvArray, from a property value*

- {aPropName:aPropValue} will be searched within the stored array, and the corresponding item will be copied into Dest, on match
- returns FALSE if no match is found, TRUE if found and copied by reference

```
function GetItemByProp(const aPropName,aPropValue: RawUTF8;
aPropValueCaseSensitive: boolean; var Dest: variant; DestByRef: boolean=false):
boolean;
```

*Retrieve a dvObject in the dvArray, from a property value*

- {aPropName:aPropValue} will be searched within the stored array, and the corresponding item will be copied into Dest, on match
- returns FALSE if no match is found, TRUE if found and copied
- create a copy of the variant by default, unless DestByRef is TRUE
- will call VariantEquals() for value comparison

```
function GetJsonByStartName(const aStartName: RawUTF8): RawUTF8;
```

*Returns a JSON object containing all properties matching the first characters of the supplied property name*

- returns null if the document is not a dvObject
- will use IdempChar(), so search would be case-insensitive

```
function GetPVariantByPath(const aPath: RawUTF8): PVariant;
```

*Retrieve a reference to a value, given its path*

- path is defined as a dotted name-space, e.g. 'doc.glossary.title'
- if the supplied aPath does not match any object, it will return nil
- if aPath is found, returns a pointer to the corresponding value

```
function GetValueByPath(const aPath: RawUTF8): variant; overload;
```

*Retrieve a value, given its path*

- path is defined as a dotted name-space, e.g. 'doc.glossary.title'
- it will return Unassigned if the path does not match the supplied aPath

```
function GetValueByPath(const aPath: RawUTF8; out aValue: variant): boolean;
overload;
```

*Retrieve a value, given its path*

- path is defined as a dotted name-space, e.g. 'doc.glossary.title'
- it will return FALSE if the path does not match the supplied aPath
- returns TRUE and set the found value in aValue

```
function GetValueByPath(const aDocVariantPath: array of RawUTF8): variant;
overload;
```

*Retrieve a value, given its path*

- path is defined as a list of names, e.g. ['doc','glossary','title']
- it will return Unassigned if the path does not match the data
- this method will only handle nested TDocVariant values: use the slightly slower GetValueByPath() overloaded method, if any nested object may be of another type (e.g. a TBSONVariant)

```
function GetValueEnumerate(const aName: RawUTF8; aTypeInfo: pointer; out aValue;
aDeleteFoundEntry: boolean=false): Boolean;
```

*Find an item in this document, and returns its value as enumerate*

- return false if aName is not found, if the instance is not a TDocVariant, or if the value is not a string corresponding to the supplied enumerate
- return true if the name has been found, and aValue stores the value
- will call Delete() on the found entry, if aDeleteFoundEntry is true

**function** GetValueIndex(aName: PUTF8Char; aNameLen: PtrInt; aCaseSensitive: boolean): integer; overload;

*Find an item index in this document from its name*

- lookup the value by name for an object document, or accept an integer text as index for an array document
- returns -1 if not found

**function** GetValueIndex(const aName: RawUTF8): integer; overload;

*Find an item index in this document from its name*

- search will follow dvoNameCaseSensitive option of this document
- lookup the value by name for an object document, or accept an integer text as index for an array document
- returns -1 if not found

**function** GetValueOrDefault(const aName: RawUTF8; const aDefault: variant): variant;

*Find an item in this document, and returns its value*

- return the supplied default if aName is not found, or if the instance is not a TDocVariant

**function** GetValueOrEmpty(const aName: RawUTF8): variant;

*Find an item in this document, and returns its value*

- return a cleared variant if aName is not found, or if the instance is not a TDocVariant

**function** GetValueOrNull(const aName: RawUTF8): variant;

*Find an item in this document, and returns its value*

- return null if aName is not found, or if the instance is not a TDocVariant

**function** GetValueOrRaiseException(const aName: RawUTF8): variant;

*Find an item in this document, and returns its value*

- raise an EDocVariant if not found and dvoReturnNullForUnknownProperty is not set in Options (in this case, it will return Null)

**function** GetValuesByStartName(const aStartName: RawUTF8; TrimLeftStartName: boolean=false): variant;

*Returns a TDocVariant object containing all properties matching the first characters of the supplied property name*

- returns null if the document is not a dvObject
- will use IdempChar(), so search would be case-insensitive

**function** GetVarData(const aName: RawUTF8; var aValue: TVarData; aSortedCompare: TUTF8Compare=nil): boolean; overload;

*Find an item in this document, and returns its value as TVarData*

- return false if aName is not found, or if the instance is not a TDocVariant
- return true and set aValue if the name has been found
- will use simple loop lookup to identify the name, unless aSortedCompare is set, and would let use a faster O(log(n)) binary search after a SortByName()

**function** GetVarData(const aName: RawUTF8; aSortedCompare: TUTF8Compare=nil): PVarData; overload;

*Find an item in this document, and returns its value as TVarData pointer*

- return nil if aName is not found, or if the instance is not a TDocVariant
- return a pointer to the value if the name has been found
- after a SortByName(aSortedCompare), could use faster binary search

**function** InitJSON(const JSON: RawUTF8; aOptions: TDocVariantOptions=[]): boolean;

*Initialize a variant instance to store some document-based object content from a supplied JSON array of JSON object content*

- a private copy of the incoming JSON buffer will be used, then it will call the other overloaded InitJSONInPlace() method
- this method is called e.g. by \_Json() and \_JsonFast() global functions
- if you call Init\*() methods in a row, ensure you call Clear in-between

**function** InitJSONFromFile(const JsonFile: TFileName; aOptions: TDocVariantOptions=[]; RemoveComments: boolean=false): boolean;

*Initialize a variant instance to store some document-based object content from a JSON array of JSON object content, stored in a file*

- any kind of file encoding will be handled, via AnyTextFileToRawUTF8()
- you can optionally remove any comment from the file content
- if you call Init\*() methods in a row, ensure you call Clear in-between

**function** InitJSONInPlace(JSON: PUTF8Char; aOptions: TDocVariantOptions=[]; aEndOfObject: PUTF8Char=nil): PUTF8Char;

*Initialize a variant instance to store some document-based object content from a supplied JSON array or JSON object content*

- warning: the incoming JSON buffer will be modified in-place: so you should make a private copy before running this method, e.g. using TSynTempBuffer
- this method is called e.g. by \_JsonFmt() \_JsonFastFmt() global functions with a temporary JSON buffer content created from a set of parameters
- if you call Init\*() methods in a row, ensure you call Clear in-between

**function** InternalAdd(const aName: RawUTF8): integer;

*Low-level method called internally to reserve place for new values*

- returns the index of the newly created item in Values[]/Names[] arrays
- you should not have to use it, unless you want to add some items directly within the Values[]/Names[] arrays, using e.g. InitFast(InitialCapacity) to initialize the document
- if aName="", append a dvArray item, otherwise append a dvObject field
- warning: FPC optimizer is confused by Values[InternalAdd(name)] so you should call InternalAdd() in an explicit previous step

**function** Reduce(const aPropNames: array of RawUTF8; aCaseSensitive: boolean; aDoNotAddVoidProp: boolean=false): variant; overload;

*Create a TDocVariant object, from a selection of properties of this document, by property name*

- always returns a TDocVariantData, even if no property name did match (in this case, it is dvUndefined)

**function** ReduceAsArray(const aPropName: RawUTF8; OnReduce: TOnReducePerItem=nil): variant; overload;

*Create a TDocVariant array, from the values of a single properties of this document, specified by name*

- always returns a TDocVariantData, even if no property name did match (in this case, it is dvUndefined)
- you can optionally apply an additional filter to each reduced item

```
function ReduceAsArray(const aPropName: RawUTF8; OnReduce: TOnReducePerValue):
variant; overload;
```

*Create a TDocVariant array, from the values of a single properties of this document, specified by name*

- always returns a TDocVariantData, even if no property name did match (in this case, it is dvUndefined)
- this overloaded method accepts an additional filter to each reduced item

```
function Rename(const aFromPropName, aToPropName: TRawUTF8DynArray): integer;
```

*Rename some properties of a TDocVariant object*

- returns the number of property names modified

```
function RetrieveValueOrRaiseException(aName: PUTF8Char; aNameLen: integer;
aCaseSensitive: boolean; var Dest: variant; DestByRef: boolean): boolean; overload;
```

*Find an item in this document, and returns its value*

- raise an EDocVariant if not found and dvoReturnNullForUnknownProperty is not set in Options (in this case, it will return Null)
- create a copy of the variant by default, unless DestByRef is TRUE

```
function SearchItemByProp(const aPropNameFmt: RawUTF8; const aPropNameArgs: array
of const; const aPropValue: RawUTF8; aPropValueCaseSensitive: boolean): integer;
overload;
```

*Search a property match in this document, handled as array or object*

- {aPropName:aPropValue} will be searched within the stored array or object, and the corresponding item index will be returned, on match
- returns -1 if no match is found
- will call VariantEquals() for value comparison

```
function SearchItemByProp(const aPropName, aPropValue: RawUTF8;
aPropValueCaseSensitive: boolean): integer; overload;
```

*Search a property match in this document, handled as array or object*

- {aPropName:aPropValue} will be searched within the stored array or object, and the corresponding item index will be returned, on match
- returns -1 if no match is found
- will call VariantEquals() for value comparison

```
function SearchItemByValue(const aValue: Variant; CaseInsensitive: boolean=false;
StartIndex: integer=0): integer;
```

*Search a value in this document, handled as array*

- aValue will be searched within the stored array and the corresponding item index will be returned, on match
- returns -1 if no match is found
- you could make several searches, using the StartIndex optional parameter

**function** ToArrayOfConst: TTVarRecDynArray; overload;

*Save an array document as an array of TVarRec, i.e. an array of const*

- will expect the document to be a dvArray - otherwise, will raise a EDocVariant exception
- would allow to write code as such:

```
Doc.InitArray(['one',2,3]);
s := FormatUTF8('%[%,%,%]',Doc.ToArrayOfConst,[],true);
// here s='[one,2,3]' since % would be replaced by Args[] parameters
s := FormatUTF8('[?,?,?]',[],Doc.ToArrayOfConst,true);
// here s='["one",2,3]' since ? would be escaped by Params[] parameters
```

**function** ToCSV(const Separator: RawUTF8=','): RawUTF8;

*Save a document as an CSV of UTF-8 encoded JSON*

- will expect the document to be a dvArray - otherwise, will raise a EDocVariant exception
- will use VariantToUTF8() to populate the result array: as a consequence, any nested custom variant types (e.g. TDocVariant) will be stored as JSON

**function** ToJSON(const Prefix: RawUTF8=''; const Suffix: RawUTF8=''; Format: TTextWriterJSONFormat=jsonCompact): RawUTF8;

*Save a document as UTF-8 encoded JSON*

- will write either a JSON object or array, depending of the internal layout of this instance (i.e. Kind property value)
- will write 'null' if Kind is dvUndefined
- implemented as just a wrapper around VariantSaveJSON()

**function** ToNonExpandedJSON: RawUTF8;

*Save an array of objects as UTF-8 encoded non expanded layout JSON*

- returned content would be a JSON object in mORMot's TSQLTable non expanded format, with reduced JSON size, i.e.

```
{ "fieldCount":3, "values":["ID", "FirstName", "LastName", ...] }
```

- will write " if Kind is dvUndefined or dvObject
- will raise an exception if the array document is not an array of objects with identical field names

**function** ToRawUTF8DynArray: TRawUTF8DynArray; overload;

*Save a document as an array of UTF-8 encoded JSON*

- will expect the document to be a dvArray - otherwise, will raise a EDocVariant exception
- will use VariantToUTF8() to populate the result array: as a consequence, any nested custom variant types (e.g. TDocVariant) will be stored as JSON

**function** ToTextPairs(const NameValueSep: RawUTF8='='; const ItemSep: RawUTF8=#13#10; Escape: TTextWriterKind=twJSONEscape): RawUTF8;

*Save a document as UTF-8 encoded Name=Value pairs*

- will follow by default the .INI format, but you can specify your own expected layout

**function** ToUrlEncode(const UriRoot: RawUTF8): RawUTF8;

*Save an object document as an URI-encoded list of parameters*

- object field names should be plain ASCII-7 RFC compatible identifiers (0..9a..zA..Z\_~), otherwise their values are skipped

**procedure** AddByPath(**const** aSource: TDocVariantData; **const** aPaths: **array of** RawUTF8);

*Add one or several properties, specified by path, from another object*

- path are defined as a dotted name-space, e.g. 'doc.glossary.title'
- matching values would be added as root values, with the path as name
- instance and supplied aSource should be a dvObject

**procedure** AddFrom(**const** aDocVariant: **Variant**);

*Add one or several values from another document*

- supplied document should be of the same kind than the current one, otherwise nothing is added

**procedure** AddItems(**const** aValue: **array of const**);

*Add one or several values to this document, handled as array*

- if instance's Kind is dvObject, it will raise an EDocVariant exception

**procedure** AddNameValuesToObject(**const** NameValuePairs: **array of const**);

*Add some properties to a TDocVariantData dvObject*

- data is supplied two by two, as Name,Value pairs
- caller should ensure that Kind=dvObject, otherwise it won't do anything
- any existing Name would be duplicated

**procedure** AddOrUpdateFrom(**const** aDocVariant: **Variant**; aOnlyAddMissing: **boolean**=false);

*Add or update or on several values from another object*

- current document should be an object

**procedure** AddOrUpdateNameValuesToObject(**const** NameValuePairs: **array of const**);

*Merge some properties to a TDocVariantData dvObject*

- data is supplied two by two, as Name,Value pairs
- caller should ensure that Kind=dvObject, otherwise it won't do anything
- any existing Name would be updated with the new Value

**procedure** AddOrUpdateObject(**const** NewValues: **variant**; OnlyAddMissing: **boolean**=false; RecursiveUpdate: **boolean**=false);

*Merge some TDocVariantData dvObject properties to a TDocVariantData dvObject*

- data is supplied two by two, as Name,Value pairs
- caller should ensure that both variants have Kind=dvObject, otherwise it won't do anything
- any existing Name would be updated with the new Value, unless OnlyAddMissing is set to TRUE, in which case existing values would remain

**procedure** Clear;

*To be called before any Init\*() method call, when a previous Init\*() has already be performed on the same instance, to avoid memory leaks*

- for instance:

```
var Doc: TDocVariantData; // stack-allocated variable
begin
 Doc.InitArray(['one',2,3.0]); // no need of any Doc.Clear here
 assert(Doc.Count=3);
 Doc.Clear; // to release memory before following InitObject()
 Doc.InitObject(['name','John','year',1972]);
end;
```

- implemented as just a wrapper around DocVariantType.Clear()

#### **procedure FillZero;**

*Fill all Values[] with #0, then delete all values*

- could be used to specifically remove sensitive information from memory

#### **procedure Init(aOptions: TDocVariantOptions=[]; aKind: TDocVariantKind=dvUndefined);**

*Initialize a TDocVariantData to store some document-based content*

- can be used with a stack-allocated TDocVariantData variable:

```
var Doc: TDocVariantData; // stack-allocated variable
begin
 Doc.Init;
 Doc.AddValue('name','John');
 assert(Doc.Value['name']='John');
 assert(variant(Doc).name='John');
end;
```

- if you call Init\*() methods in a row, ensure you call Clear in-between

#### **procedure InitArray(const Items: array of const; aOptions: TDocVariantOptions=[]);**

*Initialize a variant instance to store some document-based array content*

- array will be initialized with data supplied as parameters, e.g.

```
var Doc: TDocVariantData; // stack-allocated variable
begin
 Doc.InitArray(['one',2,3.0]);
 assert(Doc.Count=3);
end;
```

which is the same as:

```
var Doc: TDocVariantData;
 i: integer;
begin
 Doc.Init;
 Doc.AddItem('one');
 Doc.AddItem(2);
 Doc.AddItem(3.0);
 assert(Doc.Count=3);
 for i := 0 to Doc.Count-1 do
 writeln(Doc.Value[i]);
end;
```

- this method is called e.g. by \_Arr() and \_ArrFast() global functions

- if you call Init\*() methods in a row, ensure you call Clear in-between

#### **procedure InitArrayFrom(const Items: TRawUTF8DynArray; aOptions: TDocVariantOptions); overload;**

*Initialize a variant instance to store some RawUTF8 array content*

#### **procedure InitArrayFrom(const Items: TIntegerDynArray; aOptions: TDocVariantOptions); overload;**

*Initialize a variant instance to store some 32-bit integer array content*

#### **procedure InitArrayFrom(const Items: TInt64DynArray; aOptions: TDocVariantOptions); overload;**

*Initialize a variant instance to store some 64-bit integer array content*

#### **procedure InitArrayFromObjArray(const ObjArray; aOptions: TDocVariantOptions; aWriterOptions: TTextWriterWriteObjectOptions=[woDontStoreDefault]);**

*Initialize a variant instance to store a T\*ObjArray content*

- will call internally ObjectToVariant() to make the conversion

```
procedure InitArrayFromVariants(const Items: TVariantDynArray; aOptions:
TDocVariantOptions=[]; ItemsCopiedByReference: boolean=true);
```

- Initialize a variant instance to store some document-based array content*
- array will be initialized with data supplied as variant dynamic array
  - if Items is [], the variant will be set as null
  - will be almost immediate, since TVariantDynArray is reference-counted, unless ItemsCopiedByReference is set to FALSE
  - if you call Init\*() methods in a row, ensure you call Clear in-between

```
procedure InitCopy(const SourceDocVariant: variant; aOptions: TDocVariantOptions);
```

- Ensure a document-based variant instance will have one unique options set*
- this will create a copy of the supplied TDocVariant instance, forcing all nested events to have the same set of Options
  - you can use this function to ensure that all internal properties of this variant will be copied e.g. per-reference (if you set JSON\_OPTIONS[false]) or per-value (if you set JSON\_OPTIONS[false]) whatever options the nested objects or arrays were created with
  - will raise an EDocVariant if the supplied variant is not a TDocVariant
  - you may rather use \_Unique() or \_UniqueFast() wrappers if you want to ensure that a TDocVariant instance is unique
  - if you call Init\*() methods in a row, ensure you call Clear in-between

```
procedure InitCSV(CSV: PUTF8Char; aOptions: TDocVariantOptions; NameValueSep:
AnsiChar='='; ItemSep: AnsiChar=#10; DoTrim: boolean=true); overload;
```

- Initialize a variant instance to store some document-based object content from a supplied CSV UTF-8 encoded text*
- the supplied content may have been generated by ToTextPairs() method
  - if ItemSep=#10, then any kind of line feed (CRLF or LF) will be handled
  - if you call Init\*() methods in a row, ensure you call Clear in-between

```
procedure InitCSV(const CSV: RawUTF8; aOptions: TDocVariantOptions; NameValueSep:
AnsiChar='='; ItemSep: AnsiChar=#10; DoTrim: boolean=true); overload;
```

- Initialize a variant instance to store some document-based object content from a supplied CSV UTF-8 encoded text*
- the supplied content may have been generated by ToTextPairs() method
  - if ItemSep=#10, then any kind of line feed (CRLF or LF) will be handled
  - if you call Init\*() methods in a row, ensure you call Clear in-between

```
procedure InitFast; overload;
```

*Initialize a TDocVariantData to store per-reference document-based content*

- same as Doc.Init(JSON\_OPTIONS[true]);
- can be used with a stack-allocated TDocVariantData variable:

```
var Doc: TDocVariantData; // stack-allocated variable
begin
 Doc.InitFast;
 Doc.AddValue('name', 'John');
 assert(Doc.Value['name']='John');
 assert(variant(Doc).name='John');
end;
```

- see also TDocVariant.NewFast() if you want to initialize several TDocVariantData variable instances at once
- if you call Init\*() methods in a row, ensure you call Clear in-between

**procedure** InitFast(InitialCapacity: integer; aKind: TDocVariantKind); overload;

*Initialize a TDocVariantData to store per-reference document-based content*

- this overloaded method allows to specify an estimation of how many properties or items this aKind document would contain

**procedure** InitFromTypeInfo(const aValue; aTypeInfo: pointer; aEnumSetsAsText: boolean; aOptions: TDocVariantOptions);

*Initialize a variant instance to store document-based array content*

- array will be initialized from the supplied variable (which would be e.g. a T\*ObjArray or a dynamic array), using RTTI
- will use a temporary JSON serialization via SaveJSON()

**procedure** InitObject(const NameValuePairs: array of const; aOptions: TDocVariantOptions=[]);

*Initialize a TDocVariantData to store document-based object content*

- object will be initialized with data supplied two by two, as Name,Value pairs, e.g.

```
var Doc: TDocVariantData; // stack-allocated variable
```

```
begin
```

```
 Doc.InitObject(['name', 'John', 'year', 1972]);
```

which is the same as:

```
var Doc: TDocVariantData;
```

```
begin
```

```
 Doc.Init;
```

```
 Doc.AddValue('name', 'John');
```

```
 Doc.AddValue('year', 1972);
```

- this method is called e.g. by \_Obj() and \_ObjFast() global functions
- if you call Init\*() methods in a row, ensure you call Clear in-between

**procedure** InitObjectFromPath(const aPath: RawUTF8; const aValue: variant; aOptions: TDocVariantOptions=[]);

*Initialize a variant instance to store a document-based object with a single property*

- the supplied path could be 'Main.Second.Third', to create nested objects, e.g.

```
{"Main":{"Second":{"Third":value}}}
```

- if you call Init\*() methods in a row, ensure you call Clear in-between

**procedure** InitObjectFromVariants(const aNames: TRawUTF8DynArray; const aValues: TVariantDynArray; aOptions: TDocVariantOptions=[]);

*Initialize a variant instance to store some document-based object content*

- object will be initialized with names and values supplied as dynamic arrays
- if aNames and aValues are [] or do have matching sizes, the variant will be set as null
- will be almost immediate, since Names and Values are reference-counted
- if you call Init\*() methods in a row, ensure you call Clear in-between

**procedure** Reduce(const aPropNames: array of RawUTF8; aCaseSensitive: boolean; out result: TDocVariantData; aDoNotAddVoidProp: boolean=false); overload;

*Create a TDocVariant object, from a selection of properties of this document, by property name*

- if the document is a dvObject, to reduction will be applied to all its properties
- if the document is a dvArray, the reduction will be applied to each stored item, if it is a document

**procedure** ReduceAsArray(**const** aPropName: RawUTF8; **out** result: TDocVariantData;  
 OnReduce: TOnReducePerItem=nil); overload;

*Create a TDocVariant array, from the values of a single properties of this document, specified by name*

- you can optionally apply an additional filter to each reduced item

**procedure** ReduceAsArray(**const** aPropName: RawUTF8; **out** result: TDocVariantData;  
 OnReduce: TOnReducePerValue); overload;

*Create a TDocVariant array, from the values of a single properties of this document, specified by name*

- this overloaded method accepts an additional filter to each reduced item

**procedure** Reset;

*Delete all internal stored values*

- like Clear + Init() with the same options

- will reset Kind to dvUndefined

**procedure** RetrieveNameOrRaiseException(Index: integer; **var** Dest: RawUTF8);

*Retrieve an item in this document from its index, and returns its Name*

- raise an EDocVariant if the supplied Index is not in the 0..Count-1 range and

dvoReturnNullForUnknownProperty is set in Options

**procedure** RetrieveValueOrRaiseException(Index: integer; **var** Dest: **variant**;  
 DestByRef: boolean); overload;

*Retrieve an item in this document from its index, and returns its value*

- raise an EDocVariant if the supplied Index is not in the 0..Count-1 range and

dvoReturnNullForUnknownProperty is set in Options

- create a copy of the variant by default, unless DestByRef is TRUE

**procedure** Reverse;

*Reverse the order of the document object or array items*

**procedure** SetCount(aCount: integer);

*Low-level method to force a number of items*

- could be used to fast add items to the internal Values[]/Names[] arrays

- just set protected VCount field, do not resize the arrays: caller should ensure that Capacity is big enough

**procedure** SetValueOrRaiseException(Index: integer; **const** NewValue: **variant**);

*Set an item in this document from its index*

- raise an EDocVariant if the supplied Index is not in 0..Count-1 range

**procedure** SortArrayByField(**const** aItemPropName: RawUTF8; aValueCompare:  
 TVariantCompare=nil; aValueCompareReverse: boolean=false; aNameSortedCompare:  
 TUTF8Compare=nil);

*Sort the document array values by a field of some stored objet values*

- do nothing if the document is not a dvArray, or if the items are no dvObject

- will sort by UTF-8 text (VariantCompare) if no custom aValueCompare is supplied

**procedure** SortByName(Compare: TUTF8Compare=nil);

*Sort the document object values by name*

- do nothing if the document is not a dvObject
- will follow case-insensitive order (@StrComp) by default, but you can specify @StrComp as comparer function for case-sensitive ordering
- once sorted, you can use GetVarData(..,Compare) or GetAs\*(..,Compare) methods for much faster O(log(n)) binary search

**procedure** SortByValue(Compare: TVariantCompare = nil);

*Sort the document object values by value*

- work for both dvObject and dvArray documents
- will sort by UTF-8 text (VariantCompare) if no custom aCompare is supplied

**procedure** ToArrayOfConst(out Result: TTVarRecDynArray); overload;

*Save an array document as an array of TVarRec, i.e. an array of const*

- will expect the document to be a dvArray - otherwise, will raise a EDocVariant exception
- would allow to write code as such:

```
Doc.InitArray(['one',2,3]);
Doc.ToArrayOfConst(vr);
s := FormatUTF8('[%,%,%]',vr,[],true);
// here s='[one,2,3]' since % would be replaced by Args[] parameters
s := FormatUTF8('[?,?,?]',[],vr,true);
// here s='["one",2,3]' since ? would be escaped by Params[] parameters
```

**procedure** ToRawUTF8DynArray(out Result: TRawUTF8DynArray); overload;

*Save a document as an array of UTF-8 encoded JSON*

- will expect the document to be a dvArray - otherwise, will raise a EDocVariant exception
- will use VariantToUTF8() to populate the result array: as a consequence, any nested custom variant types (e.g. TDocVariant) will be stored as JSON

**procedure** ToTextPairsVar(out result: RawUTF8; const NameValueSep: RawUTF8='=';  
**const** ItemSep: RawUTF8=#13#10; Escape: TTextWriterKind=twJSONEscape);

*Save a document as UTF-8 encoded Name=Value pairs*

- will follow by default the .INI format, but you can specify your own expected layout

**property** A[const aName: RawUTF8]: PDocVariantData **read** GetArrayExistingByName;

*Direct access to a dvObject existing dvArray property from its name*

- follows dvoNameCaseSensitive and dvoReturnNullForUnknownProperty options
- A['prop'] would return a fake void TDocVariant if the property is not existing or not a dvArray, just like GetAsDocVariantSafe()
- use A\_['prop'] to force adding any missing property

**property** A\_[const aName: RawUTF8]: PDocVariantData **read** GetArrayOrAddByName;

*Direct access or add a dvObject's dvArray property from its name*

- follows dvoNameCaseSensitive and dvoReturnNullForUnknownProperty options
- A\_['prop'] would add a new property if there is none existing, or overwrite an existing property which is not a dvArray

```
property B[const aName: RawUTF8]: Boolean read GetBooleanByName write SetBooleanByName;
```

*Direct access to a dvObject Boolean stored property value from its name*

- slightly faster than the variant-based Value[] default property
- follows dvoNameCaseSensitive and dvoReturnNullForUnknownProperty options
- use GetAsBoolean if you want to check the availability of the field
- B['prop'] := true would add a new property, or overwrite an existing

```
property Capacity: integer read GetCapacity write SetCapacity;
```

*The current capacity of this document*

- allow direct access to VValue[] length

```
property Count: integer read VCount;
```

*Number of items stored in this document*

- is 0 if Kind=dvUndefined
- is the number of name/value pairs for Kind=dvObject
- is the number of items for Kind=dvArray

```
property D[const aName: RawUTF8]: Double read GetDoubleByName write SetDoubleByName;
```

*Direct access to a dvObject floating-point stored property value from its name*

- slightly faster than the variant-based Value[] default property
- follows dvoNameCaseSensitive and dvoReturnNullForUnknownProperty options
- use GetAsDouble if you want to check the availability of the field
- D['prop'] := 1.23 would add a new property, or overwrite an existing

```
property I[const aName: RawUTF8]: Int64 read GetInt64ByName write SetInt64ByName;
```

*Direct access to a dvObject Integer stored property value from its name*

- slightly faster than the variant-based Value[] default property
- follows dvoNameCaseSensitive and dvoReturnNullForUnknownProperty options
- use GetAsInt/GetAsInt64 if you want to check the availability of the field
- I['prop'] := 123 would add a new property, or overwrite an existing

```
property Kind: TDocVariantKind read GetKind;
```

*Returns the document internal layout*

- just after initialization, it will return dvUndefined
- most of the time, you will add named values with AddValue() or by setting the variant properties: it will return dvObject
- but is you use AddItem(), values will have no associated names: the document will be a dvArray
- value computed from the dvoArray and dvoObject presence in Options

```
property Names: TRawUTF8DynArray read VName;
```

*Direct access to the low-level internal array of names*

- is void (nil) if Kind is not dvObject
- transtyping a variant and direct access to TDocVariantData is the fastest way of accessing all properties of a given dvObject:

```
with TDocVariantData(aVariantObject) do
 for i := 0 to Count-1 do
 writeln(Names[i], '=', Values[i]);
```

**property** O[const aName: RawUTF8]: PDocVariantData **read** GetObjectExistingByName;

*Direct access to a dvObject existing dvObject property from its name*

- follows dvoNameCaseSensitive and dvoReturnNullForUnknownProperty options
- O['prop'] would return a fake void TDocVariant if the property is not existing or not a dvObject, just like GetAsDocVariantSafe()
- use O\_['prop'] to force adding any missing property

**property** Options: TDocVariantOptions **read** VOptions **write** SetOptions;

*How this document will behave*

- those options are set when creating the instance
- dvoArray and dvoObject are not options, but define the document Kind, so those items are ignored when assigned to this property

**property** O\_[const aName: RawUTF8]: PDocVariantData **read** GetObjectOrAddByName;

*Direct access or add a dvObject's dvObject property from its name*

- follows dvoNameCaseSensitive and dvoReturnNullForUnknownProperty options
- O\_['prop'] would add a new property if there is none existing, or overwrite an existing property which is not a dvObject

**property** S[const aName: RawUTF8]: string **read** GetStringByName **write** SetStringByName;

*Direct string access to a dvObject UTF-8 stored property value from its name*

- just a wrapper around U[] property, to avoid a compilation warning when using plain string variables (internally, RawUTF8 will be used for storage)
- slightly faster than the variant-based Value[] default property
- follows dvoNameCaseSensitive and dvoReturnNullForUnknownProperty options
- use GetAsRawUTF8() if you want to check the availability of the field
- S['prop'] := 'value' would add a new property, or overwrite an existing

**property** U[const aName: RawUTF8]: RawUTF8 **read** GetRawUTF8ByName **write** SetRawUTF8ByName;

*Direct access to a dvObject UTF-8 stored property value from its name*

- slightly faster than the variant-based Value[] default property
- follows dvoNameCaseSensitive and dvoReturnNullForUnknownProperty options
- use GetAsRawUTF8() if you want to check the availability of the field
- U['prop'] := 'value' would add a new property, or overwrite an existing

```
property Value[const aNameOrIndex: Variant]: Variant read GetValueOrItem write
SetValueOrItem;
```

*Find an item in this document, and returns its value*

- raise an EDocVariant if aNameOrIndex is neither an integer nor a string
- raise an EDocVariant if Kind is dvArray and aNameOrIndex is a string or if Kind is dvObject and aNameOrIndex is an integer
- raise an EDocVariant if Kind is dvObject and if aNameOrIndex is a string, which is not found within the object property names and dvoReturnNullForUnknownProperty is set in Options
- raise an EDocVariant if Kind is dvArray and if aNameOrIndex is a integer, which is not within 0..Count-1 and dvoReturnNullForUnknownProperty is set in Options

- so you can use directly:

```
// for an array document:
aVariant := TDocVariant.NewArray(['one',2,3.0]);
for i := 0 to TDocVariantData(aVariant).Count-1 do
 aValue := TDocVariantData(aVariant).Value[i];
// for an object document:
aVariant := TDocVariant.NewObject(['name','John','year',1972]);
assert(aVariant.Name=TDocVariantData(aVariant)['name']);
assert(aVariant.year=TDocVariantData(aVariant)['year']);
```

- due to the internal implementation of variant execution (somewhat slow \_DisplInvoke() function), it is a bit faster to execute:

```
aValue := TDocVariantData(aVariant).Value['name'];
```

instead of

```
aValue := aVariant.name;
```

but of course, if want to want to access the content by index (typically for a dvArray), using Values[] - and Names[] - properties is much faster than this variant-indexed pseudo-property:

```
with TDocVariantData(aVariant) do
 for i := 0 to Count-1 do
 Writeln(Values[i]);
```

is faster than:

```
with TDocVariantData(aVariant) do
 for i := 0 to Count-1 do
 Writeln(Value[i]);
```

which is faster than:

```
for i := 0 to aVariant.Count-1 do
 Writeln(aVariant._(i));
```

- this property will return the value as varByRef (just like with variant late binding of any TDocVariant instance), so you can write:

```
var Doc: TDocVariantData; // stack-allocated variable
begin
 Doc.InitJSON('{arr:[1,2]}');
 assert(Doc.Count=2);
 Doc.Value['arr'].Add(3); // works since Doc.Value['arr'] is varByRef
 Writeln(Doc.ToJSON); // will write '{"arr":[1,2,3]}'
end;
```

- if you want to access a property as a copy, i.e. to assign it to a variant variable which will stay alive after this TDocVariant instance is release, you should not use Value[] but rather GetValueOrRaiseException or GetValueOrNull/GetValueOrEmpty
- see U[] I[] B[] D[] O[] O\_[] A[] A\_[] \_[] properties for direct access of strong typed values

**property** Values: TVariantDynArray read VValue;

*Direct access to the low-level internal array of values*

- transtyping a variant and direct access to TDocVariantData is the fastest way of accessing all properties of a given dvObject:

```
with TDocVariantData(aVariantObject) do
 for i := 0 to Count-1 do
 writeln(Names[i], '=', Values[i]);
```

- or to access a dvArray items (e.g. a MongoDB collection):

```
with TDocVariantData(aVariantArray) do
 for i := 0 to Count-1 do
 writeln(Values[i]);
```

**property** VarType: word read VType;

*Return the custom variant type identifier, i.e. DocVariantType.VarType*

**property** \_[aIndex: integer]: PDocVariantData read GetAsDocVariantByIndex;

*Direct access to a dvArray's TDocVariant property from its index*

- simple values may directly use Values[] dynamic array, but to access a TDocVariantData members, this property is safer

- follows dvoReturnNullForUnknownProperty option to raise an exception

- \_[ndx] would return a fake void TDocVariant if aIndex is out of range, if the property is not existing or not a TDocVariantData (just like GetAsDocVariantSafe)

**TPrecisionTimer = object**(TObject)

*High resolution timer (for accurate speed statistics)*

- WARNING: under Windows, this record MUST be aligned to 32-bit, otherwise iFreq=0 - so you can use TLocalPrecisionTimer/ILocalPrecisionTimer if you want to allocate a local timer instance on the stack

**function** ByCount(Count: QWord): TShort16;

*Compute the time elapsed by count, with appened time resolution (us,ms,s)*

**function** FromExternalQueryPerformanceCounters(const CounterDiff: QWord): QWord;

*Delphi 2007 is buggy as hell low-level method to force values settings to allow thread safe timing*

- by default, this timer is not thread safe: you can use this method to set the timing values from manually computed performance counters

- the caller should also use a mutex to prevent from race conditions: see e.g.

TSynMonitor.FromExternalQueryPerformanceCounters implementation

- returns the time elapsed, in micro seconds (i.e. LastTime value)

- warning: Start, Stop, Pause and Resume methods are then disallowed

**function** LastTime: TShort16;

*Textual representation of last process timing after counter stopped*

- Time returns a total elapsed time, whereas this method only returns the latest resumed time

- with appened time resolution (us,ms,s) - from MicroSecToString()

- not to be used in normal code, but e.g. for custom performance analysis

**function** PerSec(const Count: QWord): QWord;

*Compute the per second count*

**function** ProfileCurrentMethod: IUnknown;

*Resume a paused timer until the method ends*

- will internally create a TInterfaceObject class to let the compiler generate a try..finally block as expected to call Pause at method ending
- is therefore very convenient to have consistent Resume/Pause calls
- for proper use, expect TPrecisionTimer to be initialized to 0 before execution (e.g. define it as a protected member of a class)
- typical use is to declare a fTimeElapsed: TPrecisionTimer protected member, then call fTimeElapsed.ProfileCurrentMethod at the beginning of all process expecting some timing, then log/save fTimeElapsed.Stop content
- FPC TIP: result should be assigned to a local variable of IUnknown type

**function** SizePerSec(Size: QWord): shortstring;

*Returns e.g. '16.9 MB in 102.20ms i.e. 165.5 MB/s'*

**function** Started: boolean;

*Check if Start/Resume were called at least once*

**function** Stop: TShort16;

*Stop the timer, returning the total time elapsed as text*

- with appended time resolution (us,ms,s) - from MicroSecToString()
- is just a wrapper around Pause + Time
- you can call Resume to continue adding time to this timer

**function** StopInMicroSec: TSynMonitorTotalMicroSec;

*Stop the timer, returning the total time elapsed as microseconds*

- is just a wrapper around Pause + Time
- you can call Resume to continue adding time to this timer

**function** Time: TShort16;

*Textual representation of total time elapsed*

- with appended time resolution (us,ms,s) - from MicroSecToString()
- not to be used in normal code (which could rather call the Stop method), but e.g. for custom performance analysis

**procedure** FromExternalMicroSeconds(const MicroSeconds: QWord);

*Low-level method to force values settings to allow thread safe timing*

- by default, this timer is not thread safe: you can use this method to set the timing values from manually computed performance counters
- the caller should also use a mutex to prevent from race conditions: see e.g. TSynMonitor.FromExternalMicroSeconds implementation
- warning: Start, Stop, Pause and Resume methods are then disallowed

**procedure** Init;

*Initialize the timer*

- will fill all internal state with 0
- not necessary e.g. if TPrecisionTimer is defined as a TObject field

**procedure** Pause;

*Stop the timer, ready to continue its time measurement via Resume*

- will also compute the global Time value
- do nothing if no previous Start/Resume call is pending

**procedure** Resume;

*Resume a paused timer, or start an initialized timer*

- do nothing if no timer has been initialized or paused just before
- if the previous method called was Init, will act like Start
- if the previous method called was Pause, it will continue counting

**procedure** Start;

*Initialize and start the high resolution timer*

- similar to Init + Resume

**property** LastTimeInMicroSec: TSynMonitorOneMicroSec **read** fLastTime **write** fLastTime;

*Timing in micro seconds of the last process*

- not to be used in normal code, but e.g. for custom performance analysis

**property** PauseCount: TSynMonitorCount **read** fPauseCount;

*How many times the Pause method was called, i.e. the number of tasks processeed*

**property** TimeInMicroSec: TSynMonitorTotalMicroSec **read** fTime **write** fTime;

*Time elapsed in micro seconds after counter stopped*

- not to be used in normal code, but e.g. for custom performance analysis

**ILocalPrecisionTimer = interface**(IInterface)

*Interface to a reference counted high resolution timer instance*

- implemented by TLocalPrecisionTimer

**function** ByCount(Count: cardinal): RawUTF8;

*Compute the time elapsed by count, with appened time resolution (us,ms,s)*

**function** PerSec(Count: cardinal): cardinal;

*Compute the per second count*

**function** Stop: TShort16;

*Stop the timer, returning the time elapsed, with appened time resolution (us,ms,s)*

**procedure** Pause;

*Stop the timer, ready to continue its time measure*

**procedure** Resume;

*Resume a paused timer, or start it if it hasn't be started*

**procedure** Start;

*Start the high resolution timer*

**TLocalPrecisionTimer = class(TInterfacedObject)**

*Reference counted high resolution timer (for accurate speed statistics)*

- since TPrecisionTimer shall be 32-bit aligned, you can use this class to initialize a local auto-freeing TLocalPrecisionTimer variable on stack

- to be used as such:

```
var Timer: TLocalPrecisionTimer;
(...)
 Timer := TLocalPrecisionTimer.Create;
 Timer.Start;
(...)
```

**constructor** CreateAndStart;

*Initialize the instance, and start the high resolution timer*

**function** ByCount(Count: cardinal): RawUTF8;

*Compute the time elapsed by count, with appened time resolution (us,ms,s)*

**function** PerSec(Count: cardinal): cardinal;

*Compute the per second count*

**function** Stop: TShort16;

*Stop the timer, returning the time elapsed, with appened time resolution (us,ms,s)*

**procedure** Pause;

*Stop the timer, ready to continue its time measure*

**procedure** Resume;

*Resume a paused timer, or start the timer*

**procedure** Start;

*Start the high resolution timer*

**TSynMonitorTime = class(TSynPersistent)**

*Able to serialize any cumulative timing as raw micro-seconds number or text*

- "cumulative" time would add each process value, e.g. SOA methods execution

**function** PerSecond(const Count: QWord): QWord;

*Compute a number per second, of the current value*

**property** MicroSec: TSynMonitorTotalMicroSec read fMicroSeconds write fMicroSeconds;

*Delphi 2007 is buggy as hell micro seconds time elapsed, as raw number*

**property** Text: TShort16 read GetAsText;

*Micro seconds time elapsed, as '... us-ns-ms-s' text*

**TSynMonitorOneTime = class(TSynPersistent)**

*Able to serialize any immediate timing as raw micro-seconds number or text*

- "immediate" size won't accumulate, i.e. may be e.g. last process time

**function** PerSecond(**const** Count: QWord): QWord;

*Compute a number per second, of the current value*

**property** MicroSec: TSynMonitorOneMicroSec **read** fMicroSeconds **write** fMicroSeconds;

*Delphi 2007 is buggy as hell micro seconds time elapsed, as raw number*

**property** Text: TShort16 **read** GetAsText;

*Micro seconds time elapsed, as '... us-ns-ms-s' text*

TSynMonitorSize = **class**(TSynMonitorSizeParent)

*Able to serialize any cumulative size as bytes number*

- "cumulative" time would add each process value, e.g. global IO consumption

**property** Bytes: TSynMonitorTotalBytes **read** fBytes **write** fBytes;

*Number of bytes, as raw number*

**property** Text: TShort16 **read** GetAsText;

*Number of bytes, as '... B-KB-MB-GB' text*

TSynMonitorOneSize = **class**(TSynMonitorSizeParent)

*Able to serialize any immediate size as bytes number*

- "immediate" size won't accumulate, i.e. may be e.g. computer free memory at a given time

**property** Bytes: TSynMonitorOneBytes **read** fBytes **write** fBytes;

*Number of bytes, as raw number*

**property** Text: TShort16 **read** GetAsText;

*Number of bytes, as '... B-KB-MB-GB' text*

TSynMonitorThroughput = **class**(TSynMonitorSizeParent)

*Able to serialize any bandwidth as bytes count per second*

- is usually associated with TSynMonitorOneSize properties, e.g. to monitor IO activity

**property** BytesPerSec: QWord **read** fBytesPerSec **write** fBytesPerSec;

*Number of bytes per second, as raw number*

**property** Text: TShort16 **read** GetAsText;

*Number of bytes per second, as '... B-KB-MB-GB/s' text*

TSynMonitor = **class**(TSynPersistentLock)

*A generic value object able to handle any task / process statistic*

- base class shared e.g. for ORM, SOA or DDD, when a repeatable data process is to be monitored

- this class is thread-safe for its methods, but you should call explicitly Lock/UnLock to access its individual properties

**InternalTimer**: TPrecisionTimer;

*Low-level high-precision timer instance*

**constructor** Create; overload; override;

*Initialize the instance nested class properties*

**constructor** Create(const aName: RawUTF8); reintroduce; overload; virtual;

*Initialize the instance nested class properties*

- you can specify identifier associated to this monitored resource which would be used for TSynMonitorUsage persistence

**destructor** Destroy; override;

*Finalize the instance*

**function** ComputeDetails: variant;

*Returns a TDocVariant with all published properties information*

- thread-safe method

**function** ComputeDetailsJSON: RawUTF8;

*Returns a JSON content with all published properties information*

- thread-safe method

**function** FromExternalQueryPerformanceCounters(const CounterDiff: QWord): QWord;

*Used to allow thread safe timing*

- by default, the internal TPrecisionTimer is not thread safe: you can use this method to update the timing from many threads
- if you use this method, ProcessStart, ProcessDoTask and ProcessEnd methods are disallowed, and the global fTimer won't be used any more
- will return the processing time, converted into micro seconds, ready to be logged if needed
- thread-safe method

**procedure** ComputeDetailsTo(W: TTextWriter); virtual;

*Appends a JSON content with all published properties information*

- thread-safe method

**procedure** FromExternalMicroSeconds(const MicroSecondsElapsed: QWord);

*Used to allow thread safe timing*

- by default, the internal TPrecisionTimer is not thread safe: you can use this method to update the timing from many threads
- if you use this method, ProcessStart, ProcessDoTask and ProcessEnd methods are disallowed, and the global fTimer won't be used any more
- thread-safe method

**class procedure** InitializeObjArray(var ObjArr; Count: integer); virtual;

*Create Count instances of this actual class in the supplied ObjArr[]*

**procedure** Lock;

*Lock the instance for exclusive access*

- needed only if you access directly the instance properties

**procedure** ProcessDoTask; virtual;

*Should be called each time a pending task is processed*

- will increase the TaskCount property
- thread-safe method

**procedure** ProcessEnd; **virtual**;

*Should be called when the process stops, to pause the internal timer*  
 - thread-safe method

**procedure** ProcessError(const info: variant); **virtual**;

*Should be called when an error occurred*  
 - typical use is with ObjectToVariantDebug(E,...) kind of information  
 - thread-safe method

**procedure** ProcessErrorFmt(const Fmt: RawUTF8; const Args: array of const);

*Should be called when an error occurred*  
 - just a wrapper around overloaded ProcessError(), so a thread-safe method

**procedure** ProcessErrorNumber(info: integer);

*Should be called when an error occurred*  
 - typical use is with a HTTP status, e.g. as ProcessError(Call.OutStatus)  
 - just a wrapper around overloaded ProcessError(), so a thread-safe method

**procedure** ProcessErrorRaised(E: Exception);

*Should be called when an Exception occurred*  
 - just a wrapper around overloaded ProcessError(), so a thread-safe method

**procedure** ProcessStart; **virtual**;

*Should be called when the process starts, to resume the internal timer*  
 - thread-safe method

**procedure** ProcessStartTask; **virtual**;

*Should be called when the process starts, and a task is processed*  
 - similar to ProcessStart + ProcessDoTask  
 - thread-safe method

**procedure** Sum(another: TSynMonitor);

*Could be used to manage information average or sums*  
 - thread-safe method calling LockedSum protected virtual method

**procedure** UnLock;

*Release the instance for exclusive access*  
 - needed only if you access directly the instance properties

**property** AverageTime: TSynMonitorOneTime **read** fAverageTime;

*The time spent in average during any working process*

**property** Errors: TSynMonitorCount **read** fInternalErrors;

*How many errors did occur during the processing*

**property** LastError: variant **read** fLastInternalError;

*Information about the last error which occurred during the processing*

**property** LastTime: TSynMonitorOneTime **read** fLastTime;

*The time spent during the last task processing*

**property** MaximalTime: TSynMonitorOneTime **read** fMaximalTime;

*The highest time spent during any working process*

**property** MinimalTime: TSynMonitorOneTime **read** fMinimalTime;

*The lowest time spent during any working process*

**property** Name: RawUTF8 **read** fName **write** fName;

*An identifier associated to this monitored resource*  
- is used e.g. for TSynMonitorUsage persistence/tracking

**property** PerSec: QWord **read** fPerSec;

*Average of how many tasks did occur per second*

**property** Processing: boolean **read** fProcessing **write** fProcessing;

*Indicates if this thread is currently working on some process*

**property** TaskCount: TSynMonitorCount64 **read** fTaskCount **write** fTaskCount;

*How many times the task was performed*

**property** TotalTime: TSynMonitorTime **read** fTotalTime;

*The whole time spend during all working process*

**TSynMonitorWithSize = class**(TSynMonitor)

*Handle generic process statistic with a processing data size and bandwith*

**constructor** Create; **override**;

*Initialize the instance nested class properties*

**destructor** Destroy; **override**;

*Finalize the instance*

**procedure** AddSize(**const** Bytes: QWord);

*Increase the internal size counter*  
- thread-safe method

**property** Size: TSynMonitorSize **read** fSize;

*How many total data has been handled during all working process*

**property** Throughput: TSynMonitorThroughput **read** fThroughput;

*Data processing bandwith, returned as B/KB/MB per second*

**TSynMonitorInputOutput = class**(TSynMonitor)

*Handle generic process statistic with a incoming and outgoing processing data size and bandwith*

**constructor** Create; **override**;

*Initialize the instance nested class properties*

**destructor** Destroy; **override**;

*Finalize the instance*

**procedure** AddSize(**const** Incoming, Outgoing: QWord);

*Increase the internal size counters*  
- thread-safe method

**property** Input: TSynMonitorSize **read** fInput;

*How many data has been received*

**property** InputThroughput: TSynMonitorThroughput **read** fInputThroughput;

*Incoming data processing bandwidth, returned as B/KB/MB per second*

**property** Output: TSynMonitorSize **read** fOutput;

*How many data has been sent back*

**property** OutputThroughput: TSynMonitorThroughput **read** fOutputThroughput;

*Outgoing data processing bandwidth, returned as B/KB/MB per second*

**TSynMonitorServer** = **class**(TSynMonitorInputOutput)

*Could monitor a standard Server*

- including Input/Output statistics and connected Clients count

**function** AddCurrentRequestCount(diff: integer): integer;

*How many concurrent requests are currently processed*

- returns the updated number of requests

- thread-safe method

**function** GetClientsCurrent: TSynMonitorOneCount;

*Retrieve the number of connected clients*

- thread-safe method

**procedure** ClientConnect;

*Update ClientsCurrent and ClientsMax*

- thread-safe method

**procedure** ClientDisconnect;

*Update ClientsCurrent and ClientsMax*

- thread-safe method

**procedure** ClientDisconnectAll;

*Update ClientsCurrent to 0*

- thread-safe method

**property** ClientsCurrent: TSynMonitorOneCount **read** fClientsCurrent;

*Current count of connected clients*

**property** ClientsMax: TSynMonitorOneCount **read** fClientsMax;

*Max count of connected clients*

**property** CurrentRequestCount: integer **read** fCurrentRequestCount;

*How many concurrent requests are currently processed*

- modified via AddCurrentRequestCount() in TSQLRestServer.URI()

## **TSynInterfacedObject = class(TObject)**

*An abstract ancestor, for implementing a custom TInterfacedObject like class*

- by default, will do nothing: no instance would be retrieved by QueryInterface unless the VirtualQueryInterface protected method is overridden, and \_AddRef/\_Release methods would call VirtualAddRef and VirtualRelease pure abstract methods
- using this class will leverage the signature difference between Delphi and FPC, among all supported platforms
- the class includes a RefCount integer field

**property** RefCount: integer **read** fRefCount **write** fRefCount;

*The associated reference count*

## **TSynFPUException = class(TSynInterfacedObject)**

*A simple class which will set FPU exception flags for a code block*

- using an IUnknown interface to let the compiler auto-generate a try..finally block statement to reset the FPU exception register
- to be used e.g. as such:

```
begin
 TSynFPUException.ForLibraryCode;
 ... now FPU exceptions will be ignored
 ... so here it is safe to call external library code
end; // now FPU exception will be reset as with standard Delphi
```

- it will avoid any unexpected invalid floating point operation in Delphi code, whereas it was in fact triggered in some external library code

**constructor** Create(Expected8087Flag: word); **reintroduce;**

*Internal constructor*

- do not call this constructor directly, but rather use ForLibraryCode/ForDelphiCode class methods
- for cpu32 flags are \$1372 for Delphi, or \$137F for library (mask all exceptions)
- for cpu64 flags are \$1920 for Delphi, or \$1FA0 for library (mask all exceptions)

**class function** ForDelphiCode: IUnknown;

*After this method call, all FPU exceptions will be enabled*

- this is the Delphi normal behavior
- until the method finishes (a try..finally block is generated by the compiler), then FPU exceptions will be disabled again
- you have to put this e.g. before running an Delphi code from a callback executed in an external library
- this method is thread-safe and re-entrant (by reference-counting)

**class function** ForLibraryCode: IUnknown;

*After this method call, all FPU exceptions will be ignored*

- until the method finishes (a try..finally block is generated by the compiler), then FPU exceptions will be reset into "Delphi" mode
- you have to put this e.g. before calling an external library
- this method is thread-safe and re-entrant (by reference-counting)

## **IAutoFree = interface(IInterface)**

*Interface for TAutoFree to register another TObject instance to an existing IAutoFree local variable*

**TAutoFree = class(TInterfacedObject)**

*Simple reference-counted storage for local objects*

- WARNING: both FPC and Delphi 10.4+ don't keep the IAutoFree instance up to the end-of-method -> you should not use TAutoFree for new projects :( - see <https://quality.embarcadero.com/browse/RSP-30050>
- be aware that it won't implement a full ARC memory model, but may be just used to avoid writing some try ... finally blocks on local variables
- use with caution, only on well defined local scope

**constructor** Create(const varObjPairs: array of pointer); reintroduce; overload;

*Initialize the TAutoFree class for several local variables*

- do not call this constructor, but class function Several() instead

**constructor** Create(var localVariable; obj: TObject); reintroduce; overload;

*Initialize the TAutoFree class for one local variable*

- do not call this constructor, but class function One() instead

**destructor** Destroy; override;

*Will finalize the associated TObject instances*

- note that releasing the TObject instances won't be protected, so any exception here may induce a memory leak: use only with "safe" simple objects, e.g. mORMot's TSQLRecord

**class function** One(var localVariable; obj: TObject): IAutoFree;

*Protect one local TObject variable instance life time*

- for instance, instead of writing:

```
var myVar: TMyClass;
begin
 myVar := TMyClass.Create;
 try
 ... use myVar
 finally
 myVar.Free;
 end;
end;

- you may write:
var myVar: TMyClass;
begin
 TAutoFree.One(myVar, TMyClass.Create);
 ... use myVar
end; // here myVar will be released
```

- warning: under FPC, you should assign the result of this method to a local IAutoFree variable - see bug <http://bugs.freepascal.org/view.php?id=26602>
- Delphi 10.4 also did change it and release the IAutoFree before the end of the current method, so you should better use a local variable

```
class function Several(const varObjPairs: array of pointer): IAutoFree;
```

*Protect several local TObject variable instances life time*

- specified as localVariable/objectInstance pairs

- you may write:

```
var var1,var2: TMyClass;
```

```
begin
```

```
 TAutoFree.Several([
 @var1,TMyClass.Create,
 @var2,TMyClass.Create]);
 ... use var1 and var2
```

```
end; // here var1 and var2 will be released
```

- warning: under FPC, you should assign the result of this method to a local IAutoFree variable -  
see bug <http://bugs.freepascal.org/view.php?id=26602>

- Delphi 10.4 also did change it and release the IAutoFree before the end of the current method,  
so you should better use a local variable

```
procedure Another(var localVariable; obj: TObject);
```

*Protect another TObject variable to an existing IAutoFree instance life time*

- you may write:

```
var var1,var2: TMyClass;
```

```
 auto: IAutoFree;
```

```
begin
```

```
 auto := TAutoFree.One(var1,TMyClass.Create);,
```

```
 do something
```

```
 auto.Another(var2,TMyClass.Create);
```

```
 ... use var1 and var2
```

```
end; // here var1 and var2 will be released
```

```
IAutoLocker = interface(IInterface)
```

*An interface used by TAutoLocker to protect multi-thread execution*

#### **function** ProtectMethod: IUnknown;

*Will enter the mutex until the IUnknown reference is released*

- using an IUnknown interface to let the compiler auto-generate a try..finally block statement to release the lock for the code block

- could be used as such under Delphi:

```
begin
 ... // unsafe code
 fSharedAutoLocker.ProtectMethod;
 ... // thread-safe code
end; // Local hidden IUnknown will release the lock for the method
```

- warning: under FPC, you should assign its result to a local variable - see bug

<http://bugs.freepascal.org/view.php?id=26602>

```
var LockFPC: IUnknown;
begin
 ... // unsafe code
 LockFPC := fSharedAutoLocker.ProtectMethod;
 ... // thread-safe code
end; // LockFPC will release the lock for the method
```

Or

```
begin
 ... // unsafe code
 with fSharedAutoLocker.ProtectMethod do begin
 ... // thread-safe code
 end; // Local hidden IUnknown will release the lock for the method
end;
```

#### **function** Safe: PSynLocker;

*Gives an access to the internal low-level TSynLocker instance used*

#### **procedure** Enter;

*Enter the mutex*

- any call to Enter should be ended with a call to Leave, and protected by a try..finally block, as such:

```
begin
 ... // unsafe code
 fSharedAutoLocker.Enter;
 try
 ... // thread-safe code
 finally
 fSharedAutoLocker.Leave;
 end;
end;
```

#### **procedure** Leave;

*Leave the mutex*

- any call to Leave should be preceded with a call to Enter

**TAutoLocker = class(TInterfacedObjectWithCustomCreate)**

*Reference-counted block code critical section*

- you can use one instance of this to protect multi-threaded execution
- the main class may initialize a IAutoLocker property in Create, then call IAutoLocker.ProtectMethod in any method to make its execution thread safe
- this class inherits from TInterfacedObjectWithCustomCreate so you could define one published property of a mORMot.pas' TInjectableObject as IAutoLocker so that this class may be automatically injected
- you may use the inherited TAutoLockerDebug class, as defined in SynLog.pas, to debug unexpected race conditions due to such critical sections
- consider inherit from high-level TSynPersistentLock or call low-level fSafe := NewSynLocker / fSafe^.DoneAndFreemem instead

**constructor** Create; **override**;

*Initialize the mutex*

**destructor** Destroy; **override**;

*Finalize the mutex*

**function** ProtectMethod: IUnknown;

*Will enter the mutex until the IUnknown reference is released*

- as expected by IAutoLocker interface
- could be used as such under Delphi:

**begin**

... *// unsafe code*

fSharedAutoLocker.ProtectMethod;

... *// thread-safe code*

**end**; *// local hidden IUnknown will release the lock for the method*

- warning: under FPC, you should assign its result to a local variable - see bug

<http://bugs.freepascal.org/view.php?id=26602>

**var** LockFPC: IUnknown;

**begin**

... *// unsafe code*

LockFPC := fSharedAutoLocker.ProtectMethod;

... *// thread-safe code*

**end**; *// LockFPC will release the lock for the method*

**or**

**begin**

... *// unsafe code*

**with** fSharedAutoLocker.ProtectMethod **do begin**

... *// thread-safe code*

**end**; *// local hidden IUnknown will release the lock for the method*

**end**;

**function** Safe: PSynLocker;

*Access to the locking methods of this instance*

- as expected by IAutoLocker interface

#### **procedure Enter; virtual;**

*Enter the mutex*

- as expected by IAutoLocker interface
- any call to Enter should be ended with a call to Leave, and protected by a try..finally block, as such:

```
begin
 ... // unsafe code
 fSharedAutoLocker.Enter;
 try
 ... // thread-safe code
 finally
 fSharedAutoLocker.Leave;
 end;
end;
```

#### **procedure Leave; virtual;**

*Leave the mutex*

- as expected by IAutoLocker interface

#### **property Locker: TSynLocker read fSafe;**

*Direct access to the locking methods of this instance*

- faster than IAutoLocker.Safe function

#### **ILockedDocVariant = interface(IIInterface)**

*Internal error C3517 under Delphi 5 :( ref-counted interface for thread-safe access to a TDocVariant document*

- is implemented e.g. by TLockedDocVariant, for IoC/DI resolution
- fast and safe storage of any JSON-like object, as property/value pairs, or a JSON-like array, as values

#### **function AddExistingProp(const Name: RawUTF8; var Obj: variant): boolean;**

*Add an existing property value to the given TDocVariant document object*

- returns TRUE and add the Name/Value pair to Obj if Name is existing
- returns FALSE if Name is not existing in the stored document
- this method would use a lock during the Name lookup, but would always release the lock, even if returning FALSE (see AddExistingPropOrLock)

#### **function AddExistingPropOrLock(const Name: RawUTF8; var Obj: variant): boolean;**

*Add an existing property value to the given TDocVariant document object*

- returns TRUE and add the Name/Value pair to Obj if Name is existing, using an internal lock for thread-safety
- returns FALSE if Name is not existing in the stored document, and lock the internal storage: caller should eventually release the lock via AddNewPropAndUnlock()
- could be used as such, for implementing a thread-safe cache:

```
if not cache.AddExistingPropOrLock('Articles', Scope) then
 cache.AddNewPropAndUnlock('Articles', GetArticlesFromDB, Scope);
```

here GetArticlesFromDB would occur inside the main lock

#### **function Copy: variant;**

*Makes a thread-safe copy of the internal TDocVariant document object or array*

**function** Exists(**const** Name: RawUTF8; **out** Value: **Variant**): boolean;

*Check and return a given property by name*

- returns TRUE and fill Value with the value associated with the supplied Name, using an internal lock for thread-safety
- returns FALSE if the Name was not found, releasing the internal lock: use ExistsOrLock() if you want to add the missing value

**function** ExistsOrLock(**const** Name: RawUTF8; **out** Value: **Variant**): boolean;

*Check and return a given property by name*

- returns TRUE and fill Value with the value associated with the supplied Name, using an internal lock for thread-safety
- returns FALSE and set the internal lock if Name does not exist: caller should then release the lock via ReplaceAndUnlock()

**function** Lock: TAutoLocker;

*Low-level access to the associated thread-safe mutex*

**function** ToJSON(HumanReadable: boolean=false): RawUTF8;

*Save the stored values as UTF-8 encoded JSON Object*

**procedure** AddItem(**const** Value: **variant**);

*Append a value to the internal TDocVariant document array*

- you should not use this method in conjunction with other document-based alternatives, like Exists/AddExistingPropOrLock or AddExistingProp

**procedure** AddNewProp(**const** Name: RawUTF8; **const** Value: **variant**; **var** Obj: **variant**);

*Add a property value to the given TDocVariant document object*

- this method would not expect the resource to be locked when called, as with AddNewPropAndUnlock
- will use the internal lock for thread-safety
- if the Name is already existing, would update/change the existing value
- could be used as such, for implementing a thread-safe cache:

```
if not cache.AddExistingProp('Articles',Scope) then
 cache.AddNewProp('Articles',GetArticlesFromDB,Scope);
```

here GetArticlesFromDB would occur outside the main lock

**procedure** AddNewPropAndUnlock(**const** Name: RawUTF8; **const** Value: **variant**; **var** Obj: **variant**);

*Add a property value to the given TDocVariant document object and to the internal stored document, then release a previous lock*

- call of this method should have been preceded by AddExistingPropOrLock() returning false, i.e. be executed on a locked instance

**procedure** Clear;

*Delete all stored properties*

```
procedure ReplaceAndUnlock(const Name: RawUTF8; const Value: Variant; out
LocalValue: Variant);
```

*Set a value by property name, and set a local copy*

- could be used as such, for implementing a thread-safe cache:

```
if not cache.ExistsOrLock('prop', local) then
 cache.ReplaceAndUnlock('prop', newValue, local);
```

- call of this method should have been preceded by ExistsOrLock() returning false, i.e. be executed on a locked instance

```
property Value[const Name: RawUTF8]: Variant read GetValue write SetValue;
```

*The document fields would be safely accessed via this property*

- this is the main entry point of this storage

- will raise an EDocVariant exception if Name does not exist at reading

- implementation class would make a thread-safe copy of the variant value

```
TLockedDocVariant = class(TInterfacedObjectWithCustomCreate)
```

*Allows thread-safe access to a TDocVariant document*

- this class inherits from TInterfacedObjectWithCustomCreate so you could define one published property of a mORMot.pas' TInjectableObject as ILockedDocVariant so that this class may be automatically injected

```
constructor Create(options: TDocVariantOptions); reintroduce; overload;
```

*Initialize the thread-safe document storage with the corresponding options*

```
constructor Create(FastStorage: boolean); reintroduce; overload;
```

*Initialize the thread-safe document storage*

```
constructor Create; overload; override;
```

*Initialize the thread-safe document with a fast TDocVariant*

- i.e. call Create(true) aka Create(JSON\_OPTIONS[true])

- will be the TInterfacedObjectWithCustomCreate default constructor, called e.g. during IoC/DI resolution

```
destructor Destroy; override;
```

*Finalize the storage*

```
function AddExistingProp(const Name: RawUTF8; var Obj: variant): boolean;
```

*Add an existing property value to the given TDocVariant document object*

- returns TRUE and add the Name/Value pair to Obj if Name is existing

- returns FALSE if Name is not existing in the stored document

- this method would use a lock during the Name lookup, but would always release the lock, even if returning FALSE (see AddExistingPropOrLock)

```
function AddExistingPropOrLock(const Name: RawUTF8; var Obj: variant): boolean;
```

*Add an existing property value to the given TDocVariant document object*

- returns TRUE and add the Name/Value pair to Obj if Name is existing

- returns FALSE if Name is not existing in the stored document

```
function Copy: variant;
```

*Makes a thread-safe copy of the internal TDocVariant document object or array*

**function** Exists(**const** Name: RawUTF8; **out** Value: **Variant**): boolean;

*Check and return a given property by name*

**function** ExistsOrLock(**const** Name: RawUTF8; **out** Value: **Variant**): boolean;

*Check and return a given property by name*

- this version

**function** Lock: TAutoLocker;

*Low-level access to the associated thread-safe mutex*

**function** ToJSON(HumanReadable: boolean=false): RawUTF8;

*Save the stored value as UTF-8 encoded JSON Object*

- implemented as just a wrapper around VariantSaveJSON()

**procedure** AddItem(**const** Value: **variant**);

*Append a value to the internal TDocVariant document array*

**procedure** AddNewProp(**const** Name: RawUTF8; **const** Value: **variant**; **var** Obj: **variant**);

*Add a property value to the given TDocVariant document object*

- this method would not expect the resource to be locked when called, as with

AddNewPropAndUnlock

- will use the internal lock for thread-safety

- if the Name is already existing, would update/change the existing value

**procedure** AddNewPropAndUnlock(**const** Name: RawUTF8; **const** Value: **variant**; **var** Obj: **variant**);

*Add a property value to the given TDocVariant document object and to the internal stored document*

**procedure** Clear;

*Delete all stored properties*

**procedure** ReplaceAndUnlock(**const** Name: RawUTF8; **const** Value: **Variant**; **out** LocalValue: **Variant**);

*Set a value by property name, and set a local copy*

**property** Value[**const** Name: RawUTF8]: **Variant** **read** GetValue **write** SetValue;

*The document fields would be safely accessed via this property*

- will raise an EDocVariant exception if Name does not exist

- result variant is returned as a copy, not as varByRef, since a copy will definitively be more thread safe

## Types implemented in the SynCommons unit

PBlock128 = ^TBlock128;

*Pointer to a 128-bit buffer*

PBooleanArray = ^TBooleanArray;

*Redefine here with {\$R-}*

PDACnt = ^TDACnt;

*Pointer to cross-compiler type used for dynarray reference counter*

PDALen = PPtrInt;

*Internal pointer integer type used for dynamic array header length field*

**PDocVariantData = ^TDocVariantData;**

*Pointer to a TDocVariant storage*

- since variants may be stored by reference (i.e. as varByRef), it may be a good idea to use such a pointer via DocVariantData(aVariant)^ or \_Safe(aVariant)^ instead of TDocVariantData(aVariant), if you are not sure how aVariant was allocated (may be not \_Obj/\_Json)

**PDocVariantOptions = ^TDocVariantOptions;**

*Pointer to a set of options for a TDocVariant storage*

- you may use e.g. @JSON\_OPTIONS[true], @JSON\_OPTIONS[false], @JSON\_OPTIONS\_FAST\_STRICTJSON or @JSON\_OPTIONS\_FAST\_EXTENDED

**PDWordRec = ^TDWordRec;**

*Points to the binary of an unsigned 32-bit value*

**PDynArray = ^TDynArray;**

*A pointer to a TDynArray wrapper instance*

**PDynArrayHasher = ^TDynArrayHasher;**

*Pointer to a TDynArrayHasher instance*

**PFileName = ^TFileName;**

*A pointer to a TFileName variable*

**PHash128 = ^THash128;**

*Pointer to a 128-bit hash value*

**PHash128Array = ^THash128Array;**

*Pointer to an infinite array of 128-bit hash values*

**PHash128Rec = ^THash128Rec;**

*Pointer to 128-bit hash map variable record*

**PHash160 = ^THash160;**

*Pointer to a 160-bit hash value*

**PHash192 = ^THash192;**

*Pointer to a 192-bit hash value*

**PHash256 = ^THash256;**

*Pointer to a 256-bit hash value*

**PHash256Array = ^THash256Array;**

*Pointer to an infinite array of 256-bit hash values*

**PHash256Rec = ^THash256Rec;**

*Pointer to 256-bit hash map variable record*

**PHash384 = ^THash384;**

*Pointer to a 384-bit hash value*

**PHash512 = ^THash512;**

*Pointer to a 512-bit hash value*

**PHash512Array = ^THash512Array;**

*Pointer to an infinite array of 512-bit hash values*

**PHash512Rec = ^THash512Rec;**

*Pointer to 512-bit hash map variable record*

PPatchCode = ^TPatchCode;

*Pointer to a small memory buffer used to backup a RedirectCode() hook*

PPointerClassHashed = ^TPointerClassHashed;

*A reference to a TPointerClassHashed instance*

PPrecisionTimer = ^PPrecisionTimer;

*Indirect reference to a pointer to a high resolution timer object/record*

PPrecisionTimer = ^TPrecisionTimer;

*Pointer to a high resolution timer object/record*

PPtrInt = ^PtrInt;

*A CPU-dependent signed integer type cast of a pointer of pointer  
- used for 64-bit compatibility, native under Free Pascal Compiler*

PPtrUInt = ^PtrUInt;

*A CPU-dependent unsigned integer type cast of a pointer of pointer  
- used for 64-bit compatibility, native under Free Pascal Compiler*

PQWord = ^QWord;

*Points to an unsigned Int64*

PQWordRec = ^TQWordRec;

*Points to the binary of an unsigned 64-bit value*

PRawByteString = ^RawByteString;

*Pointer to a RawByteString*

PStrCnt = ^TStrCnt;

*Pointer to cross-compiler type used for string reference counter*

PStrLen = ^TStrLen;

*Internal pointer integer type used for string header length field*

PSynDate = ^TSynDate;

*A pointer to a TSynDate instance*

PSynMonitor = ^TSynMonitor;

*References a TSynMonitor instance*

PSynNameValue = ^TSynNameValue;

*A reference pointer to a Name/Value RawUTF8 pairs storage*

PTimeLogBits = ^TTimeLogBits;

*Pointer to a memory structure for direct access to a TTimeLog type value*

PtrInt = integer;

*A CPU-dependent signed integer type cast of a pointer / register  
- used for 64-bit compatibility, native under Free Pascal Compiler*

PtrUInt = cardinal;

*A CPU-dependent unsigned integer type cast of a pointer / register  
- used for 64-bit compatibility, native under Free Pascal Compiler*

**PUnixMSTime = ^TUnixMSTime;**

*Pointer to a timestamp stored as millisecond-based Unix Time*

**PUnixTime = ^TUnixTime;**

*Pointer to a timestamp stored as second-based Unix Time*

**PUTF8Char = type PAnsiChar;**

*A simple wrapper to UTF-8 encoded zero-terminated PAnsiChar*

- PAnsiChar is used only for Win-Ansi encoded text
- the Synopse mORMot framework uses mostly this PUTF8Char type, because all data is internally stored and expected to be UTF-8 encoded

**PWord = System.PWord;**

*Redefined here to not use the wrong definitions from Windows.pas*

**QWord = type Int64;**

*Unsigned Int64 doesn't exist under older Delphi, but is defined in FPC*

- and UInt64 is buggy as hell under Delphi 2007 when inlining functions: older compilers will fallback to signed Int64 values
- anyway, consider using SortDynArrayQWord() to compare QWord values in a safe and efficient way, under a CPUx86
- you may use UInt64 explicitly in your computation (like in SynEcc.pas), if you are sure that Delphi 6-2007 compiler handles your code as expected, but mORMot code will expect to use QWord for its internal process (e.g. ORM/SOA serialization)

**RawByteString = type AnsiString;**

*Define RawByteString, as it does exist in Delphi 2009+*

- to be used for byte storage into an AnsiString
- use this type if you don't want the Delphi compiler not to do any code page conversions when you assign a typed AnsiString to a RawByteString, i.e. a RawUTF8 or a WinAnsiString

**RawJSON = type RawUTF8;**

*RawJSON will indicate that this variable content would stay in raw JSON*

- i.e. won't be serialized into values
- could be any JSON content: number, string, object or array
- e.g. interface-based service will use it for efficient and AJAX-ready transmission of TSQLTableJSON result

**RawUnicode = type AnsiString;**

*RawUnicode is an Unicode String stored in an AnsiString*

- faster than WideString, which are allocated in Global heap (for COM)
- an AnsiChar(#0) is added at the end, for having a true WideChar(#0) at ending
- length(RawUnicode) returns memory bytes count: use (length(RawUnicode) shr 1) for WideChar count (that's why the definition of this type since Delphi 2009 is AnsiString(1200) and not UnicodeString)
- pointer(RawUnicode) is compatible with Win32 'Wide' API call
- mimic Delphi 2009 UnicodeString, without the WideString or Ansi conversion overhead
- all conversion to/from AnsiString or RawUTF8 must be explicit: the compiler is not able to make valid implicit conversion on CP\_UTF16

**RawUTF8 = type AnsiString;**

*RawUTF8 is an UTF-8 String stored in an AnsiString*

- use this type instead of System.UTF8String, which behavior changed between Delphi 2009 compiler

and previous versions: our implementation is consistent and compatible with all versions of Delphi compiler

- mimic Delphi 2009 UTF8String, without the charset conversion overhead
- all conversion to/from AnsiString or RawUnicode must be explicit

**SynUnicode = WideString;**

*SynUnicode is the fastest available Unicode native string type, depending on the compiler used*

- this type is native to the compiler, so you can use Length() Copy() and such functions with it (this is not possible with RawUnicodeString type)
- before Delphi 2009+, it uses slow OLE compatible WideString (with our Enhanced RTL, WideString allocation can be made faster by using an internal caching mechanism of allocation buffers - WideString allocation has been made much faster since Windows Vista/Seven)
- starting with Delphi 2009, it uses fastest UnicodeString type, which allow Copy On Write, Reference Counting and fast heap memory allocation

**TAlgoCompressLoad = ( aclNormal, aclSafeSlow, aclNoCrcFast );**

*Deprecated TRawUTF8MethodList should be replaced by a TSynDictionary define the implemetation used by TAlgoCompress.Decompress()*

**TBits32 = set of 0..31;**

*Fast access to 32-bit integer bits*

- the compiler will generate bt/btr/bts opcodes

**TBits64 = set of 0..63;**

*Fast access to 64-bit integer bits*

- the compiler will generate bt/btr/bts opcodes
- as used by GetBit64/SetBit64/UnSetBit64

**TBits8 = set of 0..7;**

*Fast access to 8-bit integer bits*

- the compiler will generate bt/btr/bts opcodes

**TBlock128 = array[0..3] of cardinal;**

*Store a 128-bit buffer*

- e.g. an AES block
- consumes 16 bytes of memory

**TChar64 = array[0..63] of AnsiChar;**

*Some stack-allocated zero-terminated character buffer*

- as used by GetNextTChar64

**TCharConversionFlags = set of ( ccFNoTrailingZero, ccFReplacementCharacterForUnmatchedSurrogate);**

*Option set for RawUnicodeToUtf8() conversion*

**TDACnt = longint ;**

*Cross-compiler type used for dynarray reference counter*

- FPC uses PtrInt/SizeInt, Delphi uses longint even on CPU64

**TDateTimeMS = type TDateTime;**

*A type alias, which will be serialized as ISO-8601 with milliseconds*

- i.e. 'YYYY-MM-DD hh:mm:ss.sss' or 'YYYYMMDD hhmmss.sss' format

**TDateTimeMSDynArray = array of TDateTimeMS;**

*A dynamic array of TDateTimeMS values*

```
TDocVariantKind = (dvUndefined, dvObject, dvArray);
```

*Define the TDocVariant storage layout*

- if it has one or more named properties, it is a dvObject
- if it has no name property, it is a dvArray

```
TDocVariantOption = (dvoIsArray, dvoIsObject, dvoNameCaseSensitive,
dvoCheckForDuplicatedNames, dvoReturnNullForUnknownProperty,
dvoValueCopiedByReference, dvoJSONParseDoNotTryCustomVariants,
dvoJSONObjectParseWithinString, dvoSerializeAsExtendedJson, dvoAllowDoubleValue,
dvoInternNames, dvoInternValues);
```

*Possible options for a TDocVariant JSON/BSON document storage*

- dvolsArray and dvolsObject will store the "Kind: TDocVariantKind" state - you should never have to define these two options directly
- dvoNameCaseSensitive will be used for every name lookup - here case-insensitivity is restricted to a-z A-Z 0-9 and \_ characters
- dvoCheckForDuplicatedNames will be used for method TDocVariantData.AddValue(), but not when setting properties at variant level: for consistency, "aVariant.AB := aValue" will replace any previous value for the name "AB"
- dvoReturnNullForUnknownProperty will be used when retrieving any value from its name (for dvObject kind of instance), or index (for dvArray or dvObject kind of instance)
- by default, internal values will be copied by-value from one variant instance to another, to ensure proper safety - but it may be too slow: if you set dvoValueCopiedByReference, the internal TDocVariantData.VValue/VName instances will be copied by-reference, to avoid memory allocations, BUT it may break internal process if you change some values in place (since VValue/VName and VCount won't match) - as such, if you set this option, ensure that you use the content as read-only
- any registered custom types may have an extended JSON syntax (e.g. TBSONVariant does for MongoDB types), and will be searched during JSON parsing, unless dvoJSONParseDoNotTryCustomVariants is set (slightly faster)
- by default, it will only handle direct JSON [array] of {object}: but if you define dvoJSONObjectParseWithinString, it will also try to un-escape a JSON string first, i.e. handle "[array]" or "{object}" content (may be used e.g. when JSON has been retrieved from a database TEXT column) - is used for instance by VariantLoadJSON()
- JSON serialization will follow the standard layout, unless dvoSerializeAsExtendedJson is set so that the property names would not be escaped with double quotes, writing '{name:"John",age:123}' instead of '{"name":"John","age":123}': this extended json layout is compatible with <http://docs.mongodb.org/manual/reference/mongodb-extended-json> and with TDocVariant JSON unserialization, also our SynCrossPlatformJSON unit, but NOT recognized by most JSON clients, like AJAX/JavaScript or C#/Java
- by default, only integer/Int64/currency number values are allowed, unless dvoAllowDoubleValue is set and 32-bit floating-point conversion is tried, with potential loss of precision during the conversion
- dvoInternNames and dvoInternValues will use shared TRawUTF8Interning instances to maintain a list of RawUTF8 names/values for all TDocVariant, so that redundant text content will be allocated only once on heap

```
TDocVariantOptions = set of TDocVariantOption;
```

*Set of options for a TDocVariant storage*

- you can use JSON\_OPTIONS[true] if you want to create a fast by-reference local document as with \_ObjFast/\_ArrFast/\_JsonFast - i.e. [dvoReturnNullForUnknownProperty,dvoValueCopiedByReference]

- when specifying the options, you should not include dvolsArray nor dvolsObject directly in the set, but explicitly define TDocVariantDataKind

**TDynArrayAfterLoadFrom = procedure(var A) of object;**

*Optional event called by TDynArray.LoadFrom method after each item load*

- could be used e.g. for string interning or some custom initialization process
- won't be called if the dynamic array has ElemType=nil

**TDynArrayHashOne = function(const Elem; Hasher: THasher): cardinal;**

*Function prototype to be used for hashing of a dynamic array element*

- this function must use the supplied hasher on the Elem data

**TDynArrayJSONCustomReader = function(P: PUTF8Char; var aValue; out aValid: Boolean ; CustomVariantOptions: PDocVariantOptions): PUTF8Char of object;**

*Method prototype for custom unserialization of a dynamic array item*

- each element of the dynamic array will be called as aValue parameter of this callback
- can be used also at record level, if the record has a type information (i.e. shall contain a managed type within its fields)
- to be used with TTextWriter.RegisterCustomJSONSerializer() method
- implementation code could call e.g. GetJSONField() low-level function, and returns a pointer to the last handled element of the JSON input buffer, as such (aka EndOfBuffer variable as expected by GetJSONField):

```
var V: TFV absolute aValue;
begin
 (...)
 V.Detailed := UTF8ToString(GetJSONField(P,P));
 if P=nil then
 exit;
 aValid := true;
 result := P; // ',' or ']' for last item of array
end;
```

- implementation code shall follow the same exact format for the associated TDynArrayJSONCustomWriter callback

**TDynArrayJSONCustomWriter = procedure(const aWriter: TTextWriter; const aValue) of object;**

*Method prototype for custom serialization of a dynamic array item*

- each element of the dynamic array will be called as aValue parameter of this callback
- can be used also at record level, if the record has a type information (i.e. shall contain a managed type within its fields)
- to be used with TTextWriter.RegisterCustomJSONSerializer() method
- note that the generated JSON content will be appended after a '[' and before a ']' as a normal JSON array, but each item can be any JSON structure (i.e. a number, a string, but also an object or an array)
- implementation code could call aWriter.Add/AddJSONEscapeString...
- implementation code shall follow the same exact format for the associated TDynArrayJSONCustomReader callback

**TDynArrayKind = ( djNone, djBoolean, djByte, djWord, djInteger, djCardinal, djSingle, djInt64, djQWord, djDouble, djCurrency, djTimeLog, djDateTime, djDateTimeMS, djRawUTF8, djWinAnsi, djString, djRawByteString, djWideString, djSynUnicode, djHash128, djHash256, djHash512, djInterface, djVariant, djCustom );**

*Internal enumeration used to specify some standard Delphi arrays*

- will be used e.g. to match JSON serialization or TDynArray search (see TDynArray and TDynArrayHash InitSpecific method)

- djBoolean would generate an array of JSON boolean values
- djByte .. djTimeLog match numerical JSON values
- djDateTime .. djHash512 match textual JSON values
- djVariant will match standard variant JSON serialization (including TDocVariant or other custom types, if any)
- djCustom will be used for registered JSON serializer (invalid for InitSpecific methods call)
- see also djPointer and djObject constant aliases for a pointer or TObj field hashing / comparison
- is used also by TDynArray.InitSpecific() to define the main field type

**TDynArrayKinds = set of TDynArrayKind;**

*Internal set to specify some standard Delphi arrays*

**TDynArraySortCompare = function(const A,B): integer;**

*Function prototype to be used for TDynArray Sort and Find method*

- common functions exist for base types: see e.g. SortDynArrayBoolean, SortDynArrayByte, SortDynArrayWord, SortDynArrayInteger, SortDynArrayCardinal, SortDynArrayInt64, SortDynArrayQWord, SortDynArraySingle, SortDynArrayDouble, SortDynArrayAnsiString, SortDynArrayAnsiStringI, SortDynArrayUnicodeString, SortDynArrayUnicodeStringI, SortDynArrayString, SortDynArrayStringI
- any custom type (even records) can be compared then sort by defining such a custom function
- must return 0 if A=B, -1 if A<B, 1 if A>B

**TEventDynArrayHashOne = function(const Elem): cardinal of object;**

*Event handler to be used for hashing of a dynamic array element*

- can be set as an alternative to TDynArrayHashOne

**TEventDynArraySortCompare = function(const A,B): integer of object;**

*Event oriented version of TDynArraySortCompare*

**TFindFilesDynArray = array of TFindFiles;**

*Result list, as returned by FindFiles()*

**TFloatNan = ( fnNumber, fnNan, fnInf, fnNegInf );**

*The non-number values potentially stored in an IEEE floating point*

**TFloatType = ( ftSingle, ftDoub, ftExtended, ftComp, ftCurr );**

*Specify floating point (ftFloat) storage size and precision*

- here ftDouble is renamed ftDoub to avoid confusion with TSQLDBFieldType

**TGUIDShortString = string[38];**

*Stack-allocated ASCII string, used by GUIDToShort() function*

**THash128 = array[0..15] of byte;**

*Store a 128-bit hash value*

- e.g. a MD5 digest, or array[0..3] of cardinal (TBlock128)
- consumes 16 bytes of memory

**THash128Array = array[0..(maxInt div SizeOf(THash128))-1] of THash128;**

*Map an infinite array of 128-bit hash values*

- each item consumes 16 bytes of memory

**THash128DynArray = array of THash128;**

*Store several 128-bit hash values*

- e.g. MD5 digests

- consumes 16 bytes of memory per item

**THash160 = array[0..19] of byte;**

*Store a 160-bit hash value*

- e.g. a SHA-1 digest
- consumes 20 bytes of memory

**THash192 = array[0..23] of byte;**

*Store a 192-bit hash value*

- consumes 24 bytes of memory

**THash256 = array[0..31] of byte;**

*Store a 256-bit hash value*

- e.g. a SHA-256 digest, a TECCSignature result, or array[0..7] of cardinal
- consumes 32 bytes of memory

**THash256Array = array[0..(maxInt div SizeOf(THash256))-1] of THash256;**

*Map an infinite array of 256-bit hash values*

- each item consumes 32 bytes of memory

**THash256DynArray = array of THash256;**

*Store several 256-bit hash values*

- e.g. SHA-256 digests, TECCSignature results, or array[0..7] of cardinal
- consumes 32 bytes of memory per item

**THash384 = array[0..47] of byte;**

*Store a 384-bit hash value*

- e.g. a SHA-384 digest
- consumes 48 bytes of memory

**THash512 = array[0..63] of byte;**

*Store a 512-bit hash value*

- e.g. a SHA-512 digest, a TECCSignature result, or array[0..15] of cardinal
- consumes 64 bytes of memory

**THash512Array = array[0..(maxInt div SizeOf(THash512))-1] of THash512;**

*Map an infinite array of 512-bit hash values*

- each item consumes 64 bytes of memory

**THash512DynArray = array of THash512;**

*Store several 512-bit hash values*

- e.g. SHA-512 digests, or array[0..15] of cardinal
- consumes 64 bytes of memory per item

**THasher = function(crc: cardinal; buf: PAnsiChar; len: cardinal): cardinal;**

*Function prototype to be used for hashing of an element*

- it must return a cardinal hash, with as less collision as possible
- TDynArrayHashed.Init will use crc32c() if no custom function is supplied, which will run either as software or SSE4.2 hardware, with good collision for most used kind of data

**TIntelCpuFeature = ( cfFPU, cfVME, cfDE, cfPSE, cfTSC, cfMSR, cfPAE, cfMCE, cfCX8, cfAPIC, cf\_d10, cfSEP, cfMTRR, cfPGE, cfMCA, cfCMOV, cfPAT, cfPSE36, cfPSN, cfCLFSH, cf\_d20, cfDS, cfACPI, cfMMX, cfFXSR, cfSSE, cfSSE2, cfSS, cfHTT, cfTM, cfIA64, cfPBE, cfSSE3, cfCLMUL, cfDS64, cfMON, cfDSCPL, cfVMX, cfSMX, cfEST, cfTM2, cfSSSE3, cfCID, cfSDBG, cfFMA, cfCX16, cfXTPR, cfPDCM, cf\_c16, cfPCID, cfDCA, cfSSE41, cfSSE42, cfX2A,**

*The potential features, retrieved from an Intel CPU*

- see [https://en.wikipedia.org/wiki/CPUID#EAX.3D1:\\_Processor\\_Info\\_and\\_Feature\\_Bits](https://en.wikipedia.org/wiki/CPUID#EAX.3D1:_Processor_Info_and_Feature_Bits)
- is defined on all platforms, since an ARM desktop could browse Intel logs

```
TIntelCpuFeatures = set of TIntelCpuFeature;
```

*All features, as retrieved from an Intel CPU*

```
TInterfacedObjectClass = class of TInterfacedObject;
```

*Class-reference type (metaclass) of a TInterfacedObject*

```
TInterfacedObjectWithCustomCreateClass = class of TInterfacedObjectWithCustomCreate;
```

*Used to determine the exact class type of a TInterfacedObjectWithCustomCreate*

- could be used to create instances using its virtual constructor

```
TJsonChar = set of (jcJsonIdentifierFirstChar, jcJsonIdentifier, jcEndOfJSONField,
jcEndOfJSONFieldOr0, jcEndOfJSONValueField, jcDigitChar, jcDigitFirstChar,
jcDigitFloatChar);
```

*Kind of character used from JSON\_CHARS[] for efficient JSON parsing*

```
TJsonCharSet = array[AnsiChar] of TJsonChar;
```

*Defines a branch-less table used for JSON parsing*

```
TJSONCustomParserCustomSimpleKnownType = (ktNone, ktEnumeration, ktSet, ktGUID,
ktFixedArray, ktStaticArray, ktDynamicArray, ktBinary);
```

*Which kind of property does TJSONCustomParserCustomSimple refer to*

```
TJSONCustomParserRTTIExpectedEnd = (eeNothing, eeSquare, eeCurly, eeEndKeyword);
```

*How an RTTI expression is expected to finish*

```
TJSONCustomParserRTTIIs = array of TJSONCustomParserRTTI;
```

*An array of RTTI properties information*

- we use dynamic arrays, since all the information is static and we do not need to remove any RTTI information

```
TJSONCustomParserRTTIType = (ptArray, ptBoolean, ptByte, ptCardinal, ptCurrency,
ptDouble, ptExtended, ptInt64, ptInteger, ptQWord, ptRawByteString, ptRawJSON,
ptRawUTF8, ptRecord, ptSingle, ptString, ptSynUnicode, ptDateTime, ptDateTimeMS,
ptGUID, ptID, ptTimeLog, ptVariant, ptWideString, ptWord, ptCustom);
```

*The kind of variables handled by TJSONCustomParser*

- the last item should be ptCustom, for non simple types

```
TJSONCustomParserSerializationOption = (soReadIgnoreUnknownFields,
soWriteHumanReadable, soCustomVariantCopiedByReference, soWriteIgnoreDefault);
```

*How TJSONCustomParser would serialize/unserialize JSON content*

**TJSONCustomParserSerializationOptions = set of TJSONCustomParserSerializationOption;**

*How TJSONCustomParser would serialize/unserialize JSON content*

- by default, during reading any unexpected field will stop and fail the process - if soReadIgnoreUnknownFields is defined, such properties will be ignored (can be very handy when parsing JSON from a remote service)
- by default, JSON content will be written in its compact standard form, ready to be parsed by any client - you can specify soWriteHumanReadable so that some line feeds and indentation will make the content more readable
- by default, internal TDocVariant variants will be copied by-value from one instance to another, to ensure proper safety - but it may be too slow: if you set soCustomVariantCopiedByReference, any internal TDocVariantData.VValue/VName instances will be copied by-reference, to avoid memory allocations, BUT it may break internal process if you change some values in place (since VValue/VName and VCount won't match) - as such, if you set this option, ensure that you use the content as read-only
- by default, all fields are persisted, unless soWriteIgnoreDefault is defined and void values (e.g. "" or 0) won't be written
- you may use TTextWriter.RegisterCustomJSONSerializerSetOptions() class method to customize the serialization for a given type

**TLogEscape = array[0..LOGESCAPELEN\*3+5] of AnsiChar;**

*Buffer to be allocated on stack when using LogEscape()*

**TMultiPartDynArray = array of TMultiPart;**

*Used by MultiPartFormDataDecode() to return all its data items*

**TNameValuePUTF8CharDynArray = array of TNameValuePUTF8Char;**

*Used e.g. by JSONDecode() overloaded function to returns name/value pairs*

**TObjectListLocked = TSynObjectListLocked;**

*Deprecated class name, for backward compatibility only*

**TObjectListPropertyHashedAccessProp = function(aObject: TObject): pointer;**

*Function prototype used to retrieve a pointer to the hashed property value of a TObjectListPropertyHashed list*

**TOnKeyNotify = procedure(Sender: TObject; const Key: RawUTF8) of object;**

*Event signature to notify a given string key*

**TOnKeyResolve = function(const aInterface: TGUID; const Key: RawUTF8; out Obj): boolean of object;**

*Event signature to locate a service for a given string key*

- used e.g. by TRawUTF8ObjectCacheList.OnKeyResolve property

**TOnNotifySortedIntegerChange = procedure(const Sender; Value: integer) of object;**

*Event handler called by NotifySortedIntegerChanges()*

- Sender is an opaque const value, maybe a TObject or any pointer

**TOnReducePerItem = function(Item: PDocVariantData): boolean of object;**

*Method used by TDocVariantData.ReduceAsArray to filter each object*

- should return TRUE if the item match the expectations

**TOnReducePerValue = function(const Value: variant): boolean of object;**

*Method used by TDocVariantData.ReduceAsArray to filter each object*

- should return TRUE if the item match the expectations

**TOnStringTranslate = procedure (var English: string) of object;**

*A generic callback, which can be used to translate some text on the fly*

- maps procedure TLanguageFile.Translate(var English: string) signature as defined in mORMoti18n.pas
- can be used e.g. for TSynMustache's {"English text"} callback

**TOnSynNameValueConvertRawUTF8 = function(const text: RawUTF8): RawUTF8 of object;**

*Event handler used to convert on the fly some UTF-8 text content*

**TOnSynNameValueNotify = procedure(const Item: TSynNameValueItem; Index: PtrInt) of object;**

*Callback event used by TSynNameValue*

**TOnTextWriterEcho = function(Sender: TTextWriter; Level: TSynLogInfo; const Text: RawUTF8): boolean of object;**

*Callback used to echo each line of TTextWriter class*

- should return TRUE on success, FALSE if the log was not echoed: but TSynLog will continue logging, even if this event returned FALSE

**TOnTextWriterFlush = procedure(Text: PUTF8Char; Len: PtrInt) of object;**

*Event signature for TTextWriter.OnFlushToStream callback*

**TOnTextWriterObjectProp = function(Sender: TTextWriter; Value: TObject; PropInfo: pointer; Options: TTextWriterWriteObjectOptions): boolean of object;**

*Callback used by TTextWriter.WriteObject to customize class instance serialization*

- should return TRUE if the supplied property has been written (including the property name and the ending ',' character), and doesn't need to be processed with the default RTTI-based serializer

**TOnValueGreater = function(IndexA, IndexB: PtrInt): boolean of object;**

*Comparison function as expected by MedianQuickSelect()*

- should return TRUE if Values[IndexA]>Values[IndexB]
